| <b>1 Proceedings</b>  | <b>1</b> |
| Bayesian Optimal Control of Smoothly Parameterized Systems.<br><i>Yasin Abbasi-Yadkori, Csaba Szepesvári</i> . . . . .  | 1        |
| Optimal expert elicitation to reduce interval uncertainty.<br><i>Nadia Ben Abdallah, Sébastien Destercke</i> . . . . .  | 12       |
| Stochastic Integration via Error-Correcting Codes.<br><i>Dimitris Achlioptas, Pei Jiang</i> . . . . .   | 22       |
| Learning the Structure of Sum-Product Networks via an SVD-based Algorithm.<br><i>Tameem Adel, David Balduzzi, Ali Ghodsi</i> . . . . .                              | 32       |
| Robust reconstruction of causal graphical models based on conditional 2-point and 3-point information.<br><i>Séverine Affeldt, Hervé Isambert</i> . . . . .         | 42       |
| Are You Doing What I Think You Are Doing? Criticising Uncertain Agent Models.<br><i>Stefano V. Albrecht, Subramanian Ramamoorthy</i> . . . . .                      | 52       |
| Disciplined Convex Stochastic Programming: A New Framework for Stochastic Optimization.<br><i>Alnur Ali, J. Zico Kolter, Steven Diamond, Stephen Boyd</i> . . . . . | 62       |
| Intelligent Affect: Rational Decision Making for Socially Aligned Agents.<br><i>Nabiha Asghar, Jesse Hoey</i> . . . . .   | 72       |
| Representation Learning for Clustering: A Statistical Framework.<br><i>Hassan Ashtiani, Shai Ben-David</i> . . . . .  | 82       |
| Adversarial Cost-Sensitive Classification.<br><i>Kaiser Asif, Wei Xing, Sima Behpour, Brian D. Ziebart</i> . . . . .  | 92       |
| Geometric Network Comparisons.<br><i>Dena Marie Asta, Cosma Rohilla Shalizi</i> . . . . .   | 102      |
| Learning and Planning with Timing Information in Markov Decision Processes.<br><i>Pierre-Luc Bacon, Borja Balle, Doina Precup</i> . . . . .                         | 111      |
| Parameterizing the Distance Distribution of Undirected Networks.<br><i>Christian Bauckhage, Kristian Kersting, Fabian Hadji</i> . . . . .                           | 121      |
| New Limits for Knowledge Compilation and Applications to Exact Model Counting.<br><i>Paul Beame, Vincent Liew</i> . . . . .   | 131      |
| Hashing-Based Approximate Probabilistic Inference in Hybrid Domains.<br><i>Vaishak Belle, Guy Van den Broeck, Andrea Passerini</i> . . . . .                        | 141      |
| Bayesian Network Learning with Discrete Case-Control Data.<br><i>Giorgos Borboudakis, Ioannis Tsamardinos</i> . . . . .   | 151      |

|  |     |
|--|-----|
| Efficient Algorithms for Bayesian Network Parameter Learning from Incomplete Data.<br><i>Guy Van den Broeck, Karthika Mohan, Arthur Choi, Adnan Darwiche, Judea Pearl</i> . . .          | 161 |
| Bayes Optimal Feature Selection for Supervised Learning with General Performance Measures.<br><i>Saneem Ahmed C.G., Harikrishna Narasimhan, Shivani Agarwal</i> . . . . .                | 171 |
| Visual Causal Feature Learning.<br><i>Krzysztof Chalupka, Pietro Perona, Frederick Eberhardt</i> . . . . .   | 181 |
| Large-Margin Determinantal Point Processes.<br><i>Wei-Lun Chao, Boqing Gong, Kristen Grauman, Fei Sha</i> . . . . .  | 191 |
| Fast Relative-Error Approximation Algorithm for Ridge Regression.<br><i>Shouyuan Chen, Yang Liu, Michael R. Lyu, Irwin King, Shengyu Zhang</i> . . . . .                                 | 201 |
| Selective Greedy Equivalence Search: Finding Optimal Bayesian Networks Using a Polynomial<br>Number of Score Evaluations.<br><i>David Maxwell Chickering, Christopher Meek</i> . . . . . | 211 |
| Stable Spectral Learning Based on Schur Decomposition.<br><i>Nicolò Colombo, Nikos Vlassis</i> . . . . .   | 220 |
| Semi-described and semi-supervised learning with Gaussian processes.<br><i>Andreas Damianou, Neil D. Lawrence</i> . . . . .  | 228 |
| Budget Constraints in Prediction Markets.<br><i>Nikhil Devanur, Miroslav Dudík, Zhiyi Huang, David Pennock</i> . . . . .   | 238 |
| A Probabilistic Logic for Reasoning about Uncertain Temporal Information.<br><i>Dragan Doder, Zoran Ognjanović</i> . . . . .   | 248 |
| Training generative neural networks via Maximum Mean Discrepancy optimization.<br><i>Gintare Karolina Dziugaite, Daniel M. Roy, Zoubin Ghahramani</i> . . . . .                          | 258 |
| Incremental Region Selection for Mini-bucket Elimination Bounds.<br><i>Sholeh Forouzan, Alexander Ihler</i> . . . . .  | 268 |
| Estimating Mutual Information by Local Gaussian Approximation.<br><i>Shuyang Gao, Greg Ver Steeg, Aram Galstyan</i> . . . . .  | 278 |
| Psychophysical Detection Testing with Bayesian Active Learning.<br><i>Jacob R. Gardner, Xinyu Song, Kilian Q. Weinberger, Dennis Barbour, John P.<br/>Cunningham</i> . . . . .           | 286 |
| Locally Conditioned Belief Propagation.<br><i>Thomas Geier, Felix Richter, Susanne Biundo</i> . . . . .  | 296 |
| Discriminative Switching Linear Dynamical Systems applied to Physiological Condition<br>Monitoring.<br><i>Konstantinos Georgatzis, Christopher K. I. Williams</i> . . . . .              | 306 |
| Revisiting Non-Progressive Influence Models: Scalable Influence Maximization in Social<br>Networks.<br><i>Golshan Golnari, Amir Asiaee T., Arindam Banerjee, Zhi-Li Zhang</i> . . . . .  | 316 |
| Scalable Recommendation with Hierarchical Poisson Factorization.<br><i>Prem Gopalan, Jake M. Hofman, David M. Blei</i> . . . . .   | 326 |
| State Sequence Analysis in Hidden Markov Models.<br><i>Yuri Grinberg, Theodore J. Perkins</i> . . . . .  | 336 |
| Multitasking: Optimal Planning for Bandit Superprocesses.<br><i>Dylan Hadfield-Menell, Stuart Russell</i> . . . . .  | 345 |
| Importance Sampling over Sets: A New Probabilistic Inference Scheme.<br><i>Stefan Hadjis, Stefano Ermon</i> . . . . .  | 355 |
| Progressive Abstraction Refinement for Sparse Sampling.<br><i>Jesse Hostetler, Alan Fern, Thomas Dietterich</i> . . . . .  | 365 |
| Zero-Truncated Poisson Tensor Factorization for Massive Binary Tensors.<br><i>Changwei Hu, Piyush Rai, Lawrence Carin</i> . . . . .  | 375 |
| Computing Optimal Bayesian Decisions for Rank Aggregation via MCMC Sampling.<br><i>David Hughes, Kevin Hwang, Lirong Xia</i> . . . . .   | 385 |
| Do-calculus when the True Graph Is Unknown.<br><i>Antti Hyttinen, Frederick Eberhardt, Matti Järvisalo</i> . . . . .   | 395 |

|   |     |
|---|-----|
| Kernel-Based Just-In-Time Learning for Passing Expectation Propagation Messages.<br><i>Wittawat Jitkrittum, Arthur Gretton, Nicolas Heess, S. M. Ali Eslami, Balaji Lakshminarayanan, Dino Sejdinovic, Zoltán Szabó</i> . . . . . | 405 |
| Averaging of Decomposable Graphs by Dynamic Programming and Sampling.<br><i>Kustaa Kangas, Teppo Niinimäki, Mikko Koivisto</i> . . . . .  | 415 |
| Novel Bernstein-like Concentration Inequalities for the Missing Mass.<br><i>Bahman Yari Saeed Khanloo, Gholamreza Haffari</i> . . . . .   | 425 |
| Minimizing Expected Losses in Perturbation Models with Multidimensional Parametric Min-cuts.<br><i>Adrian Kim, Kyomin Jung, Yongsu Lim, Daniel Tarlow, Pushmeet Kohli</i> . . . . .   | 435 |
| Population Empirical Bayes.<br><i>Alp Kucukelbir, David M. Blei</i> . . . . .   | 444 |
| Encoding Markov logic networks in Possibilistic Logic.<br><i>Ondřej Kuželka, Jesse Davis, Steven Schockaert</i> . . . . .   | 454 |
| On the Computability of AIXI.<br><i>Jan Leike, Marcus Hutter</i> . . . . .  | 464 |
| Tracking with ranked signals.<br><i>Tianyang Li, Harsh Pareek, Pradeep Ravikumar, Dhruv Balwada, Kevin Speer</i> . . . . .  | 474 |
| Classification of Sparse and Irregularly Sampled Time Series with Mixtures of Expected Gaussian<br>Kernels and Random Features.<br><i>Steven Cheng-Xian Li, Benjamin Marlin</i> . . . . .   | 484 |
| Complexity of the Exact Solution to the Test Sequencing Problem.<br><i>Wenhao Liu, Ross D. Shachter</i> . . . . .   | 494 |
| Finite-Sample Analysis of Proximal Gradient TD Algorithms.<br><i>Bo Liu, Ji Liu, Mohammad Ghavamzadeh, Sridhar Mahadevan, Marek Petrik</i> . . . . .  | 504 |
| Estimating the Partition Function by Discriminance Sampling.<br><i>Qiang Liu, Jian Peng, Alexander Ihler, John Fisher III</i> . . . . .   | 514 |
| A Finite Population Likelihood Ratio Test of the Sharp Null Hypothesis for Compliers.<br><i>Wen Wei Loh, Thomas S. Richardson</i> . . . . .   | 523 |
| Structure Learning Constrained by Node-Specific Degree Distribution.<br><i>Jianzhu Ma, Feng Zhao, Jinbo Xu</i> . . . . .  | 533 |
| Active Search and Bandits on Graphs using Sigma-Optimality.<br><i>Yifei Ma, Tzu-Kuo Huang, Jeff Schneider</i> . . . . .   | 542 |
| Off-policy learning based on weighted importance sampling with linear computational complexity.<br><i>A. Rupam Mahmood, Richard S. Sutton</i> . . . . .   | 552 |
| Impact of Learning Strategies on the Quality of Bayesian Networks: An Empirical Evaluation.<br><i>Brandon Malone, Matti Järvisalo, Petri Myllymäki</i> . . . . .  | 562 |
| Learning the Structure of Causal Models with Relational and Temporal Dependence.<br><i>Katerina Marazopoulou, Marc Maier, David Jensen</i> . . . . .  | 572 |
| Hamiltonian ABC.<br><i>Edward Meeds, Robert Leenders, Max Welling</i> . . . . .   | 582 |
| (Nearly) Optimal Differentially Private Stochastic Multi-Arm Bandits.<br><i>Nikita Mishra, Abhradeep Thakurta</i> . . . . .   | 592 |
| Equitable Partitions of Concave Free Energies.<br><i>Martin Mladenov, Kristian Kersting</i> . . . . .   | 602 |
| Non-parametric Revenue Optimization for Generalized Second Price auctions..<br><i>Mehryar Mohri, Andrés Muñoz Medina</i> . . . . .  | 612 |
| Polynomial-time algorithm for learning optimal tree-augmented dynamic Bayesian networks.<br><i>José L. Monteiro, Susana Vinga, Alexandra M. Carvalho</i> . . . . .  | 622 |
| Learning and Inference in Tractable Probabilistic Knowledge Bases.<br><i>Mathias Niepert, Pedro Domingos</i> . . . . .  | 632 |
| Multi-Context Models for Reasoning under Partial Knowledge: Generative Process and Inference<br>Grammar.<br><i>Ardavan S. Nobandegani, Ioannis N. Psaromiligkos</i> . . . . .   | 642 |
| Annealed Gradient Descent for Deep Learning.<br><i>Hengyue Pan, Hui Jiang</i> . . . . .   | 652 |

|  |     |

# Preface

The Conference on Uncertainty in Artificial Intelligence (UAI) is the premier international conference on research related to representation, inference, learning and decision making in the presence of uncertainty within the field of Artificial Intelligence. This volume contains the schedule and abstracts of all papers that were accepted for the 31st UAI Conference, held in Amsterdam, The Netherlands, from July 12 to 16, 2015. Papers appearing in this volume were subjected to a rigorous review process. 291 papers were submitted to the conference (excluding papers that were withdrawn or rejected outright because of potential double submission) and each was peer-reviewed by 3 or more reviewers with the supervision of one Senior Program Committee member. A total of 99 papers were accepted, 28 for oral presentation and 71 for poster presentation, for an acceptance rate of 34%. We are very grateful to the program committee and senior program committee members for their diligent efforts. We are confident that the proceedings, like past UAI conference proceedings, will become an important archival reference for the field.

We are pleased to announce that the Microsoft Best Paper Award is awarded to Vaishak Belle, Guy Van Den Broeck, and Andrea Passerini for their paper “Hashing-based approximate probabilistic inference in hybrid domains”. The Facebook Best Student Paper Award is awarded to Bo Liu (co-authored with Ji Liu, Mohammad Ghavamzadeh, Sridhar Mahadevan, and Marek Petrik) for their paper “Finite-sample analysis of proximal gradient TD algorithms”. The Google Best Student Paper Award is awarded to Wen Sun (co-authored with J. Andrew Bagnell) for their paper “Online Bellman residual algorithms with predictive error guarantees”.

In addition to the presentation of technical papers, we are very pleased to have four distinguished invited speakers at UAI 2015: Peter Bühlmann (ETH Zürich), David MacKay (Cambridge University), David Silver (Google DeepMind), and, as Banquet Speaker, Raphael Slawinski (Mount Royal University). The UAI 2015 tutorials program, chaired by Silja Renooij, consists of four tutorials: “Optimal algorithms for learning Bayesian network structures” by Changhe Yuan, James Cussens, and Brandon Malone, “Computational complexity of Bayesian networks” by Johan Kwisthout and Cassio De Campos, “Belief functions for the working scientist” by Thierry Denoeux and Fabio Cuzzolin, and “Non-parametric causal models” by Robin Evans and Thomas Richardson.

UAI 2015 also hosts three workshops, coordinated by workshops chair Irina Rish: “12th Annual Bayesian Applications Workshop” (John Mark Agosta and Rommel Novaes Carvalho), “StarAI – Statistical Relational AI” (Mathias Niepert, Guy Van den Broeck, Siraam Natarajan, and David Poole) and “Advances in Causal Inference” (Ricardo Silva, Tom Claassen, Robin Evans, Jonas Peters, and Ilya Shpitser).

*Marina Meila and Tom Heskes (Program Co-Chairs)*  
*Jin Tian (General Chair)*

# Organizing Committee

## **General Chair**

Jin Tian, Iowa State University, USA

## **Program Chairs**

Marina Meila, University of Washington, USA

Tom Heskes, Radboud University, Netherlands

## **Tutorials Chair**

Silja Renooij, Universiteit Utrecht, Netherlands

## **Workshops Chair**

Irina Rish, Watson Research Center, USA

## **Proceedings Chair**

Daniel Lowd, University of Oregon, USA

## **Publicity Chair**

Jonas Peters, ETH Zürich, Switzerland

## **Local Arrangements Chair**

Joris Mooij, University of Amsterdam, Netherlands

# Acknowledgments

The success of a conference such as UAI depends greatly on the efforts of many individuals who volunteer their time to provide expert and detailed reviews of submitted papers. In particular, the Program Committee and Senior Program Committee for UAI 2015 were responsible for generating reviews and recommendations for the 291 submissions to the conference. Each submitted paper was reviewed by at least 3 members of the Program Committee. The Senior Program Committee then assessed the individual reviews for each paper, moderated discussion among Program Committee members if needed, and generated meta-reviews and recommendations for the program chairs. We are extremely grateful for the efforts of all of the individuals listed below.

## Senior Program Committee

## Abstract

We study Bayesian optimal control of a general class of smoothly parameterized Markov decision problems (MDPs). We propose a *lazy* version of the so-called posterior sampling method, a method that goes back to Thompson and Strens, more recently studied by Osband, Russo and van Roy. While Osband et al. derived a bound on the (Bayesian) regret of this method for undiscounted total cost episodic, finite state and action problems, we consider the continuing, average cost setting with no cardinality restrictions on the state or action spaces. While in the episodic setting, it is natural to switch to a new policy at the episode-ends, in the continuing average cost framework we must introduce switching points explicitly and in a principled fashion, or the regret could grow linearly. Our lazy method introduces these switching points based on monitoring the uncertainty left about the unknown parameter. To develop a suitable and easy-to-compute uncertainty measure, we introduce a new “average local smoothness” condition, which is shown to be satisfied in common examples. Under this, and some additional mild conditions, we derive rate-optimal bounds on the regret of our algorithm. Our general approach allows us to use a single algorithm and a single analysis for a wide range of problems, such as finite MDPs or linear quadratic regulation, both being instances of smoothly parameterized MDPs. The effectiveness of our method is illustrated by means of a simulated example.

## 1 INTRODUCTION

The topic of this paper is Bayesian optimal control, where the problem is to design a policy that achieves optimal performance on the average over control problem instances

that are randomly sampled from a given distribution. This problem naturally arises when the goal is to design a controller for mass-produced systems, where production is imperfect but the errors follow a regular pattern and the goal is to maintain a good average performance over the controlled systems, rather than to achieve good performance even for the system with the largest errors.

In a Bayesian setting, the optimal policy (which exists under appropriate regularity conditions) is history dependent. Given the knowledge of the prior, the transition dynamics and costs, the problem in a Bayesian setting is to find an efficient way to *calculate* the actions that the optimal policy would take given some history. This problem was studied for finite state and action spaces by Asmuth et al. (2009) and Kolter and Ng (2009). Both works propose specific computationally efficient algorithms, which are shown to be  $\epsilon$ -Bayes-optimal with probability  $1 - \delta$  with the exception of  $O(\text{poly}(1/\epsilon))$  many steps, where for both algorithms  $\epsilon$  and  $\delta$  are both part of the input. While Kolter and Ng (2009) suggest to add an exploration bonus to the rewards while using the mean estimates for the transition probabilities and considers a finite horizon setting, Asmuth et al. (2009) consider discounted total rewards and a variant of posterior sampling, originally due to Thompson (1933) and first adapted to reinforcement learning by Strens (2000). More recently, the algorithm of Strens (2000) was revisited by Osband et al. (2013) in the context of episodic, finite MDPs. An attractive feature of posterior sampling is that it requires neither the target accuracy  $\epsilon$ , nor the failure probability  $\delta$  as its inputs. Rather, the guarantee presented by Osband et al. (2013) is that the algorithm’s (Bayesian) regret, i.e., the excess cost due to not following the optimal policy, is bounded by  $\tilde{O}(\sqrt{T})$ <sup>1</sup> both with high probability and in expectation. The reader interested in further algorithms for Bayesian reinforcement learning (including algorithms for infinite state spaces) may consult the papers of Araya-López et al. (2012), Vlassis et al. (2012) and Guez et al. (2013), which together give an excellent overview of the literature.

---

<sup>1</sup> $\tilde{O}(\cdot)$  hides poly-logarithmic factors.

The starting point of our paper is the work of Osband et al. (2013). In particular, just like Osband et al. (2013), we build on the posterior sampling algorithm of Strens (2000), which itself was derived from an algorithm of Thompson (1933) developed for the so-called bandit setting. Unlike Osband et al. (2013) and Strens (2000), we allow the state-action space to be infinite (subject to some regularity conditions discussed later) and we consider the *infinite horizon, continuing, average-cost setting*. As far as we know, ours is the first work deriving (Bayesian) regret bounds for any algorithms of this generality. The major assumption that we make is that *the Markov dynamics is smoothly parameterized in some unknown parameters* with known (local) “smoothness” map such that the posterior concentrates in the metric derived from this map. It is shown that this assumption is met in some common examples, such as finite MDPs, and also in linearly parameterized systems, which encompass, systems with linear dynamics.

Following a proposal of Strens (2000) who also considered the non-episodic setting, the algorithm works in phases: At the beginning of each phase, a policy is computed based on solving the optimal control problem for a random parameter vector drawn from the posterior over the parameter vectors. The algorithm keeps the policy until the parameter uncertainty is reduced by a substantial margin, when a new phase begins and the process is repeated. The idea of ending a phase when uncertainty is reduced by a significant margin goes back at least to the work of Jaksch et al. (2010).

While in the case of episodic problems the issue of how long a policy should be kept does not arise, in a continuing problem with no episodic structure, if policies are changed too often, performance will suffer (see, e.g., Example 1 of Guez et al. (2014)). To address this challenge, for non-episodic problems, Strens (2000) suggested that the lengths of phases should be adjusted to the “planning horizon” (Strens, 2000), which however, is ill-defined for the average cost setting that we consider in this paper. A major contribution of this work is that we show how the smoothness map can be used to derive the length of the phases.

In a recent and independent work, Osband and Van Roy (2014) propose and analyze a similar algorithm for episodic problems. Also, Gopalan and Mannor (2015) show a frequentist analysis of Thompson sampling for finite MDP problems.

The continuing setting is very common in practice; this setting is the most natural for controlled mechanical systems (e.g., CD/DVD drive control, control of manufacturing robots), or for process optimization (e.g., controlling a queuing system, resource management), where “resets” are rare or unnatural.

Under some additional technical conditions, we show that the expected (Bayesian) regret of our algorithm is  $\tilde{O}(\sqrt{T})$

where  $T$  is the number of time steps and  $\Sigma_T$  is controlled by the precision with which the optimal control problems are solved, thus providing an explicit bound on the cost of using imprecise calculations. In summary, the main result of the paper shows that near-optimal Bayesian optimal control is possible for a wide range of problems as long as we can efficiently sample from the parameter posteriors, the length of phases for how long the same policy is followed is carefully controlled and if we can efficiently solve the arising classical optimal control problems. Due to the lack of space, the proofs of some of our claims are given in the supplementary material.

We emphasize two contributions: (1) the invention of a class of systems which unifies many previous approaches, and permits an elegant proof. (2) the introduction of a Concentrating Posterior assumption which significantly shortens our proof compared to previous proofs and improves the bound, as we avoid the use of measure concentration arguments which were always used previously.

## 2 PROBLEM SETTING

We consider problems when the transition dynamics is parameterized with a matrix  $\Theta_* \in \mathbb{R}^{m \times n}$ , which is *randomly chosen* at time 0 (before the interaction with the learner starts) from a known prior  $P_0$  with support  $\mathcal{S} \subset \mathbb{R}^{m \times n}$ . Let  $P_t$  denote the posterior of  $\Theta_*$  at time  $t$  based on  $x_1, a_1, \dots, a_{t-1}, x_t$ . Let  $\mathcal{X} \subset \mathbb{R}^n$  be the state space and  $\mathcal{A} \subset \mathbb{R}^d$  be the action space,  $x_t \in \mathcal{X}$  be the state at time  $t$  and  $a_t \in \mathcal{A}$  be the action at time  $t$ , which is chosen based on  $x_1, a_1, \dots, a_{t-1}, x_t$ . It is assumed that  $x_1$  is sampled from a fixed distribution (although, it should become clear later that this assumption is not necessary). For  $M \succeq 0$  positive semidefinite, define  $\|\Theta\|_M^2 = \|\Theta^\top M \Theta\|_2$ , where  $\|\cdot\|_2$  denotes the spectral norm of matrices (later we will drop the subindex 2). The set of positive semidefinite  $m \times m$  matrices will be denoted by  $\mathbb{S}^+(m)$ . Our main assumption concerning the transition law is as follows:

### Assumption A1 (Smoothly Parameterized Dynamics)

The next state satisfies  $x_{t+1} = f(x_t, a_t, \Theta_*, z_{t+1})$ , where  $z_{t+1} \sim U[0, 1]$  is independent of the past and  $\Theta_*$ . Further, there exists a (known) map  $M : \mathcal{X} \times \mathcal{A} \rightarrow \mathbb{S}^+(m)$  such that for any  $\Theta, \Theta' \in \mathcal{S}$ , if  $y = f(x, a, \Theta, z)$ ,  $y' = f(x, a, \Theta', z)$  with  $z \sim U[0, 1]$ , then  $\mathbb{E}[\|y - y'\|] \leq \|\Theta - \Theta'\|_{M(x,a)}$ .

The first part of the assumption just states that given  $\Theta_*$ , the dynamics is Markovian with state  $x_t$ , while the second part demands that small changes in the parameter lead to small changes in the next state. The assumption that the map  $M$  is “known” makes it possible to use  $M$  in the design of our algorithms.

Our next assumption connects the concentration of the posterior with  $M$ :

**Assumption A2 (Concentrating Posterior)** Let  $\tilde{\mathcal{F}}_t = \sigma(x_1, a_1, \dots, a_{t-1}, x_t)$  be the  $\sigma$ -algebra generated by observations up to time  $t$ ,  $V_t = V + \sum_{s=1}^{t-1} M(x_s, a_s)$ , where  $V$  is an  $m \times m$  positive definite matrix. Then, there exists a positive constant  $C$  such that for any  $t \geq 1$ , for some  $\tilde{\mathcal{F}}_t$ -measurable random variable  $\hat{\Theta}_t$ , letting  $\Theta'_t \sim P_t$  it holds that  $\max \left\{ \mathbb{E} \left[ \|\Theta'_t - \hat{\Theta}_t\|_{V_t}^2 \right], \mathbb{E} \left[ \|\Theta_* - \hat{\Theta}_t\|_{V_t}^2 \right] \right\} \leq C$ .

The idea here is that  $\hat{\Theta}_t$  is an estimate of  $\Theta_*$  based on past information available at time  $t$ , such as a maximum a posteriori (MAP) estimate (note that this estimate will *not* be needed by our algorithm). Since  $V_t$  is increasing at a linear rate, the assumption requires that  $\hat{\Theta}_t$  converges to  $\Theta$  at an  $O(1/\sqrt{t})$  rate. When  $\Theta = \Theta_*$ , this means that  $\hat{\Theta}_t$  should converge to  $\Theta_*$  at this rate, which is indeed what we expect. When  $\Theta = \Theta'_t$ , again, we expect this to be true since  $\Theta'_t$  is expected to be in the  $O(1/\sqrt{t})$  vicinity of  $\Theta_*$ . Note how this assumption connects  $M$  with the behavior of the posterior. One novelty of our analysis, as compared to that of Osband et al. (2013), is that while Osband et al. relies on measure-concentration, we require only the above (weaker) “variance concentration”. We will show explicit examples where this variance term is easy to control using a direct calculation. Since we avoid measure-concentration, our analysis has the potential to give much tighter regret bounds for the Bayesian setting than available previously, though the study of this remains for future work. The examples we deal with include finite MDPs (where the state is represented by unit vectors) and systems with linear dynamics (i.e., when  $x_{t+1} = Ax_t + Ba_t + w_{t+1}$ , where  $w_{t+1} \sim p_w(\cdot|x_t, a_t)$ ), amongst others. Explicit expressions for the map  $M$  will be given in Section 6 for these systems. In general, for systems with additive noise, finding  $M$  essentially reduces to finding a suitable local linearization of the system’s dynamics.

The problem we study is to design a controller (also known as a policy) that at every time step  $t$ , based on past states  $x_1, \dots, x_t$  and actions  $a_1, \dots, a_{t-1}$ , selects an action  $a_t$  so as to minimize the expected long-run average loss  $\mathbb{E} \left[ \limsup_{n \rightarrow \infty} \frac{1}{n} \sum_{t=1}^n \ell(x_t, a_t) \right]$ . We consider any noise distribution and any loss function  $\ell$  as long as a boundedness assumption on the variance and a smoothness assumption on the *value function* are satisfied (see Assumptions A2 and A3-ii below). It is important to note that we allow  $\ell$  to be a nonlinear function of the last state-action pair, i.e., the framework allows one to go significantly beyond the scope of linear quadratic control as many nonlinear control problems can be transformed into a linear form (but with a nonlinear loss function) using the so-called dynamic feedback linearization techniques (Isidori, 1995).

To measure the performance of an algorithm, we use the (expected) regret  $R_T$ :  $R_T = \mathbb{E} \left[ \sum_{t=1}^T (\ell(x_t, a_t) - J(\Theta_*)) \right]$ . Here,  $(x_t, a_t)_{t=1}^T$  de-

notes the state-action trajectory and  $J(\Theta_*)$  is the average loss of the optimal policy given (random) parameter  $\Theta_*$ . The slower the regret grows, the closer is the performance to that of an optimal policy. If the growth rate of  $R_T$  is sublinear ( $R_T = o(T)$ ), the average loss per time step will converge to the optimal average loss as  $T$  gets large and in this sense we can say that the algorithm is asymptotically-optimal. Our main result shows that, under some conditions, the construction of such asymptotically-optimal policies can be reduced to the ability of efficiently sampling from the posterior of  $\Theta_*$  and being able to solve classical (non-Bayesian) optimal-control problems. Furthermore, our main result also implies that  $R_T = \tilde{O}(\sqrt{T})$ .

### 3 THE LAZY PSRL ALGORITHM

Our algorithm is an instance of the posterior sampling reinforcement learning (PSRL) (Osband et al., 2013). As explained beforehand, this algorithm is based on the work on Thompson (1933) and was proposed by Strens (2000). To emphasize that the algorithm keeps the current policy for a while, we call it LAZY PSRL. Our contribution is to suggest a specific schedule for updating the policy. The pseudocode of the algorithm is shown in Figure 1.

Recall that  $P_0$  denotes the prior distribution of the parameter matrix  $\Theta_*$ . Let  $P_t$  denote the posterior of  $\Theta_*$  at time  $t$  based on  $x_1, a_1, \dots, a_{t-1}, x_t$  and  $\tau_t < t$  the last round when the algorithm chose a new policy. Further, let  $V_t = V + \sum_{s=1}^{t-1} M(x_s, a_s)$ , where  $V$  is some fixed,  $m \times m$  positive definite matrix. Let  $G$  be a constant that controls the replanning frequency. Then, at time  $t$ , Lazy PSRL sets  $\tilde{\Theta}_t = \tilde{\Theta}_{t-1}$  unless  $\det(V_t) > G \det(V_{\tau_t})$  in which case it chooses  $\tilde{\Theta}_t$  from the posterior  $P_t$ :  $\tilde{\Theta}_t \sim P_t$ . The action taken at time step  $t$  is a near-optimal action for the system whose transition dynamics is specified by  $\tilde{\Theta}_t$ . We assume that a subroutine,  $\pi^*$ , taking the current state  $x_t$  and the parameter  $\tilde{\Theta}_t$  is available to calculate such an action. The inexact nature of calculating a near-optimal action will also be taken in our analysis.

### 4 RESULTS FOR BOUNDED STATE- AND FEATURE-SPACES

In this section, we study problems with a bounded state space. In particular, the number of states might be infinite, but we assume that the norm of the state vector is bounded by a constant. Before stating our main result, we state some extra assumptions.

Our first extra assumption concerns the existence of “regular” solutions to the average cost optimality equations (ACOE), an assumption which is usually thought to be mild in the context of average-cost problems:

```

Inputs:  $P_0$ , the prior distribution of  $\Theta_*$ ,  $V$ ,  $G$ .
 $V_{\text{last}} \leftarrow V, V_0 \leftarrow V$ .
for  $t \leftarrow 1, 2, \dots$  do
  if  $\det(V_t) > G \det(V_{\text{last}})$  then
    Sample  $\tilde{\Theta}_t \sim P_t$ .
     $V_{\text{last}} \leftarrow V_t$ .
  else
     $\tilde{\Theta}_t \leftarrow \tilde{\Theta}_{t-1}$ .
  end if
  Calculate near-optimal action  $a_t \leftarrow \pi^*(x_t, \tilde{\Theta}_t)$ .
  Execute action  $a_t$  and observe the new state  $x_{t+1}$ .
  Update  $P_t$  with  $(x_t, a_t, x_{t+1})$  to obtain  $P_{t+1}$ .
  Update  $V_{t+1} \leftarrow V_t + M(x_t, a_t)$ .
end for

```

Figure 1: Lazy PSRL for smoothly parameterized control problems

**Assumption A3 (Existence of Regular ACOE Solutions)**  
The following hold:

- (i) There exists  $H > 0$  such that for any  $\Theta \in \mathcal{S}$ , there exist a scalar  $J(\Theta)$  and a function  $h(\cdot, \Theta) : \mathcal{X} \rightarrow [0, H]$  that satisfy the average cost optimality equation (ACOE): for any  $x \in \mathcal{X}$ ,

$$J(\Theta) + h(x, \Theta) = \min_{a \in \mathcal{A}} \left\{ \ell(x, a) + \int h(y, \Theta) p(dy | x, a, \Theta) \right\}, \quad (1)$$

where  $p(\cdot | x, a, \Theta)$  is the next-state distribution given state  $x$ , action  $a$  and parameter  $\Theta$ .

- (ii) There exists  $B > 0$  such that for all  $\Theta \in \mathcal{S}$ , and for all  $x, x' \in \mathcal{X}$ ,  $|h(x, \Theta) - h(x', \Theta)| \leq B \|x - x'\|$ .

With a slight abuse of the concepts, we will call the quantity  $J(\Theta)$  the average loss of the optimal policy, while function  $h(\cdot, \Theta)$  will be called the value function (for the system with parameter  $\Theta$ ). The review paper by Arapostathis et al. (1993) gives a number of sufficient (and sometimes necessary) conditions that guarantee that a solution to ACOE exists. Lipschitz continuity usually follows from that of the transition dynamics and the losses.

Let us now discuss the condition that  $h$  should have a bounded range. A uniform lower bound on  $h$  follows, for example if the immediate cost function  $\ell$  is lower bounded. Then, if the state space is bounded, uniform boundedness of the functions  $h(\cdot, \Theta)$  follows from their uniform Lipschitzness:

**Proposition 1.** *Assume that the value function  $h(\cdot, \Theta)$  is bounded from below ( $\inf_x h(x, \Theta) > -\infty$ ) and is  $B$ -Lipschitz. Then, if the diameter of the state space is*

*bounded by  $X$  (i.e.,  $\sup_{x, x' \in \mathcal{X}} \|x - x'\| \leq X$ ) then there exists a solution  $h'(\cdot, \Theta)$  to (1) such that the range of  $h$  is included in  $[0, BX]$ .*

Finally, we assume that the map  $M : \mathcal{X} \times \mathcal{A} \rightarrow \mathbb{S}^+(m)$  is bounded:

**Assumption A4 (Boundedness)** There exist  $\Phi > 0$  such that for all  $x \in \mathcal{X}$  and  $a \in \mathcal{A}$ ,  $\text{trace}(M(x, a)) \leq \Phi^2$ .

This assumption may be strong. In the next section we discuss an extension of the result of this section to the case when this assumption is not met.

The main theorem of this section bounds the regret of Lazy PSRL under the assumptions mentioned so far. In this result, we allow  $\pi^*$  to return a  $\sigma_t$ -suboptimal action, where  $\sigma_t > 0$ . By this, we mean that the action  $a_t$  satisfies

$$\ell(x_t, a_t) + \int h(y, \tilde{\Theta}_t) p(dy | x_t, a_t, \tilde{\Theta}_t) \leq \min_{a \in \mathcal{A}} \left\{ \ell(x_t, a) + \int h(y, \tilde{\Theta}_t) p(dy | x_t, a, \tilde{\Theta}_t) \right\} + \sigma_t. \quad (2)$$

One can control the suboptimality error in terms of the error of an approximate solution to the Bellman equation and the error of the subroutine that finds an action that minimizes the obtained approximate action values.

**Theorem 2.** *Assume that A1–A4 hold for some values of  $C, B, X, \Phi > 0$ . Consider Lazy PSRL where in time step  $t$ , the action chosen is  $\sigma_t$ -suboptimal. Then, for any time  $T$ , the regret of Lazy PSRL satisfies  $R_T = \tilde{O}(\sqrt{T}) + \Sigma_T$ , where  $\Sigma_T = \sum_{t=1}^T \mathbb{E}[\sigma_t]$  and the constant hidden by  $\tilde{O}(\cdot)$  depends on  $V, C, B, X, G$  and  $\Phi$ .*

In particular, the theorem implies that Lazy PSRL is asymptotically optimal as long as  $\sum_{t=1}^T \mathbb{E}[\sigma_t] = o(T)$  and it is  $O(\epsilon)$ -optimal if  $\mathbb{E}[\sigma_t] \leq \epsilon$ . The fact that the regret is bounded by the sum of suboptimality factors in solving Bellman equation is not trivial. Indeed, as actions have long term effects and we have a closed-loop system, one might suspect that the regret could blow up as a function of these errors. In this respect, the significance of our theorem is that the learner need not worry too much about each planning subproblem as the overall effect is only additive.

Due to lack of space, the proof, which combines the proof techniques of Osband et al. (2013) with that of Abbasi-Yadkori and Szepesvári (2011) in a novel fashion, is presented in the appendix.

## 5 FORCEFULLY STABILIZED SYSTEMS

For some applications, such as robotics, where the state can grow unbounded, the boundedness assumption (Assumption A4) is rather problematic. For such systems, it is common to use a stabilizing controller  $\pi_{\text{stab}}$  that is automatically turned on and is kept on as long as the state vector is

“large”. The stabilizing controller, however, is usually expensive (uses lots of energy), as it is designed to be robust so that it is guaranteed to drive back the state to the safe region for all possible systems under consideration. Hence a good controller should avoid relying on the stabilizing controller.

In this section, we will replace Assumption A4 with an assumption that a stabilizing controller is available. We will use this controller to override the actions coming from our algorithm as soon as the state leaves the (bounded) safe region  $\mathcal{R} \subset \mathbb{R}^n$  until it returns to it. The corresponding pseudocode is shown in Figure 2.

**Inputs:**  $P_0$ , the prior distribution of  $\Theta_*$ ,  $V$ , the safe region  $\mathcal{R} \subset \mathbb{R}^n$ .  
Initialize Lazy PSRL with  $P_0$  and  $V$ ,  $x_1$ .  
**for**  $t = 1, 2, \dots$  **do**  
  **if**  $x_t \in \mathcal{R}$  **then**  
    Get action  $a_t$  from Lazy PSRL  
  **else**  
    Get action  $a_t$  from  $\pi_{\text{stab}}$   
  **end if**  
  Execute action  $a_t$  and observe the new state  $x_{t+1}$ .  
  Feed  $a_t$  and  $x_{t+1}$  to Lazy PSRL.  
**end for**

Figure 2: Stabilized Lazy PSRL

We assume that the stabilizing controller is effective in the following sense:

**Assumption A5 (Effective Stabilizing Controller)** There exists  $\Phi > 0$  such that the following holds: Pick any  $x \in \mathcal{R}$ ,  $a \in \mathcal{A}$  and let  $x'_1, a'_1, x'_2, a'_2, \dots$  be the sequence of state-action pairs obtained when from time step two the Markovian stabilizing controller  $\pi_{\text{stab}}$  is applied to the controlled system whose dynamics is given by  $\Theta \in \mathcal{S}$ :  $x'_1 = x$ ,  $a'_1 = a$ ,  $x'_{t+1} \sim p(\cdot|x'_t, a'_t, \Theta)$ ,  $a'_{t+1} \sim \pi_{\text{stab}}(\cdot|x'_t)$ . Then,  $\mathbb{E}[\text{trace}(M(x'_t, a'_t))] \leq \Phi^2$  for any  $t \geq 1$ , where  $M : \mathcal{X} \times \mathcal{A} \rightarrow \mathbb{S}^+(m)$  is the map of Assumption A1 underlying  $\{p(\cdot|x, a, \Theta)\}$ .

The assumption is reasonable as it only requires that the trace of  $M(x'_t, a'_t)$  is bounded *in expectation*. Thus, large spikes, that no controller may prevent, can exist as long as they happen with a sufficiently low probability.

The next theorem shows that Stabilized Lazy PSRL is near Bayes-optimal for the system  $p'$  obtained from  $p$  by overwriting the action  $a$  by the action  $\pi_{\text{stab}}(x)$  if  $x$  is outside of the safe region  $\mathcal{R} \subset \mathbb{R}^n$ :

$$p'(dy|x, a, \Theta) = \begin{cases} p(dy|x, a, \Theta), & \text{if } x \in \mathcal{R}; \\ p(dy|x, \pi_{\text{stab}}(x), \Theta), & \text{otherwise.} \end{cases}$$

**Theorem 3.** Consider a parameterized system with the transition probability kernel family  $\{p(\cdot|x, a, \Theta)\}_{\Theta \in \mathcal{S}}$  and let  $\pi_{\text{stab}} : \mathcal{X} \rightarrow \mathcal{A}$  be a deterministic Markovian controller. Let the smooth parameterization Assumption A1 hold for  $\{p(\cdot|x, a, \Theta)\}$ , the ACOE solution regularity Assumption A3 hold for  $\{p'(\cdot|x, a, \Theta)\}$ . Consider running the Stabilized Lazy PSRL algorithm of Figure 2 on  $p(\cdot|x, a, \Theta_*)$  and let the concentration Assumption A2 hold along the trajectory obtained. Then, if in addition Assumption A5 holds then the regret of Stabilized Lazy PSRL against the Bayesian optimal controller of  $\{p'(\cdot|x, a, \Theta)\}_{\Theta}$  with prior  $P_0$  and immediate cost  $\ell$  satisfies  $R_T = \tilde{O}(\sqrt{T}) + \Sigma_T$ , where  $\Sigma_T = \sum_{t=1}^T \mathbb{E}[\mathbf{1}\{x_t \in \mathcal{R}\} \sigma_t]$  and  $\sigma_t$  is the suboptimality of the action computed by Lazy PSRL at time step  $t$ .

If the optimal controller  $\pi^*$  for  $p$  does not excite the condition that turns on the stabilizing controller, then this controller is also optimal for  $p'$ . In this case, Stabilized Lazy PSRL will have the same regret against  $\pi^*$  than what it has against the optimal controller of  $p'$  and the theorem implies that it will achieve sublinear regret in the original system, as long as  $\Sigma_T$  is sublinear.

## 6 EXAMPLES

The purpose of this section is to illustrate the results obtained. In particular, we will consider applying the results to finite MDPs and linearly parameterized controlled systems and show that for these cases all the assumptions can be satisfied and Lazy PSRL can achieve a low expected regret. We believe that our results will be applicable to many more settings, such as hybrid discrete-continuous systems where the discrete states control which continuous dynamics is used.

### 6.1 Finite MDPs

Consider an MDP problem with finite state and action spaces. Let the state space be  $\mathcal{X} = \{1, 2, \dots, n\}$  and the action space be  $\mathcal{A} = \{1, 2, \dots, d\}$ . We represent the state variable by an  $n$ -dimensional binary vector  $x_t$  that has only one non-zero element at the current state and will write the dynamics in the form  $x_{t+1} = \Theta_* \varphi(x_t, a_t) + \eta_t$ , where  $\Theta_*$  will collect the transition matrices into a single big matrix and  $\eta_t$  is a “Markov noise”. The feature map,  $\varphi : \mathcal{X} \times \mathcal{A} \rightarrow \mathbb{R}^{nd}$  and the parameter matrix are defined as follows: for  $1 \leq k \leq nd$ ,

$$\varphi_k(x, a) = \begin{cases} 1, & \text{if } k = (a-1)n + x; \\ 0, & \text{otherwise,} \end{cases} \quad \Theta_* = \begin{pmatrix} \Theta_*^{(1)} \\ \Theta_*^{(2)} \\ \vdots \\ \Theta_*^{(d)} \end{pmatrix}.$$

Let  $s \in [n]$  be a state and  $a \in [d]$  be an action. The  $s$ th row of matrix  $\Theta_*^{(a)}$  is a distribution over the state space that shows the transition probabilities when we take action  $a$  in state  $s$ . Thus, any row of  $\Theta_*^{(a)}$  sums to one and  $\mathbb{E}[x_{t+1}|x_t, a_t] = \Theta_*^\top \varphi(x_t, a_t)$ .

An appropriate prior for each row is a Dirichlet distribution. Let  $\alpha_1, \dots, \alpha_n$  be positive numbers and let  $V' = \text{diag}(\alpha_1, \dots, \alpha_n)$ . Then  $V = \text{diag}(V', \dots, V') \in \mathbb{R}^{nd \times nd}$  is our ‘‘smoother’’. Let the prior for the  $s$ th row of  $\Theta_*^{(a)}$  be the Dirichlet distribution with parameters  $(\alpha_1, \dots, \alpha_n)$ :  $(P_0)_{s,:} = D(\alpha_1, \dots, \alpha_n)$ . At time  $t$ , the posterior has the form

$$(P_t)_{s,:} = D(\alpha_1 + c_t(s, a, 1), \dots, \alpha_n + c_t(s, a, n)),$$

where  $c_t(s, a, s')$  is the number of observed transitions to state  $s'$  after taking action  $a$  in state  $s$  during the first  $t$  time steps. Matrix  $V_t$  is a diagonal matrix with diagonal elements depending only on the number of times a state-action pair is observed. In particular,

$$(V_t)_{n(a-1)+s, n(a-1)+s} = \sum_{s'} (\alpha_{s'} + c_t(s, a, s')).$$

Vector  $\widehat{\Theta}_{t,(:,s')}$  is an  $nd$ -dimensional vector and its elements show the empirical frequency of transition to state  $s'$  from different state-action pairs. The mean of distribution  $(P_t)_{s,:}$  is the vector  $\widehat{\Theta}_{t,(n(a-1)+s,:)}$  where

$$\widehat{\Theta}_{t,(n(a-1)+s,:)} = \frac{\alpha_{s'} + c_t(s, a, s')}{\sum_{s''} (\alpha_{s''} + c_t(s, a, s''))}.$$

We now show that matrix-valued map  $M$  can be chosen to be  $M(x, a) = (\sqrt{2}/2)\mathbb{I}$ :

**Proposition 4.** *The above choice makes Assumptions A1 and A2 satisfied.*

*Proof.* Let us first show that Assumption A1 holds. Because  $\mathbb{E}[y|x, a] = \Theta^\top \varphi(x, a)$ ,  $\mathbb{E}[y'|x, a] = \Theta'^\top \varphi(x, a)$ , and  $y$  and  $y'$  have only one non-zero element,

$$\begin{aligned} \mathbb{E}[\|y - y'\|] &= \sqrt{2}\mathbb{P}(y \neq y') = \sqrt{2}(1 - \mathbb{P}(y = y')) \\ &= \sqrt{2}\left(1 - \Theta_{(x,a),:}^\top \Theta'_{(x,a),:}\right) \\ &= \frac{\sqrt{2}}{2} \left\| \Theta_{(x,a),:} - \Theta'_{(x,a),:} \right\|^2, \end{aligned}$$

where the last step holds because each row of  $\Theta$  and  $\Theta'$  sum to one.

Let us now prove that Assumption A2 holds: Let  $N = (\Theta_* - \widehat{\Theta}_t)^\top$ ,  $\alpha_{s,a,s'} = \alpha_{s'} + c_t(s, a, s')$  and  $\bar{\alpha}_{s,a} = \sum_{s'} \alpha_{s,a,s'} = V_{t,(n(a-1)+s, n(a-1)+s)}$ . Let  $\|\cdot\|_F$  denote the

Frobenius norm. We have that

$$\begin{aligned} \mathbb{E}\left[\left\|\|NV_t^{1/2}\|^2 \mid \mathcal{F}_t\right.\right] &\leq \mathbb{E}\left[\left\|\|NV_t^{1/2}\|_F^2 \mid \mathcal{F}_t\right.\right] \\ &= \mathbb{E}\left[\sum_{s,a} V_{t,(n(a-1)+s, n(a-1)+s)} \sum_{s'} N_{s',n(a-1)+s}^2 \mid \mathcal{F}_t\right] \\ &= \sum_{s,a} \bar{\alpha}_{s,a} \sum_{s'} \mathbb{E}\left[N_{s',n(a-1)+s}^2 \mid \mathcal{F}_t\right]. \end{aligned}$$

Because each row of  $\Theta_*$  has a Dirichlet distribution and rows of  $\widehat{\Theta}_t$  are means of these distributions,  $\mathbb{E}\left[N_{s',n(a-1)+s}^2 \mid \mathcal{F}_t\right]$  is simply the variance of the corresponding Dirichlet variable. Thus,

$$\begin{aligned} \mathbb{E}\left[\left\|\|NV_t^{1/2}\|^2 \mid \mathcal{F}_t\right.\right] &\leq \sum_{s,a} \sum_{s'} \frac{\bar{\alpha}_{s,a} \alpha_{s,a,s'} (\bar{\alpha}_{s,a} - \alpha_{s,a,s'})}{\bar{\alpha}_{s,a}^2 (1 + \bar{\alpha}_{s,a})} \\ &\leq n^2 d. \end{aligned}$$

□

An immediate corollary of this is that Lazy PSRL will enjoy low regret in finite MDPs:

**Corollary 5.** *Consider Lazy PSRL applied to a finite MDP with  $n$  states,  $d$  actions with  $M$  as above, and a Dirichlet prior as specified above. Assume that the set  $\mathcal{S}$  system parameters under which Assumption A3 is satisfied is a measurable set with positive Lebesgue measure. Suppose that at time step  $t$ , the action chosen is  $\sigma_t$ -suboptimal. Then, for any time  $T$ , the regret of Lazy PSRL satisfies  $R_T = \widetilde{O}(\sqrt{T}) + \Sigma_T$ .*

*Proof.* The boundedness condition (Assumption A4) trivially holds, Assumption A3 holds by assumption, while Proposition 4 shows that the remaining two assumptions of Theorem 2 are satisfied. □

## 6.2 Linearly Parametrized Problems with Gaussian Noise

Next, we consider linearly parametrized problems with Gaussian noise:

$$x_{t+1} = \Theta_*^\top \varphi(x_t, a_t) + w_{t+1}, \quad (3)$$

where  $w_{t+1}$  is a zero-mean normal random variable. The nonlinear dynamics shown in (3) shares similarities to, but allows significantly greater generality than the Linear Quadratic (LQ) problem considered by Abbasi-Yadkori and Szepesvári (2011). In particular, in the LQ problem,  $\Theta_*^\top = (A_*, B_*)$  and  $\varphi(x_t, a_t)^\top = (x_t^\top, a_t^\top)$ . (However, Abbasi-Yadkori and Szepesvári (2011) assume only that the noise is subgaussian.)

Next, we describe a conjugate prior under the assumption that the noise is Gaussian with a known covariance matrix. Without loss of generality, we assume that

$\mathbb{E} [w_{t+1} w_{t+1}^\top | \mathcal{F}_t] = I$ . A conjugate prior is appealing as the posterior has a compact representation that allows for computationally efficient sampling methods. Assume that the columns of matrix  $\Theta_*$  are independently sampled from the following prior: for  $i = 1 \dots n$ ,

$$P_0(\Theta_{*,(:,i)}) \propto \exp\left(\Theta_{*,(:,i)}^\top V \Theta_{*,(:,i)}\right) \mathbf{1}\{\Theta_{*,(:,i)} \in \mathcal{S}\}$$

and  $\mathcal{S}$  is the set of system parameters under which Assumption A3 is satisfied, which is assumed to be a measurable set with positive Lebesgue measure. Then, by Bayes' rule, the posterior for column  $i$  of  $\Theta_*$ ,  $P_t(\Theta_{*,(:,i)})$ , is proportional to

$$e^{(-0.5(\Theta_{*,(:,i)} - \hat{\Theta}_{t,(:,i)})^\top V_t (\Theta_{*,(:,i)} - \hat{\Theta}_{t,(:,i)}))} \mathbf{1}\{\Theta_{*,(:,i)} \in \mathcal{S}\}.$$

We now show an appropriate choice for  $M$  (which should not be surprising):

**Proposition 6.** *With the choice  $M(x, a) = \varphi(x, a)\varphi(x, a)^\top$ , Assumptions A1 and A2 are satisfied.*

Note that this choice is essentially the same as in Proposition 4.

*Proof.* Let us first show that Assumption A1 holds. Because  $y = \Theta^\top \varphi(x, a) + w$ ,  $y' = \Theta'^\top \varphi(x, a) + w$ , we have  $\|y - y'\|^2 = \|\Theta - \Theta'\|_{\varphi(x, a)\varphi(x, a)^\top}^2$ , which shows that this assumption is indeed satisfied with the said choice of  $M$ .

Let us now prove that Assumption A2 holds: Let  $\Lambda$  be a random variable with probability distribution function

$$P(\lambda) \propto \exp\left(-\frac{1}{2}(\lambda - \hat{\Theta}_{t,(:,i)})^\top V_t (\lambda - \hat{\Theta}_{t,(:,i)})\right).$$

Notice that  $(\Lambda - \hat{\Theta}_{t,(:,i)})^\top V_t^{1/2} = Z \sim \mathcal{N}(0, I)$  has the standard normal distribution. Hence  $\mathbb{P}(\|Z_j\| > \alpha) \leq e^{-\alpha^2/2}$ . Thus, since  $\mathbb{P}(\|Z\| > \alpha) \leq m e^{-\alpha^2/(2m^2)}$ , we have

$$\begin{aligned} \mathbb{E} \left[ \left\| \left( \Theta_{*,(:,i)} - \hat{\Theta}_{t,(:,i)} \right)^\top V_t^{1/2} \right\|^2 \middle| \mathcal{F}_t \right] &= \mathbb{E} \left[ \|Z\|^2 \middle| \mathcal{F}_t \right] \\ &= \int_0^\infty \mathbb{P}(\|Z\|^2 > \epsilon) \leq 2m^3. \end{aligned}$$

Thus,

$$\begin{aligned} \mathbb{E} \left[ \left\| \left( \Theta_* - \hat{\Theta}_t \right)^\top V_t^{1/2} \right\|^2 \middle| \mathcal{F}_t \right] &\leq \mathbb{E} \left[ \left\| \left( \Theta_* - \hat{\Theta}_t \right)^\top V_t^{1/2} \right\|_F^2 \middle| \mathcal{F}_t \right] \\ &= \sum_{i=1}^n \mathbb{E} \left[ \left\| \left( \Theta_{*,(:,i)} - \hat{\Theta}_{t,(:,i)} \right)^\top V_t^{1/2} \right\|^2 \middle| \mathcal{F}_t \right] \\ &\leq 2nm^3. \end{aligned}$$

This shows that Assumption A2 is satisfied, thus finishing the proof.  $\square$

An immediate corollary of this is that Lazy PSRL will enjoy low regret when applied to linearly parametrized problems with Gaussian noise. We assume an effective stabilizing controller is available. This is necessary, as the noise may make the state arbitrarily large.

**Corollary 7.** *Consider Stabilized Lazy PSRL applied to a linearly parametrized problem with Gaussian noise with  $M$  as in Proposition 6. Let the underlying MDP satisfy Assumption A3. Suppose in time step  $t$ , the action chosen is  $\sigma_t$ -suboptimal. Then, for any time  $T$ , the regret of Stabilized Lazy PSRL satisfies  $R_T = \tilde{O}(\sqrt{T}) + \Sigma_T$ .*

*Proof.* The claim follows immediately from Proposition 6 and Theorem 3.  $\square$

## 7 EXPERIMENTS

In this section we illustrate the behavior of LAZY PSRL on a queuing and a web server control application.

### 7.1 Queuing Control Application

The queuing problem is described in (de Farias and Van Roy, 2003). The queue has a buffer size of 99. For time  $t$ , let  $x_t \in \{0, 1, \dots, 99\}$  be the state. The action  $a_t$  is the departure probability or service rate and is chosen from the set  $\{0.1625, 0.325, 0.4875, 0.65\}$ . Let  $p$  be the (unknown) arrival rate. The dynamics is defined as follows

$$x_{t+1} = \begin{cases} x_t - 1 & \text{with probability } a_t; \\ x_t + 1 & \text{with probability } p; \\ x_t & \text{otherwise.} \end{cases}$$

From state  $x_t = 0$ , transitions to states 1 and 0 happen with probabilities  $p$  and  $1 - p$ . From state  $x_t = 99$ , transitions to states 98 and 99 happen with probabilities  $a_t$  and  $1 - a_t$ . The loss function is  $\ell(x_t, a_t) = x_t^2 + 500p^2$ .

#### 7.1.1 Numerical Results

The purpose of this experiment is to show how the LAZY PSRL algorithm can take advantage of the problem structure to obtain better performance. We compare the LAZY PSRL algorithm with UCRL (Jaksch et al., 2010). For the LAZY PSRL algorithm, we use the Beta distribution  $\text{Beta}(1, 1)$  as the prior for the unknown parameter  $p$  (the conditions of our theorem can be seen to be satisfied along the lines of the previous section with  $M(x, a) = \text{const}$ ). The constant  $G$  in Figure 1 is chosen to be  $G = 2$ . The UCRL algorithm is an optimistic algorithm that maintains a confidence interval around each transition probability

$P(x'|x, a)$  and, in each round, finds the transition dynamics and the corresponding policy that attains the smallest average loss. Specifically, the algorithm solves the optimization problem  $\hat{P} = \operatorname{argmin}_P J(P)$ , where  $J(P)$  is the average loss of the optimal policy when the system dynamics is  $P$ . Then, the algorithm plays the optimal controller given the parameter  $\hat{P}$ . As we show next, the LAZY PSRL algorithm achieves lower average cost.

The time horizon in these experiments is  $T = 1,000$ . We repeat each experiment 10 times and report the mean and the standard deviation of the observations. Figure 3 shows average cost vs. number of rounds. Details of the implementation of the UCRL algorithm are in (Jaksch et al., 2010).

Figure 3 show the average cost of the algorithms. The LAZY PSRL algorithm outperforms the UCRL algorithm. We explain this observation by noting that the UCRL algorithm is learning components of the transition dynamics independently (400 components in total), while the LAZY PSRL algorithm takes advantage of the problem structure to speed up the learning.

## 7.2 Web Server Control Application

In this section we illustrate the behavior of LAZY PSRL on a simple LQR control problem. We choose an LQR control problem because it is a continuous state-action problem. Equally important is that this allowed us to compare the performance of LAZY PSRL to a competing method, the OFULQ algorithm of Abbasi-Yadkori (2012). The experiments go beyond the scope of the theory, as we did not use a stabilizing controller, though the control problem itself is such that the zero-dynamics (i.e., the dynamics under zero control) is stable, making it less likely that a stabilizing controller would be necessary for the method to work. In the next section we describe the control problem, which will be followed by the description of our results.

The problem is taken from Section 7.8.1 of the book by Hellerstein et al. (2004) (this example is also used in Section 3.4 of the book by Aström and Murray (2008)). An Apache HTTP web server processes the incoming connections that arrive on a queue. Each connection is assigned to an available process. A process drops the connection if no requests have been received in the last KEEPALIVE seconds. At any given time, there are at most MAXCLIENTS active processes. The values of the KEEPALIVE and MAXCLIENTS parameters, denoted by  $a_{ka}$  and  $a_{mc}$  respectively, are chosen by a control algorithm. Increasing  $a_{mc}$  and  $a_{ka}$  results in faster and longer services to the connections, but also increases the CPU and memory usage of the server. The state of the server is determined by the average processor load  $x_{cpu}$  and the relative memory usage  $x_{mem}$ . An *operating point of interest* of the system is given by  $x_{cpu} = 0.58, a_{ka} = 11s, x_{mem} = 0.55, a_{mc} = 600$ . A

linear model around the operating point is assumed, resulting in a model of the form

$$\begin{pmatrix} x_{cpu}^\Delta(t+1) \\ x_{mem}^\Delta(t+1) \end{pmatrix} = \begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{21} \end{pmatrix} \begin{pmatrix} x_{cpu}^\Delta(t) \\ x_{mem}^\Delta(t) \end{pmatrix} + \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{21} \end{pmatrix} \begin{pmatrix} a_{ka}^\Delta(t) \\ a_{mc}^\Delta(t) \end{pmatrix} + \begin{pmatrix} w_1(t+1) \\ w_2(t+1) \end{pmatrix},$$

where  $(w_1(t+1), w_2(t+1))_t$  is an i.i.d. sequence of Gaussian random variables, with a diagonal covariance matrix  $\mathbb{E}[w(t+1)^\top w(t+1)] = \sigma^2 I$ . Note that these state and action variables are in fact the deviations from the operating point. We test  $\sigma = 0.1$  and  $\sigma = 1.0$  in our experiments. The matrices  $A, B, Q, R$  are included in the appendix.

### 7.2.1 Numerical Results

We compare the LAZY PSRL algorithm with OFULQ (Abbasi-Yadkori, 2012). For the LAZY PSRL algorithm, we use the standard normal distribution as the prior. The OFULQ algorithm is an optimistic algorithm that maintains a confidence ellipsoid  $D$  around the unknown parameter and, in each round, finds the parameter and the corresponding policy that attains the smallest average loss. Specifically, the algorithm solves the optimization problem

$$(\tilde{A}, \tilde{B}) = \operatorname{argmin}_{(A,B) \in D} J(A, B), \quad (4)$$

where  $J(A, B)$  is the average loss of the optimal policy when the system dynamics is  $(A, B)$ . Then, the algorithm plays the optimal controller given the parameter  $(\tilde{A}, \tilde{B})$ . The objective function  $J$  is not convex and thus, solving the optimistic optimization can be very time consuming. As we show next, the LAZY PSRL algorithm can have lower regret while avoiding the high computational costs of the OFULQ algorithm.

The time horizon in these experiments is  $T = 1,000$ . We repeat each experiment 10 times and report the mean and the standard deviation of the observations. Figure 4 shows regret vs. computation time. The horizontal axis shows the amount of time (in seconds) that the algorithm spends to process  $T = 1,000$  rounds. We change the computation time by changing constant  $G$  in Figure 1, i.e. by changing how frequent an algorithm updates its policy.<sup>2</sup> Details of the implementation of the OFULQ algorithm are in (Abbasi-Yadkori, 2012).

The first two subfigures of Figure 4 show the regret of the algorithms when the standard deviation of the noise is  $\sigma = 0.1$ . The regret of the LAZY PSRL algorithm is slightly worse than what we get for the OFULQ algorithm in this case. The LAZY PSRL algorithm outperforms

<sup>2</sup>For example, in Figure 4-(d), the average number of policy changes are (33.4, 45.2, 88, 127.1). In Figure 4-(c) the average number of policy changes are (5.6, 14.3, 30.8, 73.2, 140.2, 163).

Figure 3: Average cost for a queuing problem.

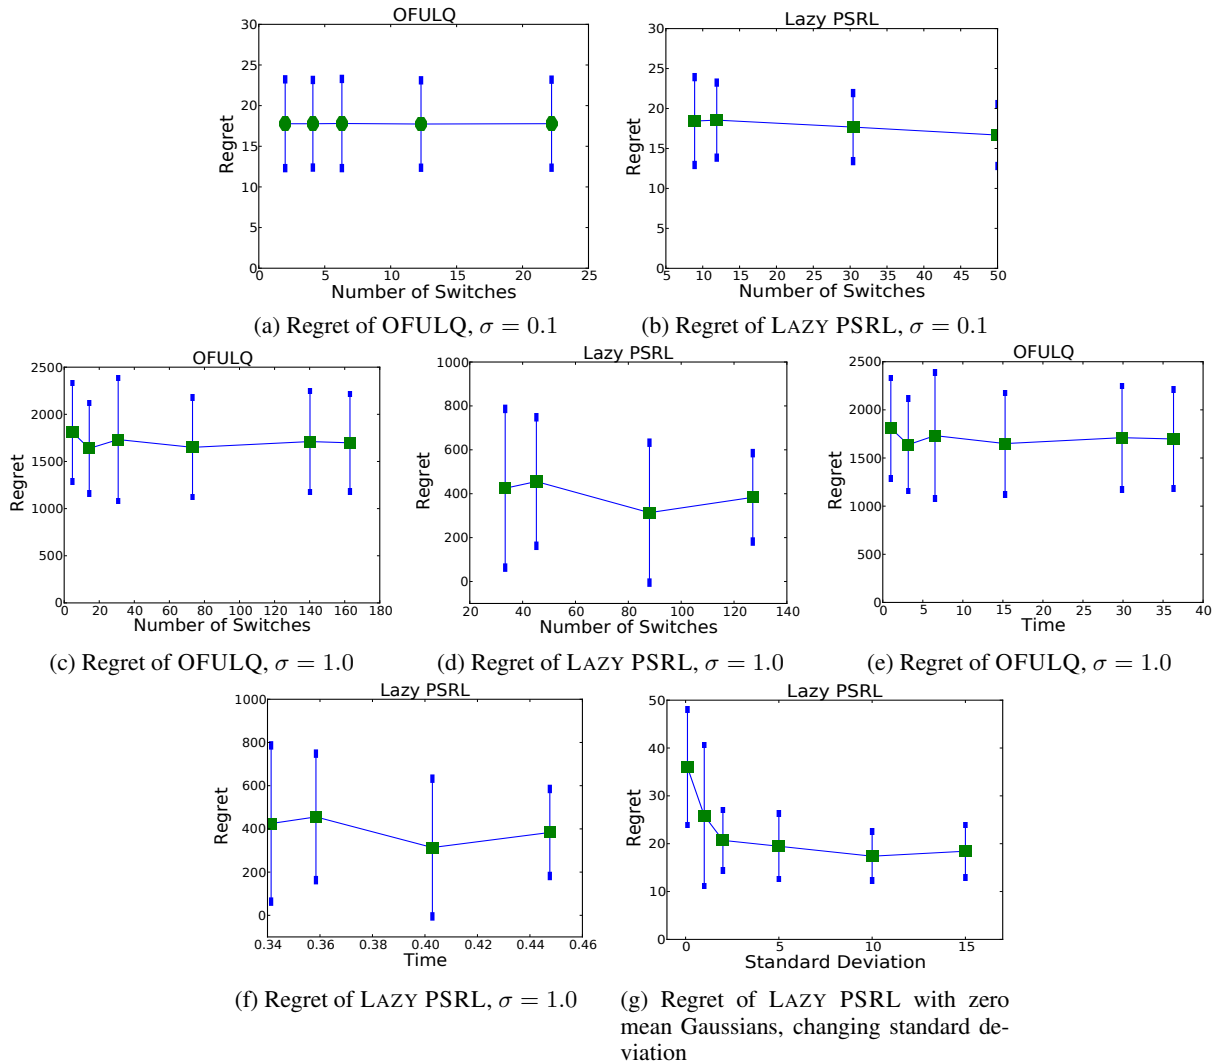

Figure 4: Regret for a web server control problem.

the OFULQ algorithm when the noise variance is larger (next two subfigures). We explain this observation by noting that a larger noise variance implies larger confidence ellipsoids, which results in more difficult optimistic opti-

mization problems (4). Finally, we performed experiments with different prior distributions. Figure 4-(e) shows regret of the LAZY PSRL algorithm when we change the prior.

## Abstract

Reducing uncertainty is an important problem in many applications such as risk and reliability analysis, system design, etc. In this paper, we study the problem of optimally querying experts to reduce interval uncertainty. Surprisingly, this problem has received little attention in the past, while similar issues in preference elicitation or social choice theory have witnessed a rising interest. We propose and discuss some solutions to determine optimal questions in a myopic way (one-at-a-time), and study the computational aspects of these solutions both in general and for some specific functions of practical interest. Finally, we illustrate the application of the approach in reliability analysis problems.

## 1 INTRODUCTION

When data on some quantity or model of interest is sparse or non-existing, elicitation, i.e., the process of extracting human judgement through questions, is often a valuable and sometimes the unique source of additional knowledge. There is a substantial literature dating back to the sixties on elicitation and is mainly related to probability encoding (Winkler, 1969; Spetzler and Stael von Holstein, 1975) and preference elicitation (Keeney et al., 1979). Elicitation is used in a broad range of fields including risk assessment (Cooke, 1991), reliability analysis, preference model elicitation (Viappiani and Kroer, 2013; Guerin et al., 2013), etc. to support assessment and decision making.

A critical part of the elicitation is then how to choose the questions to ask. Those need to be simple (i.e., do not require high cognitive effort) and in terms and format experts are familiar with. Furthermore, when the elicitation is conducted to reach some objective, for instance bringing an answer to a question, selecting the best alternative in a set, or estimating some quantity with a desired level precision, the process of information acquisition need to be optimal

for the elicitation to be effective and the least possible time or effort consuming.

How to choose sequences of optimal questions, or even the notion of optimal queries, has received surprisingly little attention when the aim is to reduce our uncertainty over some quantities. Indeed, the great majority of techniques to do so prescribe generic questions, without considering the consequences of answers on some final goal (Aspinall and Cooke, 2013) (the work of Curtis and Wood (Curtis and Wood, 2004), settled in a probabilistic context, is an exception). This contrasts with other fields such as preference elicitation of social choice theory, with works dating back two decades ago (Boutilier et al., 1997; Wang and Boutilier, 2003; Boutilier et al., 2006) and still thriving today (Viappiani and Kroer, 2013; Benabbou et al., 2014; Boutilier et al., 2013).

The goal of this paper is to explore similar ideas when the goal is to reduce interval uncertainty by asking successive simple questions to the experts. We want to develop querying strategies that are adaptive and optimal, i.e., that select at each stage of the elicitation the best questions based on the answers to the previous ones. In this paper, we focus on so-called myopic (Wang and Boutilier, 2003; Chajewska and Koller, 2000) strategies, where optimal questions are selected one-at-a-time.

The remainder of the paper is organized as follows. In Section 2, we formalize the sequential elicitation model for the problem of interval uncertainty reduction in the general case. Within this same section (Section 2.3), we describe different query selection strategies, and analyse their computational costs in the general case, which is an important aspect to consider in adaptive procedures. Section 3 then discusses the case of specific yet important (in practice) type of functions, namely monotonic and multi linear functions. In the last section, we illustrate how the approach can be used in reliability analysis.

## 2 GENERAL FRAMEWORK

### 2.1 PROBLEM STATEMENT

Let  $\Phi$  be a function mapping a set of  $n$  logically independent inputs  $(x_1, \dots, x_n)$ , each of them being defined on  $X_i$ , to an output  $y$  in  $Y$  :

$$\begin{aligned} \Phi : \mathbf{X} = \times_{i=1 \dots n} X_i &\rightarrow Y \\ \mathbf{x} = (x_1, \dots, x_n) &\mapsto \Phi(\mathbf{x}) = y. \end{aligned}$$

In this paper, we are interested in the situation where  $x_i$  is a precise but ill-known value, whose uncertainty is described by an interval  $X_i = [\underline{X}_i, \overline{X}_i] \subset \mathbb{R}$  of the real line. Such kind of uncertainty, where the true value is exact, is sometimes called epistemic (by opposition to aleatory). A natural way to quantify the amount of uncertainty in  $X_i$  is by its width

$$U_{X_i}(x_i) = U_{X_i} = \overline{X}_i - \underline{X}_i.$$

We also require the function  $\Phi$  to be continuous, so that the response  $y$  corresponding to the initial state of knowledge on the inputs lies in the bounded interval :

$$Y = \Phi(\mathbf{X}) = \left[ \min_{\mathbf{x} \in \mathbf{X}} \Phi(\mathbf{x}), \max_{\mathbf{x} \in \mathbf{X}} \Phi(\mathbf{x}) \right] = [\underline{Y}, \overline{Y}]. \quad (1)$$

**Example 1.** Consider the function  $\Phi(x_1, x_2, x_3) = x_1 x_2 - x_2 x_3$  with  $X_1 = X_2 = X_3 = [0, 1]$ , then we have

$$\underline{Y} = \Phi(\underline{X}_1, \overline{X}_2, \overline{X}_3) = -1; \overline{Y} = \Phi(\overline{X}_1, \overline{X}_2, \underline{X}_3) = 1.$$

The problem we are considering is the following : we want to reduce our uncertainty  $U_Y = \overline{Y} - \underline{Y}$  by asking question to experts, to attain some objectives. For instance, we may want to reduce the uncertainty under some threshold  $U_Y \leq s_0$  or simply reduce the most  $U_Y$  in a given number of questions. As expert elicitation is time-consuming and cognitively demanding for the expert, and economically expensive for the decision maker, we want to ask as few questions as possible, or to be the most effective possible on those questions we ask. In other words, we want the querying strategy to be optimal. This is what we develop in the next sections.

### 2.2 QUERIES AND ANSWERS

In expert elicitation in general, and when the elicitation is made of many successive questions, it is important to use simple questions that not require high cognitive effort (for understanding and answering) for the expert to be efficient throughout the interview. Possible simple queries formats include local bound queries (“ $x_i \leq \alpha$ ?”), pairwise comparison judgements (“ $x_i \leq x_j$ ?”), etc. (Braziunas and Boutilier, 2007).

In our method, we use questions of the type “ $x_i \leq \alpha$ ?”, with  $\alpha \in X_i$ . We denote such a query  $Q_i^\alpha$  and the set of possible queries  $\mathcal{Q} = \{Q_i^\alpha, i \in N = \{1, 2, \dots, n\}, \alpha \in X_i\}$ .

In the particular case of local bound queries, the set of possible answers  $\mathcal{A}$  is binary :  $\mathcal{A} = \{Yes, No\}$ . We recall that, for simplicity and for conciseness, we assume that the expert is an oracle, so the “I don’t know” answer is not considered here<sup>1</sup>. Note that the ideas presented in the paper could easily be applied to other sets of questions/answers  $\mathcal{Q}, \mathcal{A}$ , yet binary questions are the simplest and the most natural to ask to experts.

When a question  $Q_i^\alpha$  is asked and answer  $A \in \mathcal{A}$  is given,  $X_j$  remains unchanged for every  $j \neq i$ , while  $X_i$  is updated to  $X_i(Q_i^\alpha, A)$  as follows :

$$X_i(Q_i^\alpha, A) = \begin{cases} X_i \cap [-\infty, \alpha] & \text{if } A = Yes \\ X_i \cap [\alpha, -\infty] & \text{if } A = No \end{cases} \quad (2)$$

which satisfies  $X_i(Q_i^\alpha, A) \subseteq X_i$  and  $X_j(Q_i^\alpha, A) = X_j$  for every  $j \neq i$ . Consequently, the output uncertainty set is updated from  $Y$  into  $Y(Q_i^\alpha, A)$  :

$$Y(Q_i^\alpha, A) = \Phi(X_{-i} \times X_i(Q_i^\alpha, A)), \quad (3)$$

where  $X_{-i} = \times_{j \neq i} X_j$  denotes the Cartesian product of all unchanged intervals. As for any  $Q \in \mathcal{Q}$  and  $A \in \mathcal{A}$  we have  $Y(Q, A) \subseteq Y$  by simple interval inclusion, the following relation always holds :

$$U_Y \geq U_{Y(Q,A)} \quad (4)$$

therefore ensuring an uncertainty reduction.

**Example 2.** In Example 1, assume we ask the question  $Q_1^{0.5}$  and receive the answer *Yes*, then

$$X_1(Q_1^{0.5}, Yes) = [0, 0.5]$$

$$\overline{Y}(Q_1^{0.5}, Yes) = \Phi(\overline{X}_1, \overline{X}_2, \underline{X}_3) = 0.5.$$

### 2.3 QUERY SELECTION STRATEGIES

A query selection strategy corresponds to define and choose optimal questions. There are two main ways to do so : myopically, where questions are selected and asked one at a time, successively, and sequentially, where the set of successive questions is selected globally. Here, we retain the myopic approach for the following reasons : it is often simpler to solve, sometimes allowing for analytical exact solutions, and does not require to specify the number of asked questions in advance, a particularly interesting feature in iterative and interactive querying process.

1. Should the expert return “I don’t know” to  $Q_i^\alpha$ , then a simple strategy is to remove  $Q_i^\alpha$  (and possibly questions with similar values of  $\alpha$ ) from the question set  $\mathcal{Q}$  and then select the optimal one among the remaining ones.

The selection process of the myopic approach consists in solving the following optimization problem at each iteration :

$$Q^* = \arg \min_{Q \in \mathcal{Q}} U_Y(Q), \quad (5)$$

where  $U_Y(Q)$  is the uncertainty reduction induced by query  $Q$ . However, as the answer  $\mathcal{A}$  that will be given to  $Q$  is unknown, we face a typical problem of decision making under uncertainty.

In our case, the decision is a couple  $(i, \alpha) \in N \times X_i$ , the uncertain event is the answer to the question, and the outcome we want to maximize is the uncertainty reduction in the output  $Y$ . Re-writing the decision problem using notations of our query selection problem leads to the following characterization of the optimal queries :

$$Q^* = (i^*, \alpha^*) = \arg \min_{i \in N} \min_{\alpha \in X_i} U_Y(Q_i^\alpha), \quad (6)$$

which is a two stage optimization problem. First, we determine the optimal local bound value for each input  $i$ , and calculate the uncertainty reduction induced by that local query. Then, we select the entity  $i^*$  that leads to the highest uncertainty reduction in  $y$ .

---

**Algorithm : Iterative elicitation for uncertainty reduction**

---

```

Inputs :  $X_i (i \in N), s_0$ 
while  $U_Y \geq s_0$  do
  for  $i$  in  $N$  do
    Compute  $\alpha^* = \arg \min_{\alpha \in X_i} U_Y(Q_i^\alpha)$ 
    Compute  $U_Y(Q_i^{\alpha^*})$ 
  end for
   $i^* = \arg \min_{i \in N} U_Y(Q_i^{\alpha^*})$ 
  Ask query : “ $x_{i^*} \leq \alpha^*$ ?”
  Obtain answer
  Update  $X_{i^*}$ 
  Compute  $U_Y$ 
end while

```

---

In the following, we describe the computations involved in the first optimization step (the computation of  $U_Y(Q_i^\alpha)$ ) for a given  $i \in N$  for different decision criteria.

### 2.3.1 Maximin strategy

The maximin strategy corresponds to a pessimistic view, where the value  $U_Y(Q_i^\alpha)$  corresponds to the answer that yields the lowest uncertainty reduction :

$$\begin{cases} U_Y^{Mm}(Q_i^\alpha) = \max_{A \in \mathcal{A}} U_Y(Q_i^\alpha, A) \\ \alpha^{*,Mm} = \arg \min_{\alpha \in X_i} \max(U_Y(Q_i^\alpha, N_o), U_Y(Q_i^\alpha, Y_{es})) \end{cases}$$

We can show that solving the optimization problem to get the optimizing  $\alpha^*$  is equivalent to finding the intersection

of the two functions  $U_Y(Q_i^\alpha, Y_{es}), U_Y(Q_i^\alpha, N_o)$  of  $\alpha$ . The following propositions indicates that a general and efficient method to find the solution is to use a dichotomy search on the space  $[\underline{X}_i, \overline{X}_i]$

**Proposition 1.** *Functions  $U_Y(Q_i^\alpha, Y_{es})$  and  $U_Y(Q_i^\alpha, N_o)$  measuring the uncertainty level on  $Y$  induced by a positive and a negative answer to  $Q_i^\alpha$  and defined on  $X_i$  are – increasing and decreasing in  $\alpha$ , respectively, and – intersect at least once at  $M_i \subset X_i$  ( $M_i$  is a single point or an interval).*

**Proof.** *We have that*

$$U_Y(Q_i^\alpha, Y_{es}) = \max_{X_{-i} \times [\underline{X}_i, \alpha]} \Phi(\mathbf{x}) - \min_{X_{-i} \times [\underline{X}_i, \alpha]} \Phi(\mathbf{x}) \quad (7)$$

*To show that  $U_Y(Q_i^\alpha, Y_{es})$  is increasing in  $\alpha$ , we need to show that  $U_Y(Q_i^\alpha, Y_{es}) \leq U_Y(Q_i^\beta, Y_{es})$  for  $\alpha \leq \beta$ . This result follows from  $X_{-i} \times [\underline{X}_i, \alpha] \subseteq X_{-i} \times [\underline{X}_i, \beta]$ .*

*The same reasoning can be applied to*

$$U_Y(Q_i^\alpha, N_o) = \max_{X_{-i} \times [\alpha, \overline{X}_i]} \Phi(\mathbf{x}) - \min_{X_{-i} \times [\alpha, \overline{X}_i]} \Phi(\mathbf{x}) \quad (8)$$

*to show that  $U_Y(Q_i^\alpha, N_o)$  is decreasing in  $\alpha$ .*

*To demonstrate the second part of the proposition, simply observe that :*

$$\begin{aligned} \max_{\alpha \in X_i} U_Y(Q_i^\alpha, Y_{es}) &= U_Y(Q_i^{\overline{X}_i}, Y_{es}) = U_Y, \\ \max_{\alpha \in X_i} U_Y(Q_i^\alpha, N_o) &= U_Y(Q_i^{\underline{X}_i}, N_o) = U_Y, \end{aligned}$$

*where  $U_Y$  is the uncertainty before the question. As both functions have the same maximum, are continuous (since  $\Phi$  is), and are respectively increasing and decreasing in  $\alpha$ , they have at least one point of intersection.*

When  $M_i$  is an interval  $[\underline{M}_i, \overline{M}_i]$ , we simply take the middle point  $\alpha^{*,Mm} = \frac{\underline{M}_i + \overline{M}_i}{2}$ . In some situations, it may also happen that the intersection occurs on the bounds of  $X_i$  for all  $i$ , which means that the proposed optimal question is likely to be uninformative, unless the expert answer reduces the interval  $[\underline{X}_i, \overline{X}_i]$  to a point, which is unlikely. When such a scenario occurs, we use a different strategy that defines optimality as the highest reduction of uncertainty, no more on  $Y$ , but on  $X_i$ . This heuristic is equivalent, when  $X_i$ s are intervals, to choosing the largest interval  $i^* = \arg \max_i U_{X_i}$  and to pick the mid of this interval, i.e.,  $\alpha^{*,Mm} = \frac{\underline{X}_{i^*} + \overline{X}_{i^*}}{2}$ .

In Section 3, we will show that for specific functions, there are more efficient ways than a naive dichotomic search to determine  $\alpha^{*,Mm}$ .

### 2.3.2 Maximax strategy

While the maximin strategy is pessimistic, the maximax strategy is optimistic and takes as value  $U_Y(Q_i^\alpha)$  the answer that yields the highest uncertainty reduction :

$$\begin{cases} U_{Y(Q_i^\alpha)}^{MM} = \min_{A \in \mathcal{A}} U_{Y(Q_i^\alpha, A)} \\ \alpha^{*, MM} = \arg \min_{\alpha \in X_i} \min(U_{Y(Q_i^\alpha, No)}, U_{Y(Q_i^\alpha, Yes)}). \end{cases}$$

It is straightforward from Proposition 1 that the local bound optimization step leads to an optimal value  $\alpha^{*, MM}$  that coincides either with the upper or lower bound of  $X_i$ . The maximax strategy is therefore not interesting in our problem, as it will lead to questions that are most likely to receive a useless answer. We will therefore not retain this approach in this paper.

### 2.3.3 Hurwicz' strategy

Hurwicz's strategy evaluates the value of a question  $Q$  by a convex combination between the maximin and maximax strategies. It therefore allows to go from a pessimistic to an optimistic point of view and reads :

$$\begin{cases} U_{Y(Q_i^\alpha)}^{H(p)} = pU_{Y(Q_i^\alpha)}^{MM} + (1-p)U_{Y(Q_i^\alpha)}^{Mm} \\ \alpha^{*, H(p)} = \arg \min_{\alpha \in X_i} (p \min(U_{Y(Q_i^\alpha, Yes)}, U_{Y(Q_i^\alpha, No)}) + (1-p) \max(U_{Y(Q_i^\alpha, Yes)}, U_{Y(Q_i^\alpha, No)})). \end{cases}$$

Here,  $p \in [0, 1]$  is an optimism coefficient, and we retrieve the maximax and maximin strategies when  $p = 1$  and  $p = 0$ , respectively. Note that we can use the fact that for any  $\alpha \leq \underline{M}_i$  ( $\alpha \geq \overline{M}_i$ ), we have  $U_{Y(Q_i^\alpha, No)} \geq U_{Y(Q_i^\alpha, Yes)}$  ( $U_{Y(Q_i^\alpha, No)} \leq U_{Y(Q_i^\alpha, Yes)}$ ) to rewrite the above equations into :

$$\begin{cases} L = \min_{\alpha \in [\underline{X}_i, \inf M_i]} (pU_{Y(Q_i^\alpha, Yes)} + (1-p)U_{Y(Q_i^\alpha, No)}) \\ R = \min_{\alpha \in [\sup M_i, \overline{X}_i]} (pU_{Y(Q_i^\alpha, No)} + (1-p)U_{Y(Q_i^\alpha, Yes)}) \\ \alpha^{*, H(p)} = \min(L, R). \end{cases}$$

### 2.3.4 Bayesian strategy

Up to now, we have not considered any a priori information about the likelihood of answering Yes or No. However, this can lead to consider very unlikely answers, such as answering *Yes* to  $Q_i^{\underline{X}_i}$  (as is the case in the maximax strategy). One alternative is then the Bayesian strategy, where we assume the existence of a probability distribution  $P$  over the set of answers  $\mathcal{A}$ , this probability modelling our subjective beliefs about the likelihood of getting the different answers. We then evaluate a query  $Q$  by the expected reduction  $\mathbb{E}_P(U_{Y(Q, A)})$  of uncertainty on  $y$  induced by the possible answers :

$$\begin{cases} U_{Y(Q_i^\alpha)}^B = \mathbb{E}_P(U_{Y(Q_i^\alpha, A)}) = \sum_{A \in \mathcal{A}} P(A)U_{Y(Q_i^\alpha, A)} \\ \alpha^{*, B} = \arg \min_{\alpha \in X_i} (P(Yes|Q_i^\alpha)U_{Y(Q_i^\alpha, Yes)} + P(No|Q_i^\alpha)U_{Y(Q_i^\alpha, No)}). \end{cases}$$

When the available evidence suggests that a quantity  $x_i$  lies in an interval  $X_i$ , it is common to follow Laplace's indifference principle and quantify uncertainty by assuming a

uniform probability distribution over that set. Under this assumption, the probability of the positive and negative answers to a question  $Q_i^\alpha$  are proportional to the width of the sub-interval of  $X_i$  they lead to :

$$P(Yes|Q_i^\alpha) = P(\underline{X}_i \leq x_i \leq \alpha) = \frac{\alpha - \underline{X}_i}{\overline{X}_i - \underline{X}_i}$$

and

$$P(No|Q_i^\alpha) = P(\alpha \leq x_i \leq \overline{X}_i) = \frac{\overline{X}_i - \alpha}{\overline{X}_i - \underline{X}_i}.$$

These probabilities can then be modified according to the information we have (for instance, if we have reasons to think that the true value is closer to  $\overline{X}_i$ ).

**Remark 1.** Note that when  $U_{Y(Q_i^\alpha, Yes)} = U_{Y(Q_i^\alpha, No)} = U_{Y(Q_i^\alpha)}$ , then  $\mathbb{E}_P(U_{Y(Q_i^\alpha, A)}) = U_{Y(Q_i^\alpha)}$ , whatever the values of  $P$ . This means, among other things, that the function  $U_{Y(Q_i^\alpha)}^B$  has value  $U_{Y(Q_i^{\alpha^*, Mm})}^B = U_{Y(Q_i^{\alpha^*, Mm})}^{Mm}$ , since the minimax is obtained at the intersection  $M_i$  of  $U_{Y(Q_i^\alpha, Yes)}$  and  $U_{Y(Q_i^\alpha, No)}$ .

This means that we have :  $\min_{X_i} U_{Y(Q_i^\alpha)}^B = U_{Y(Q_i^{\alpha^*, B})}^B \leq U_{Y(Q_i^{\alpha^*, Mm})}^{Mm} = \min_{X_i} U_{Y(Q_i^\alpha)}^{Mm}$ , hence the expected uncertainty reduction with a Bayesian strategy is at least as high as the one obtained by the maximin strategy. However, in contrast with this latter, the Bayesian strategy does not offer guarantees about the uncertainty reduction, in the sense that the actual reduction may be lower than the expected one.

Also, while Proposition 1 means that  $\alpha^{*, Mm}$  can be obtained by a dichotomic search, this cannot be done in general for the Bayesian strategy, which therefore requires heavier computations.

**Example 3.** Consider the function  $\Phi(x_1, x_2, x_3) = x_1x_2 - x_2x_3 + x_2$  with  $X_1 = X_3 = [0.1, 1]$  and  $X_2 = [0, 1]$ . Figure 1 shows the various strategies for  $Q_2^\alpha$ . We can see that the maximin, the Laplacian and Hurwicz's strategies recommend respectively  $\alpha^{*, Mm} = 3/4$ ,  $\alpha^{*, B} = 1/2$ , and  $\alpha^{*, H(1/2)} = 0$ . Another remark is that  $U_{Y(Q_2^\alpha, Yes)}$  and  $U_{Y(Q_2^\alpha, No)}$  are both linear. We will see in the next section that this is true for multi linear functions in general.

## 3 QUERYING ON SPECIFIC FUNCTIONS

Here, we study what becomes of the previous strategies when applying them to specific functions. Indeed, finding an optimal strategy requires computing  $U_{Y(Q_i^\alpha, Yes)}$ ,  $U_{Y(Q_i^\alpha, No)}$  and their intersections, which comes down to finding bounds of  $\Phi$  over various domains (see Eqs. (7)-(8)). It is therefore important to identify those sub-cases for which computations can be simplified. More precisely, we look at monotonic functions and multi linear functions, that are both of practical interest.

FIGURE 1 – Optimal recommendations of different query selection strategies.

### 3.1 MONOTONIC FUNCTIONS

Several application in diverse areas use monotonic functions, such as reliability analysis (Marichal, 2014), multi-criteria decision making (Grabisch and Labreuche, 2008), etc.

When considering such functions, either increasing or decreasing in each variable  $x_i$ , computations are greatly facilitated, as

$$U_Y = \Phi(\overline{X}_I, \underline{X}_{\overline{I}}) - \Phi(\underline{X}_I, \overline{X}_{\overline{I}}),$$

where  $I$  denotes the set of variables in which  $\Phi$  is increasing, and  $\overline{I}$  its complement.

Moreover, when  $\Phi$  is locally monotonic<sup>2</sup> with respect to each argument  $i$ , its upper and lower bounds are reached on the vertices of the hypercube  $\times_{i=1\dots n} X_i$ . Again, this may allow to reduce the computations involved in the calculation of  $U_Y$ .

### 3.2 MULTI LINEAR FUNCTIONS

A Multi-linear function over variables  $x_1, \dots, x_n$  is a polynomial form that can be written as

$$\Phi(x_1, \dots, x_n) = \sum_{A \subseteq N} d_A \prod_{i \in A} x_i \quad (9)$$

with  $d_A \in \mathbb{R}$  some real-valued coefficients. Such functions play an important role in many AI applications. As any pseudo-Boolean function can be rewritten in this form (Hammer and Rudeanu, 1968), they concern all problems where pseudo-Boolean functions have a role, such as cooperative game theory (Owen, 1972), multi-criteria decision-making (Grabisch and Labreuche, 2003), combinatorial optimization (Yannakakis, 1991), reliability theory (Bhattacharjya and Deleris, 2012; Marichal, 2014), etc. Multi linear functions also play an important role in

<sup>2</sup>  $\phi$  is locally monotone in  $x_i$  if, all other variables being fixed, it is either decreasing or increasing in  $x_i$ . Function  $\phi$  of Example 1 is locally monotone in  $x_2$ , as it is either increasing or decreasing in  $x_2$  once  $x_1$  and  $x_3$  are fixed.

inferences of Bayesian networks or related models (Darwiche, 2003; de Campos and Cozman, 2004).

From a computational point of view, having  $\Phi$  multi-linear presents different advantages. First, as  $\phi$  is locally monotonic in each variable (fixing every variable values but one in Eq. (9) gives a linear function, which is either increasing or decreasing), we know that its upper and lower bounds are reached on vertices of  $\times_{i=1\dots n} X_i$ . Second, provided  $0 \notin X_i$ , the maximin strategy will lead to a unique value  $\alpha^{*,M^m}$ , due to the fact that  $U_Y(Q_i^\alpha, Y_{es})$ ,  $U_Y(Q_i^\alpha, N_o)$  will be strictly increasing and decreasing, respectively (since bounds of Eq. (9) will be strictly monotone functions).

### 3.3 MULTI LINEAR MONOTONIC FUNCTIONS

Combining monotonicity and multi linear properties provide very interesting properties to compute our optimal strategies, and are still useful in several applications, such as reliability analysis that we use as a case study in the next section. The first property relates to the shape of  $U_Y(Q_i^\alpha, Y_{es})$  and  $U_Y(Q_i^\alpha, N_o)$

**Proposition 2.** *If  $\Phi$  is a multi linear function monotonic in each variable, then for every  $i \in N$ ,  $U_Y(Q_i^\alpha, Y_{es})$  and  $U_Y(Q_i^\alpha, N_o)$  are linear in  $\alpha$ .*

**Proof.** *If  $\Phi$  is monotonic in each variable, then in the first term of Eq. (7), the maximum is reached on the upper bounds of each  $X_i$ , i.e., on  $\overline{X}_j$  for all  $j \in N_{-i}$  and  $\overline{X}_i = \alpha$ , while the lower bound is reached on  $\underline{X}_j$  for all  $j \in N$  (independent of  $\alpha$ ). The function  $\Phi$  being linear in  $x_i$ ,  $\max \Phi(\mathbf{x})$  is therefore linear in  $\alpha$ , and so is  $U_Y(Q_i^\alpha, Y_{es})$ . The same reasoning applies to Eq. (8).*

This has several consequences on the computations of strategies :

- The maximin strategy recommends a unique query bound  $M_i$  in  $X_i$ , as  $U_Y(Q_i^\alpha, Y_{es})$  and  $U_Y(Q_i^\alpha, N_o)$  intersection will be a unique point ;
- Computing  $U_Y(Q_i^\alpha, Y_{es})$  and  $U_Y(Q_i^\alpha, N_o)$  will require only three computations, as they are linear (requiring each two evaluations) and as they have the same maximal value. Computing  $M_i$  then comes down to evaluate the intersection point of two lines ;
- Hurwicz’s solution will be reached either at the end-points of the interval  $X_i$  or will coincide with the maximin solution. The result follows from the fact that the convex combination of linear functions ( $U_Y(Q_i^\alpha, Y_{es})$  and  $U_Y(Q_i^\alpha, N_o)$ ) is also linear, and is therefore monotonic in  $\alpha$ .

Furthermore, we have the following property regarding the Bayesian strategy :

**Proposition 3.** *If  $\Phi$  is a multi linear function monotonic in each variable, the Bayesian strategy adopting a uniform distribution over  $X_i$  has a unique minimum  $\alpha$  in the interior of  $X_i$*

**Proof.** (sketch) Function  $U_{Y(Q_i^\alpha)}^B$  is convex since it is the sum of the product of two linear functions of  $\alpha$ , therefore it is quadratic and convex. In addition, it satisfies :  $U_{Y(Q_i^{X_i})}^B = U_{Y(Q_i^{\bar{X}_i})}^B$ .

Since it can not be a constant function (the scenario  $U_{Y(Q_i^\alpha, Y_{es})} = U_{Y(Q_i^\alpha, N_o)}$  for every  $\alpha \in X_i$  does not occur for multi linear functions), its global minimum exists, is unique, and is reached inside the interval  $X_i$ .

## 4 APPLICATION IN RELIABILITY ANALYSIS

When systems are complex or newly designed, full system dependability data are often too expensive and/or difficult to obtain, making it impossible to directly estimate quantities of interest. The common approach to improve the estimation of such quantities is to focus on enhancing the state of knowledge at the component-level, where information is more likely to be available either via measurements or expert elicitation.

In this section, we illustrate how our elicitation model can be used to refine the state of knowledge at the component level in order to estimate the reliability of a system. We begin by recalling some basic elements related to systems reliability and briefly describe the mathematical properties of the system function. Then, we describe and discuss the results of the proposed elicitation procedure on simple yet common system architectures, to finish by a real-world example involving railway safety systems.

### 4.1 PRELIMINARIES ON RELIABILITY ESTIMATION

Consider a network  $S$  with  $n$  components indexed in  $N = \{1, 2, \dots, n\}$ . We describe a static problem, i.e., we do not refer to time explicitly when describing the system behavior. Every component  $i$  is either operating or failing and its state is represented by a boolean variable  $e_i$  that associates 0 and 1 to the failed, working state, respectively. The system state is completely determined by the joint state of its components through the *structure function*  $\Phi_S$  – a boolean function. For the majority of systems, forming the class of semi-coherent systems, the structure function satisfies these three conditions :

- $\Phi_s$  non-decreasing in each  $e_i$
- $\Phi_s(0, 0, \dots, 0) = 0$
- $\Phi_s(1, 1, \dots, 1) = 1$ .

In reality, the state of component can not be determined exactly, and the usual framework is to assume that is a random variable. The probability that the component is functioning is called the elementary reliability :

$$p_i = Pr(e_i = 1).$$

When the components are independent, i.e., when their state variables are stochastically independent, the reliability of the system :

$$R = Pr(\Phi_s(e_1, \dots, e_n) = 1),$$

can be determined from the reliability of its components via the *reliability function*  $\Phi$  :

$$R = \Phi(p_1, \dots, p_n), \quad (10)$$

which is the multi linear extension of  $\Phi_s$  (Marichal, 2014) and so writes :

$$\Phi(p_1, \dots, p_n) = \sum_{A \subseteq N} d_A \prod_{i \in A} p_i$$

where coefficients  $d_A$  are the Mobius transform of the mass function associated with the structure function<sup>3</sup>. In practice, the exact expression of the reliability function can be directly generated using the inclusion-exclusion formula (Lin et al., 1976) based on determining the minimal path set (i.e., the minimal set of components that must be in working state that guarantees the functioning of the system) and cut sets (the minimal set of components such that if all of them fail, the system is guaranteed to fail whatever the value of the others components).

Therefore, when facing a new system with ill-known probabilities, we have a multi linear function  $\phi$  with interval-valued variables  $p_i$ , to which we can apply our previous findings.

### 4.2 CLASSICAL STRUCTURES

We first consider a bridge structure with 5 non redundant components. The reliability block diagram – a graphical depiction of the functional relationship between components – of this structure is given below :

FIGURE 2 – Reliability block diagram of a series parallel system.

<sup>3</sup>. The Mobius transform of the mass function associated to  $\Phi_s$  is given by :

$$d_A = \sum_{B \subseteq A} (-1)^{|A|-|B|} \Phi_s(B).$$

The system reliability is given by :

$$\begin{aligned}
R &= p_1 p_2 + p_4 p_5 + p_1 p_3 p_5 + p_2 p_3 p_4 \\
&- p_1 p_2 p_3 p_4 - p_1 p_2 p_3 p_5 - p_1 p_2 p_4 p_5 - p_1 p_3 p_4 p_5 \\
&- p_2 p_3 p_4 p_5 + p_1 p_2 p_3 p_4 p_5.
\end{aligned}$$

We assume the initial state of knowledge to be the following :  $p_1 \in P_1 = [0.5, 0.92]$ ,  $p_2 \in P_2 = [0.2, 0.9]$ ,  $p_3 \in P_3 = [0.5, 0.9]$ ,  $p_4 \in P_4 = [0.4, 0.8]$ , and  $p_5 \in P_5 = [0.4, 0.85]$ . The system reliability ranges in the interval  $[0.3, 0.97]$ , so its initial uncertainty is 0.67.

We use the elicitation procedure to refine the state of knowledge over  $p_i$  ( $i \in \{1, \dots, 5\}$ ) via a sequence of queries on the elemental reliabilities. The objective is to reduce the system reliability uncertainty up to 0.05 (i.e.,  $s_0 = 0.05$ ), after which we stop asking questions.

To evaluate the efficiency of our procedure, we compare its performance to two basic strategies :

1. a random strategy that compares at each stage the reliability of component  $i$ , selected at random in  $N$ , with some random  $\alpha \in P_i$ . For the results to be significant, the performance of the strategy at each iteration is averaged over a high number (herein 1000) of runs.
2. a baseline strategy that asks at each stage about the most uncertain component, and the query bound is the midpoint of the largest interval (this strategy was referred to as the ‘‘halve largest Gap Strategy’’ in the context of preference elicitation (Boutillier et al., 2006)) :

$$Q_{Baseline}^* = \left( i^*, \frac{\bar{X}_{i^*} + \underline{X}_{i^*}}{2} \right)$$

where :

$$i^* = \arg \max_{i \in N} U_{X_i}.$$

FIGURE 3 –  $U_R$  reduction using different selection strategies.

We implemented the elicitation procedure described in Section 2.3 assuming the true values to be the following :

$p_1^* = 0.6$ ,  $p_2^* = 0.7$ ,  $p_3^* = 0.65$ ,  $p_4^* = 0.7$ ,  $p_5^* = 0.78$ . Figure 3 shows the performance in terms of uncertainty reduction in  $R$  of our four strategies. The Bayesian slightly outperforms the baseline and the maximin strategies, but remains comparable to them, while all of them do much better than the random elicitation. In general, it takes twice the number of queries to the random strategy to reach the results of the other strategies (e.g., to divide uncertainty by half, it requires 10 questions for the random strategy, and about 5 for the others).

However, the performances of the Bayesian, maximin and baseline strategies highly depend on the initial situations. Figure 4 compares our previous experiment with another situation where the initial state of knowledge is very poor, i.e., a situation of near ignorance where  $P_i = [0.1, 0.9]$  for all  $i \in N$ . Results for both scenarios differentiated by the color and the line style (blue continuous lines and black dashed lines for the first and the second scenarios, respectively). The most notable difference between the two scenarios concerns the maximin strategy. Indeed, its performance in the second scenario significantly departs from the non-random strategies (to which it was very close in the first scenario). The maximin strategy is in this case probably too cautious, missing potentially good opportunities to reduce the uncertainty.

FIGURE 4 – Sensitivity of the performance of the selection strategies to the initial state of knowledge.

The good results of the baseline strategy for the bridge system are mainly due to the fact that every component is important in the system, hence gaining knowledge on any one of them reduces uncertainty in similar ways. This is not always true : consider a simple series parallel system composed of four independent and non-identical components (Fig. 5). The system reliability is :

$$R = p_1 p_2 p_3 p_4 + p_1 p_4 + p_2 p_4 + p_3 p_4 - p_1 p_3 p_4 - p_2 p_3 p_4 - p_1 p_2 p_4.$$

Let the initial state of knowledge on the elementary reliabilities be the following :  $p_1 \in [0.01, 0.99]$ ,  $p_2 \in [0.01, 0.99]$ ,  $p_3 \in [0.97, 0.99]$ ,  $p_4 \in [0.7, 0.9]$ , and the true values be :  $p_1 = 0.6$ ,  $p_2 = 0.7$ ,  $p_3 = 0.98$ ,  $p_4 = 0.8$ .

FIGURE 5 – Reliability block diagram of a series parallel system.

The results of the sequential elicitation procedure using the baseline strategy can be visualized in Figure 6 which plots the uncertainty on each component at every stage. A jump in the curve of component  $i$  at stage  $k + 1$  indicates that the  $k^{\text{th}}$  optimal query inquired about that component, and its magnitude corresponds to the uncertainty reduction after the question has been answered. Note that up to the 6<sup>th</sup> question, the strategy inquired about the reliability of components 1 and 2, being the most uncertain.

FIGURE 6 – Sequence of optimal components using the baseline strategy.

However, reducing uncertainty on components 1 and 2 does not reduce our global uncertainty, as shows Figure 7. In this case the baseline strategy performs actually very bad, not only compared to the maximin strategy, but also to the random up to the 6<sup>th</sup> query. This is due to the fact that the baseline strategy does not consider the importance components have on the overall system reliability.

### 4.3 REAL CASE SYSTEM

Up to now, we considered simple structures with distinct (non-redundant) components. However, the majority of real systems are complex and redundant, i.e., some of their components are duplicated. Redundancy ensures a backup in case of failure of one of the critical parts, and aims at increasing the overall reliability of the system.

When a system has redundancies, its reliability function is no longer multi linear, and depending on the redundancy architecture (parallel, triple modular, etc.), it becomes po-

FIGURE 7 – Maximin, random, and baseline strategies for the case of series parallel system.

ynomial in the reliability of the redundant components, while remaining linear in the others. We are concerned here with the study of this type of systems/functions.

As a case study, we consider a real system used in the European railways traffic management system : the Radio Block Center system (RBC), whose role is to collect data about the position of trains and to provide movement authorisation (Flammini et al., 2006). Because of the relatively recent exploitation of the system, sufficient data to estimate the reliability of the RBC are lacking.

The RBC is composed of 5 different components, each of them being redundant. The architecture of the RBC is pictured in Figure 8, where the 2/3 symbol means that the subsystem composed of components 5 works if and only if at least 2 out of the three components work.

FIGURE 8 – Reliability block diagram of the RBC.

The reliability function can be written as :

$$R = (1 - (1 - p_1)^3)(1 - (1 - p_2)^2)(1 - (1 - p_3)^2)(1 - (1 - p_4)^2)p_{tmr};$$

with

$$p_{tmr} = (3p_5^2) - 2(p_5^3)(1 - (1 - p_6)^2).$$

We consider the case where some initial evidence suggests that the reliability of the RBC components ranges in  $[0.5, 1]$ , and that the true values are :  $p_1 = 0.83$ ,  $p_2 = 0.77$ ,  $p_3 = 0.8$ ,  $p_4 = 0.55$ ,  $p_5 = 0.72$ ,  $p_6 = 0.78$ . Results of the query strategy are plotted in Figure 9. Here, the maximin strategy outperforms the Bayesian one, which is consistent with Remark 1. The baseline does not do well and significant uncertainty reduction only occurs when asking about component 5, which is indeed the most important in this architecture.

FIGURE 9 – Performance of the query strategies for the RBC system.

The computations involved in the elicitation procedure for this systems, and more complex systems in general, remain tractable as they only require optimization of polynomials and can still take advantage of the increasingness of function  $\Phi$ . This makes our procedure of practical use in real-time elicitation involving real experts – this will be the object of a forthcoming work concerned with the estimation of the RBC reliability using expert elicitation.

## 5 CONCLUSION

In this paper, we addressed the problem of optimal expert elicitation when the goal is to reduce interval uncertainty. We described different optimal querying strategies to determine the best question to ask at each stage of the procedure, studied their computational costs, and illustrated their use in a common estimation problem in reliability analysis.

For the particular problem of interval uncertainty reduction using local bound queries, the optimal elicitation approach proves to be effective and computationally tractable, especially for the maximin approach. We also discussed some cases, such as monotonic and multi linear functions, for which these computations are even easier. In future works, we plan to consider (1) more general uncertainty models, such as belief functions (Shafer, 1976) or probability sets (Augustin et al., 2014) which are particularly appealing to model, e.g. non-completely reliable experts (allowing for instance to relax the assumption that the expert is an oracle) and (2) other types of queries formats and answers, such as comparative assessments.

The strategies we described in this paper are myopic. Such strategies offer natural advantages (any-time stop, computational easiness), yet may select a sequence of questions that are globally sub-optimal, despite being locally optimal. A natural extension of this work is then to address the sequential approach for selecting the optimal set of queries to ask, and compare it with the myopic method. Clearly, this includes dealing with a computationally challenging pro-

blem, given the multistage nature of the optimization task, as well as some potential difficulties when choosing the values of strategies (e.g., the over-cautious nature of maximin could lead to strategies with very low average performances).

## Abstract

We consider the task of summing a non-negative function  $f$  over a discrete set  $\Omega$ , e.g., to compute the partition function of a graphical model. Ermon et al. have shown that in a probabilistic approximate sense summation can be reduced to maximizing  $f$  over random subsets of  $\Omega$  defined by parity (XOR) constraints. Unfortunately, XORs with many variables are computationally intractable, while XORs with few variables have poor statistical performance. We introduce two ideas to address this problem, both motivated by the theory of error-correcting codes. The first is to maximize  $f$  over explicitly generated random affine subspaces of  $\Omega$ , which is equivalent to *unconstrained* maximization of  $f$  over an exponentially smaller domain. The second idea, closer in spirit to the original approach, is to use systems of linear equations defining Low Density Parity Check (LDPC) error-correcting codes. Even though the equations in such systems only contain  $O(1)$  variables each, their sets of solutions (codewords) have excellent statistical properties. By combining these ideas we achieve dramatic speedup over the original approach and levels of accuracy that were completely unattainable.

## 1 INTRODUCTION

The partition function of a graphical model with unnormalized probability function  $f$  over a domain  $\Omega$  is the integral (sum) of  $f$  over  $\Omega$ . The partition function is a central object of Bayesian statistics. While some inference tasks, such as MAP or MLE, can be completed without it, knowledge of (an approximation of) the partition function is necessary for marginalization, prediction, sampling, and model comparison, as a proper distribution is required. In general, partition function estimation is intractable [1] and, in practice, becomes problematic rapidly as  $|\Omega|$  increases.

To overcome this problem approximation schemes, such as MCMC [7], or variational methods [5] are commonly used. However, variational methods, in general, do not provide accuracy certificates/guarantees, while the mixing time of MCMC is similarly unpenetratable in most applications. In recent years, Ermon, Gomes, Sabharwal, and Selman have pioneered an alternative approach [14, 13, 15]. The general idea is to reduce the counting problem into a collection of random optimization problems, the final estimate being a statistic over the optima found. Each random problem amounts to maximizing  $f$  over a random set  $R \subseteq \Omega$ , defined via a random system of parity constraints. Realizing this idea, the WISH algorithm [14] is shown to yield a constant-factor approximation for the partition function *given access to an optimization oracle*. Importantly, the approximation guarantee requires the induced optimization problems to be solved to optimality, an assumption that clearly does not hold in general. Nevertheless, empirically, the WISH algorithm achieves remarkable accuracy compared to other established algorithms [14, 13, 15], leveraging the practical advancements in optimization software.

The idea of adding parity constraints originates in the work of Sipser [16] as a reduction technique. Most famously, it was used by Valiant and Vazirani [19] to reduce SAT to Unique SAT. A variant of the technique plays an important role in the proof of Toda's theorem [18]. The idea has since been applied to various counting problems including #SAT [11], # $k$ -SAT [17], and #CSP [12]. WISH [14] can be regarded as a natural generalization to weighted CSPs (or, equivalently, Markov Random Fields (MRFs)).

To provably approximate the partition function of an MRF with  $n$  variables, the parity constraints added must each have  $n/2$  variables on average. Unfortunately, the addition of such long constraints makes the MAP problem dramatically harder since each constraint (i) amounts to a clique involving half the variables of the MRF, and (ii) collapses the probability function whenever violated. In practice, this additional hardness can cause a MAP solver to submit dramatically suboptimal solutions under any reasonable time constraint, impairing the accuracy of estimation.

In all prior works the addition of random parity constraints is framed as *hashing* and the statistical properties of the resulting subsets of the domain is discussed in terms of independence properties of the corresponding families of hash functions. We break with this paradigm by taking a step back and asking: “how can we define subsets of the domain so that they are *computation-friendly* while having *good statistical properties*?” We answer the question twice, the two answers corresponding to two different notions of “friendliness” under the same notion of “goodness”.

Regarding goodness we will see that the key statistical property is pairwise *negative correlation* of membership, i.e., that for any two distinct  $\sigma, \sigma' \in \Omega$ , it should be that  $\Pr[\text{Both } \sigma, \sigma' \in R] \leq \Pr[\sigma \in R] \Pr[\sigma' \in R]$ . (Long parity constraints achieve this with equality.) Equivalently, conditioning on  $\sigma \in R$  should not make any  $\sigma' \neq \sigma$  more likely to be in  $R$  (but can make it less). Visualizing this as  $\sigma \in R$  exerting a repulsive force suggests an error-correcting code. Indeed, any linear error-correcting code  $C \subseteq \Omega = \{0, 1\}^n$  with  $2^{n-d}$  elements can be specified as  $C = \{\sigma \in \Omega : A\sigma = b\}$ , where  $A \in \{0, 1\}^{d \times n}$  is any rank  $d$  matrix and operations are over  $\text{GF}(2)$ , i.e., as the set of solutions to parity constraints.

Equipped with this idea, our first notion of computation-friendliness can be seen as “dimensionality reduction”. That is, instead of operating over  $\{0, 1\}^n$  and maximizing  $f$  over  $R$  by setting  $f(\sigma) = 0$  for  $\sigma \in \Omega \setminus R$ , we can operate over  $R$  directly by taking  $G \in \{0, 1\}^{n \times d}$  to be a *generator* of the subspace  $A\sigma = b$  and maximizing  $f(Gx + v)$  over  $x \in \{0, 1\}^d$ . We thus get an *unconstrained* optimization problem over a domain of size  $2^d$  instead of  $2^n$ . For any optimizer treating  $f$  as a black box, as is typical in MAP estimation, this makes optimizing  $f$  dramatically easier.

Our second notion of computation-friendliness can be seen as endowing  $\Omega \setminus R$  with a “gradient” (pointing towards  $R$ ), so that satisfying  $A\sigma = b$  does not impose significant computational burden. Again drawing insights from the theory of error-correcting codes, the idea is to desire the number of violated equations of  $A\sigma = b$  to be a function that has few local minima that are not global minima, i.e., not codewords, thus making its global minima easily accessible by some naive local method such as gradient descent. In other words, to make the optimizer’s life easy, we would like  $C = R$  to be an “easily decodable” code. This is precisely what we will achieve by taking the random sets  $R$  to correspond to the codewords of LDPC codes constructed by the Progressive-Edge-Growth construction [3].

Finally we note that independently of how the optimization problems are constructed, the *number* of instances that need to be solved can be reduced significantly in practice by using branch-and-bound. Combined with the two ideas mentioned above, this gives a dramatic speedup over WISH and entirely new levels of accuracy.

## 2 BACKGROUND

For the benefit of clarity, as in previous works, we will restrict our exposition to  $\Omega = \{0, 1\}^n$  and only approximate the partition function,  $Z$ , within a fixed constant factor, e.g., 32 (recall that, typically,  $Z \sim \exp(n)$ ). All ideas presented generalize readily to  $\Omega = D^n$  for any finite  $D$ .

### 2.1 BINARY MARKOV RANDOM FIELD

Given  $\Omega = \{0, 1\}^n$  and a collection of non-negative functions,  $\mathcal{F} = \{\psi_\alpha\}$ , defined on subcubes of  $\Omega$ , let

$$f(\sigma) = \prod_{\psi_\alpha \in \mathcal{F}} \psi_\alpha(\{\sigma\}_\alpha) ,$$

where  $\{\sigma\}_\alpha$  is the subset of variables entailed by  $\psi_\alpha$ . The *partition function* is the sum of  $f$  over all configurations:

$$Z = \sum_{\sigma \in \Omega} f(\sigma) .$$

### 2.2 ESTIMATION BY STRATIFICATION

We start by briskly revisiting (and, to some extent, reformulating) the groundbreaking work of Ermon et al. [14] connecting partition function estimation to optimization.

The first key idea is to stratify  $f$  over  $\Omega$  into quantiles and estimate  $Z$  by bounding from above and below the contribution of each quantile. Specifically, and w.l.o.g., assume that the configurations are sorted in descending order according to  $f$ , i.e.,  $f(\sigma_1) \geq f(\sigma_2) \geq \dots \geq f(\sigma_{2^n})$ . Let  $b_i = f(\sigma_{2^i})$ . Now, define the *lower sum* as

$$L := b_0 + \sum_{i=0}^{n-1} b_{i+1} 2^i$$

and the *upper sum* as

$$U := b_0 + \sum_{i=0}^{n-1} b_i 2^i .$$

Trivially,  $L \leq Z \leq U$ . Moreover,

$$\begin{aligned} 2L &= b_0 + \left( b_0 + \sum_{i=0}^{n-1} b_{i+1} 2^{i+1} \right) \\ &= b_0 + \sum_{i=0}^n b_i 2^i \geq U . \end{aligned}$$

Hence, if we compute  $b_0, b_1, \dots, b_n$ , taking any  $\hat{Z} \in [L, U]$  yields a 2-approximation of  $Z$ .

More generally, if for some integer  $c \geq 0$  and all  $i \in [n]$  an estimate  $\hat{b}_i \in [b_{i+c}, b_{i-c}]$  is available, then letting  $\hat{U}$  and  $\hat{L}$  be the counterparts of  $U$  and  $L$  with  $b_i$  replaced by  $\hat{b}_i$  we see that  $\hat{L} \leq L \leq Z \leq U \leq \hat{U}$  and  $\hat{U}/\hat{L} \leq 2^{2c+1}$ . Thus, any  $\hat{Z} \in [\hat{L}, \hat{U}]$  is a  $2^{2c+1}$ -approximation of  $Z$ , e.g., yielding a 32-approximation for  $c = 2$ .

### 2.3 STRATIFICATION BY THINNING

The second key idea is to estimate each  $b_i = f(\sigma_{2^i})$  as the maximum of  $f$  over a random set  $R_i \subseteq \Omega$  of (expected) size  $2^{n-i}$ . As mentioned, the essential requirement for this approach to work is *pairwise negative correlation* of membership in  $R_i$ . Including each element of  $\Omega$  in  $R_i$  independently with probability  $2^{-i}$  achieves this trivially but at the cost of an exponentially large, and thus inoperable, representation of  $R_i$ . The foundation of this entire line of research has been that it is possible to achieve *pairwise* independence for membership in  $R$  in compact form via hashing. We introduce a somewhat more general, and ultimately more fruitful, point of view reflected in our definition of Thinning Sets below.

**Thinning Sets.** A random variable  $R_i$  taking values in  $2^\Omega$  is an  $i$ -thinner if

- $\forall \sigma, \Pr[\sigma \in R_i] = 2^{-i}$  (Uniform)
- $\forall \sigma \neq \sigma', \Pr[\sigma \in R_i \wedge \sigma' \in R_i] \leq 2^{-2i}$  (Universal)

Given an  $i$ -thinner  $R_i$  and a solver capable of maximizing  $f$  over  $R_i$ , estimating  $b_i$  is entirely straightforward. Theorem 1 below is identical to the main result of [14], except for thinning sets replacing hash functions (for completeness we prove Theorem 1 in Section 5.)

**Theorem 1** ([14]). *Let  $R_i$  be any  $i$ -thinner random variable. Let  $\{m_j\}_{j=1}^t$  be i.i.d. random variables distributed as  $m_j = \max_{\sigma \in R_i} f(\sigma)$ . If  $M = \text{median}(m_1, \dots, m_t)$ , then for every  $c \geq 2$ ,*

$$\Pr[b_{i+c} \leq M \leq b_{i-c}] \geq 1 - 2 \exp\left(-\frac{t}{2}(1 - 2^{-c+1})^2\right).$$

One way to create an  $i$ -thinner is to take the solutions of a random system of linear equations over  $\text{GF}(2)$ , i.e., modulo 2. Let  $A \sim \text{Ber}(m \times n)$  denote that  $A$  is an  $m \times n$  random matrix whose entries are independent random variables with  $\Pr[a_{ij} = 1] = \Pr[a_{ij} = 0] = 1/2$ , for all  $i, j$ .

**Random Linear Code.** *The random set*

$$R_i = \{\sigma \in \{0, 1\}^n : A\sigma = b\} \quad (1)$$

*is an  $i$ -thinner if  $A \sim \text{Ber}(i \times n)$  and  $b \sim \text{Ber}(i \times 1)$ .*

In coding theory the set  $R_i$  in (1) is known as a random linear code, while the distribution  $A \sim \text{Ber}(i \times n)$  is known as the Shannon ensemble. Note that the rows of  $A$  have, on average,  $n/2$  non-zero entries. We will refer to it as the *dense parity* ensemble, to distinguish it from other distributions on  $\{0, 1\}^{i \times n}$  which we will encounter shortly. By Theorem 1, we can thus estimate  $b_i$  given an oracle  $\mathcal{O}$  for

$$\max_{\substack{\sigma \in \{0, 1\}^n \\ A\sigma = b}} f(\sigma). \quad (2)$$

The idea of adding long random parity constraints to achieve unweighted counting, e.g., to count the number of satisfying assignments of a CNF formula goes back to [11]. Ermon et al. in [14], after  $i$ -thinning  $\Omega$  in the manner above, solved the optimization problem (2) with ToulBar2 [2], dedicated software for MAP estimation in graphical models (the parity constraints added as factors to  $f$  evaluating to 0 when violated). In later work [13], the authors translated (2) to an Integer Linear Program, thus bringing to bear CPLEX, a powerful commercial optimization software. Finally, for reasons to be discussed shortly, in [15], the dense parity ensemble was replaced by the *sparse parity ensemble* wherein the entries of  $A$  are i.i.d. Bernoulli random variables where  $\Pr[a_{ij} = 1] = p < 1/2$ .

## 3 OUR CONTRIBUTION

### 3.1 RANDOM AFFINE MAPS

Instead of starting with  $\Omega = \{0, 1\}^n$  and restricting it via  $i$  random parity equations to a subset  $R_i$  of (expected) size  $2^{n-i}$ , we will *start* with  $\{0, 1\}^{n-i}$  and generate  $R_i$  as the image of  $\{0, 1\}^{n-i}$  under a random affine transformation  $g : \{0, 1\}^{n-i} \rightarrow \{0, 1\}^n$ , where  $g(x) = Ax + b$ . Thus, instead of solving the constrained optimization problem

$$\max_{\substack{\sigma \in \{0, 1\}^n \\ A\sigma = b}} f(\sigma),$$

we will solve the *unconstrained* optimization problem

$$\max_{x \in \{0, 1\}^{n-i}} (f \circ g)(x),$$

over the *exponentially* smaller set  $\{0, 1\}^{n-i}$ . The benefit of such dimensionality reduction increases with  $i$ , i.e., smaller  $R_i$ , in contrast to thinning by parity constraints which typically has worsening behavior as  $i$  is increased.

### 3.2 LOW DENSITY PARITY CHECK CODES

In certain settings, such as when performing “light” thinning or when the function  $f$  can be optimized better than black box, operating directly on the restriction of  $\Omega$  induced by parity constraints is preferable to operating through a random affine map. In these settings, instead of forming the constraint matrix  $A$  by having its entries be i.i.d. Bernoulli random variables (either sparse or dense) we will take  $A$  to be the parity check matrix of a Low Density Parity Check (LDPC) code. As we demonstrate experimentally, this has a stunning effect on the performance of CPLEX.

In the eyes of a solver operating on the variable representation of  $\Omega$  (as opposed to a local search solver) a 3-XOR is greatly preferable to an  $(n/2)$ -XOR, even though both shrink the domain by half. This is because repairing a violated constraint of arity  $k$  represents a  $k$ -way choice, i.e.,

a branching factor of  $k$ . This motivated the introduction of sparse i.i.d. Bernoulli parity check matrices in [11] and later in [15]. While a step in the right direction, this does not go far enough. To cover the remaining distance, we exploit insights from the modern theory of LDPC codes.

Imagine a code  $\mathcal{C} = \{\sigma \in \{0, 1\}^n : A\sigma = b\}$ , for some fixed matrix  $A$  and vector  $b$ . Imagine further that  $\sigma \in \mathcal{C}$  is transmitted along a channel that *erases* a subset of the bits of  $\sigma$ , so that the recipient receives  $\tau \in \{0, 1, *\}^n$ . Clearly, equations (checks) with no  $*$  variables offer no new information regarding  $\sigma$ . On the other hand, equations with two or more  $*$  variables are ambiguous, as they can be satisfied in multiple ways. But any equation with exactly one  $*$  variable is ideal: its erased bit can be recovered unambiguously; moreover, this recovery may cause other equations that had two  $*$  variables to now only have one. Such a cascade of “safe steps” will recover  $\sigma$  unless it encounters a *stopping set*: a non-empty set  $V$  of erased bits, such that no equation entails exactly 1 element of  $V$ . The amazing performance of LDPC codes is, to first order, due to the absence of small stopping sets. Thus, if  $\tau$  does not have too many erased bits, safe steps will suffice to recover  $\sigma$ .

To readers familiar with satisfiability algorithms the parallel between “safe” decoding and unit-clause propagation (UCP) will be immediate. The linear equations defining code  $\mathcal{C}$  can be thought of as a formula  $F$  very carefully designed to have the following property: if one selects a random subset of variables and assigns them random values (subject only to no empty clause being created), then for the vast majority of random choices (corresponding to the unerased bits in the communication setting) the residual formula should be solvable by UCP alone. It is not hard to imagine that adding such a formula  $F$  to a formula  $F'$  will induce little “additional hardness” to any solver capable of recognizing the presence of “safe” choices: as soon as enough variables are instantiated to get within the “radius of attraction” of a solution to  $F$ , the solver devolves to a “safe choice decoder”, setting variables at a rapid pace with minimal branching. We conjecture that this is precisely what causes the stunning improvement we observe in the performance of CPLEX when switching from dense/sparse parity ensembles to LDPC codes. Unfortunately, verifying this directly is non-trivial as CPLEX is commercial software. As implicit evidence we offer the observed complete insensitivity of stochastic local search to the structure of  $A$  (we use LocalSolver [9] in our experiments).

### 3.3 BRANCH AND BOUND

Recall that to form our estimate  $\widehat{Z}$  we multiply each  $\widehat{b}_i = f(\sigma_{2^i})$  by  $2^i$ . As a result, in most cases,  $\widehat{Z}$  is dominated by the contribution of a set of quantiles  $I \subseteq [n]$ , where  $|I| \ll n$ . (Indeed, in physical terms, failure of this to be true is the signature of criticality.) With this observation

in mind, rather than estimating all  $\{\widehat{b}_i\}_{i=1}^n$  in sequence, we can save computation by starting with  $S = \{\widehat{b}_0, \widehat{b}_n\}$  and estimating more and more quantiles until sufficient accuracy is achieved. In particular, simply enlarging  $S$  by the unestimated quantile of greatest remaining potential contribution, gives a speedup ranging from 2x to 10x in our experiments, with 7x being the most common case.

## 4 RANDOM AFFINE MAPS

Throughout this section let  $d := n - i$ , where  $i \in [n]$ . Let  $A \in \{0, 1\}^{n \times d}$  be a matrix of rank  $d$  and let  $b \in \{0, 1\}^n$ . If  $g(x) = Ax + b$ , then the image of  $\{0, 1\}^d$  under  $g$  is an affine subspace of  $\{0, 1\}^n$  containing  $2^d$  distinct elements (since  $A$  has full rank). Let  $\{0, 1\}_d^{n \times d}$  denote the set of all full rank, i.e., rank  $d$ , matrices in  $\{0, 1\}^{n \times d}$ .

**Theorem 2.** *Let  $A$  be uniform over  $\{0, 1\}_d^{n \times d}$  and let  $v$  be uniform over  $\{0, 1\}^n$ . The image of  $\{0, 1\}^d$  under  $x \mapsto Ax + v$  is an  $(n - d)$ -thinner.*

Theorem 1 immediately implies the following.

**Corollary 1.** *Let  $A$  be uniform over  $\{0, 1\}_d^{n \times d}$  and let  $v$  be uniform over  $\{0, 1\}^n$ . Let  $\{m_j\}_{j=1}^t$  be i.i.d. random variables distributed as*

$$\max_{x \in \{0, 1\}^d} f(Ax + v) .$$

*If  $M = \text{median}(m_1, \dots, m_t)$ , then for every  $c \geq 2$ ,*

$$\Pr[b_{i+c} \leq M \leq b_{i-c}] \geq 1 - 2 \exp\left(-\frac{t}{2}(1 - 2^{-c+1})^2\right) .$$

In other words, replacing long parity constraints with random affine maps, retains all statistical guarantees while giving rise to optimization instances over  $\{0, 1\}^{n-i}$  instead of  $\{0, 1\}^n$ . As in the estimation of the partition function,  $i$  ranges from 1 to  $n$ , at some point it becomes much more efficient to operate on  $f \circ g$  in the reduced domain than to operate on  $f$  on  $\Omega$ . Moreover, because  $|R_i| = 2^{n-i}$  deterministically, rather than in expectation, the variance of each estimate  $m_i$  is smaller than for a random linear code.

To sample uniformly from  $\{0, 1\}_d^{n \times d}$  it is convenient and efficient to employ rejection sampling: trivially generate  $A \sim \text{Ber}(n \times d)$  and accept only if  $\text{rank}(A) = d$ . Uniformity follows from the uniformity of  $A \sim \text{Ber}(n \times d)$  over  $\{0, 1\}^{n \times d}$ . By Lemma 1, the number of trials needed is a geometric random variable with mean less than 4.

**Lemma 1.**  $|\{0, 1\}_d^{n \times d}| > 2^{dn-2}$ .

### 4.1 EVALUATION

In Figure 1 we compare parity constraints vs. affine maps on the  $10 \times 10$  Ising grid with  $F = 0.1$  and  $C = 1.0$ , a noted hard problem in [14]. For the exact definition of

Figure 1:  $10 \times 10$  Ising grid with  $C = 1.0$  and  $F = 0.1$ . *Experiment:* for  $i \in [0, 100]$  generate  $R_i$  via  $i$  random parity constraints, or as a random affine subspace of dimension  $n - i$ ; seek  $\max_{\sigma \in R_i} f(\sigma)$  for 30 seconds (see legend). *Plot:* for each  $i$ , repeat the experiment 10 times and report the binary logarithm of the median value found. We also plot the number  $100 - i$  as a visual aid.

$f$  see (9) in Section 7. The parity constraints are generated from the dense parity ensemble and the sparse parity ensemble adopted in [15] and we use the ILP formulation proposed in [13], with CPLEX being the solver. To optimize  $f \circ g$  for random affine maps we use LocalSolver [9], since CPLEX is an ILP solver and does not natively support affine transformations over  $\text{GF}(2)$ . While not as strong as CPLEX on constrained optimization problems, LocalSolver is specialized in stochastic local search under black-box evaluation, hence a suitable choice for our setting.

As can be seen in Figure 1, when there are more than, roughly, 10 parity constraints, the performance of both random parity ensembles deteriorates rapidly, in sharp contrast to the robust performance of LocalSolver under affine maps. Note that since the  $y$ -axis is in  $\log_2$ -scale and each  $b_i$  contributes roughly  $b_i 2^i$  to the partition function, the fact that the solutions found by LocalSolver are nearly parallel to the line  $100 - i$  imply that the under-performance of optimization under parity constraints is highly relevant and will have dramatic effect on the accuracy of estimation.

Moreover, as shown in Figure 2, the best solutions found under parity constraints in 10 minutes are still inferior to those found via random affine maps in 30 seconds. In particular, when there are 50 constraints, CPLEX cannot find a solution better than the initial one under either parity ensemble, suggesting that the hardness of optimization under parity constraints overwhelms the solver. Notably, the original MAP inference  $\max_{\sigma \in \Omega} f(\sigma)$  can be solved to provable optimality in 0.1 second by CPLEX, highlighting that the hardness is due to the parity constraints.

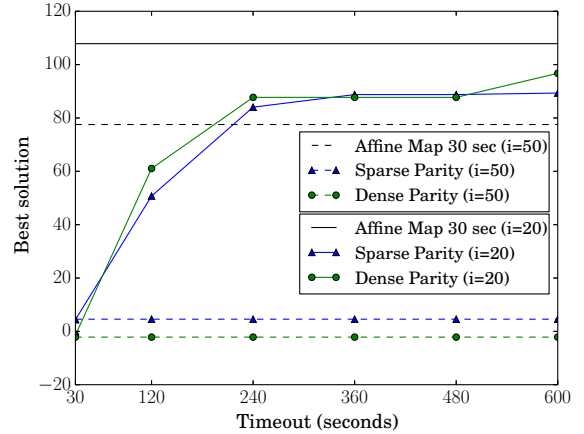

Figure 2:  $10 \times 10$  Ising grid with  $C = 1.0$  and  $F = 0.1$ . *Experiment:* for  $i \in \{20, 50\}$  generate  $R_i$  via  $i$  random parity constraints; seek  $\max_{\sigma \in R_i} f(\sigma)$  with a timeout of  $t \in \{30, 120, 240, 360, 480, 600\}$  seconds (see legend). *Plot:* for each pair  $(i, t)$  repeat the experiment 10 times and report the binary logarithm of the values found.

## 4.2 PROOF OF THEOREM 2 AND LEMMA 1

We will refer to  $A$  as a *generator* matrix for the subspace, which we will represent by the pair  $(A, v)$ .

**Lemma 2.** *If  $A$  is uniform over  $\{0, 1\}_d^{n \times d}$  and  $v$  is uniform over  $\{0, 1\}^n$ , then  $(A, v)$  is uniform over all affine subspaces of dimension  $d$ . In particular, for any fixed  $v_0$ , the subspace  $(A, v_0)$  is uniform over all affine subspaces of dimension  $d$  that contain  $v_0$ .*

*Proof.* It suffices to prove the second statement as the independence of  $A$  and  $v$  implies the first.

We will prove that for any fixed  $v_0$  and any affine subspace  $\mathcal{A}$  of dimension  $d$  that contains  $v_0$ , the number of matrices  $A \in \{0, 1\}_d^{n \times d}$  such that  $(A, v_0) = \mathcal{A}$  is independent of  $\mathcal{A}$ .

Clearly,  $(A, v_0) = \mathcal{A}$  iff the columns of  $A$  are linearly independent elements of  $\mathcal{A}$ . For  $k \in [d]$ , let  $a_k$  be the  $k$ -th column of  $A$  and let  $a_0 = \mathbf{0}$ . Linear independence is equivalent to  $a_k \notin \text{span}(a_0, \dots, a_{k-1})$  for all  $k \in [d]$ . Since  $|\text{span}(a_1, \dots, a_k)| = 2^k$  if the first  $k$  columns are linearly independent, we see that for every  $k \in [d]$  there are  $2^d - 2^{k-1}$  valid choices for the  $k$ -th column.  $\square$

*Proof of Theorem 2.* By the first part of Lemma 2,  $(A, v)$  is uniform over all affine subspaces of dimension  $d$ . Therefore, by symmetry,  $\Pr[\sigma \in (A, v)]$  is the same for all  $\sigma \in \{0, 1\}^n$ . Since  $(A, v)$  contains  $2^d$  elements, uniformity follows. To prove universality we need to show that  $\Pr[\sigma' \in (A, v) \mid \sigma \in (A, v)] \leq \Pr[\sigma' \in (A, v)]$ . For this we first observe that, by the second part of Lemma 2,

$$\Pr[\sigma' \in (A, v) \mid \sigma \in (A, v)] = \Pr[\sigma' \in (A, \sigma)] .$$

Since  $\sigma \neq \sigma'$ , this last probability equals the probability that  $\tau = \sigma' - \sigma \neq \mathbf{0}$  belongs in  $(A, 0)$ . Let  $a_k$  be the  $k$ -th column of  $A$  and let  $A_k$  comprise the first  $k$  columns of  $A$ . If we generate  $A$  column by column we see that this last probability equals  $1 - \prod_{k=1}^d \Pr[a_k \notin \text{span}(A_{k-1} \cup \{\tau\})]$  which is the same for all  $\tau \neq \mathbf{0}$ .  $\square$

*Proof of Lemma 1.* If we construct  $A$  column by column then, as shown in Lemma 2, there are  $2^n - 2^{k-1}$  choices for the  $k$ -th column that lead to  $A$  being full rank. Induction thus shows  $\prod_{k=1}^d (2^n - 2^{k-1}) \geq \frac{1}{4} (2^{dn} + 2)$ .  $\square$

## 5 THINNING AS ERROR-CORRECTION

Let us start by deriving the statistical desiderata of thinning sets from first principles. This will illuminate the suitability of error-correcting codes for thinning and offer insight. Recall that our goal is to estimate  $b_i = f(\sigma_{2^i})$ , for  $i \in [n]$ . We start by observing that for this it suffices to construct a random variable  $m_i$  such that for some (small) integer  $c$  and any  $\epsilon > 0$ ,

$$\Pr[m_i \leq b_{i-c}] \geq 1/2 + \epsilon \quad (3)$$

$$\Pr[m_i \geq b_{i+c}] \geq 1/2 + \epsilon \quad (4)$$

This is because if we take  $\hat{b}_i$  to be the median of  $t$  independent realizations of  $m_i$ , by Hoeffding's inequality,

$$\Pr[b_{i+c} \leq \hat{b}_i \leq b_{i-c}] \geq 1 - 2 \exp(-2\epsilon^2 t) \ .$$

Thus, in order for  $\Pr[m_i \in [b_{i+c}, b_{i-c}]] = 1 - \exp(-\Theta(s))$  it suffices to take  $O(s/\epsilon^2)$  samples.

Achieving (3) is trivial. Let  $\Omega_j = \{\sigma_1, \sigma_2, \dots, \sigma_{2^j}\}$ . If  $R_i \subseteq \Omega$  is any random set such that  $\Pr[\sigma \in R_i] = 2^{-i}$  for all  $\sigma \in \Omega$  and  $m_i = \max_{\sigma \in R_i} f(\sigma)$ , then

$$\Pr[m_i > b_{i-c}] < |\Omega_{i-c}| 2^{-i} = 2^{-c} \quad (5)$$

In other words, for  $m_i$  to be unlikely to be ‘‘too big’’ it suffices for  $R_i$  to have the right (expected) size, without any requirement of its geometry beyond uniformity. For example,  $R_i$  could even be a random subcube of  $\Omega$ , an extremely computation-friendly constraint: pick  $i$  variables at random and assign them random values.

Achieving (4) is far more subtle. This is because in order for  $\Pr[m_i \geq b_{i+c}]$  to not vanish the random variable  $X_i = |\Omega_{i+c} \cap R_i|$  must be well-behaved. In particular, observe that  $\mathbb{E}X_i = 2^c$  and we aim for  $c$  to be small, e.g.,  $c = 2$ , so the expectation of  $X_i$  is modest. If  $X_i$  realizes its modest expectation via a lottery phenomenon, i.e., typically  $X_i = 0$  but rarely  $X_i$  is very large we are in trouble. To control for this possibility we use the Paley-Zygmund inequality asserting that if  $X$  is any non-negative integer random variable, then  $\Pr[X > 0] \geq (\mathbb{E}X)^2/\mathbb{E}X^2$ . Taking  $R_i$  to be a random cube is thus exposed as a bad idea:

if  $\Omega_{i+c}$  is also a cube, their potential alignment implies  $\mathbb{E}X_i^2 \gg (\mathbb{E}X_i)^2$ .

To minimize  $\mathbb{E}X_i^2$  we would like to find random sets  $R_i$  that behave like ‘‘mists’’, minimizing the probability of having an atypically large intersection with any fixed set. Error-correcting codes are ideal for this, with linear codes particularly so, as they are specified via linear equations. Motivated by these considerations, let

$$R_i = \{\sigma \in \{0, 1\}^n : A\sigma = b\} \ ,$$

where the vector  $b \in \{0, 1\}^i$  is uniformly random, while  $A \in \{0, 1\}^{i \times n}$  is *arbitrary* (even deterministic), for now.

It is easy to see that the uniformity of  $b$  over  $\{0, 1\}^i$  alone suffices to make  $R_i$  uniform over  $\{0, 1\}^n$ , i.e., for all  $\sigma$ ,

$$\Pr[\sigma \in R_i] = 2^{-i} \ . \quad (6)$$

At the same time, for any  $S \subseteq \Omega$ , if  $X_i = |S \cap R_i|$ , then

$$\begin{aligned} \mathbb{E}X_i^2 &= \mathbb{E} \left( \sum_{\sigma \in S} \mathbf{1}_{\sigma \in R_i} \right)^2 \\ &= \sum_{\sigma, \sigma' \in S} \mathbb{E}(\mathbf{1}_{\sigma \in R_i} \mathbf{1}_{\sigma' \in R_i}) \\ &= \mathbb{E}X_i + \sum_{\substack{\sigma, \sigma' \in S \\ \sigma \neq \sigma'}} \Pr[A\sigma = b = A\sigma'] \ . \end{aligned}$$

To deal with the sum above note that, trivially,

$$\Pr[A\sigma = b = A\sigma'] = \Pr[A\sigma = b \wedge A(\sigma - \sigma') = \mathbf{0}] \ .$$

Fix any distinct pair  $\sigma, \sigma'$ . Choosing  $A$  first (to determine if  $A(\sigma - \sigma') = \mathbf{0}$ ) and then choosing  $b$  (to determine if  $A\sigma = b$ ) we see that  $\Pr[A\sigma = b = A\sigma'] = 2^{-i} \Pr[A(\sigma - \sigma') = \mathbf{0}]$ . Therefore, without any assumptions on either the set  $S$  or the distribution of  $A$ , we can conclude that

$$\mathbb{E}X_i^2 = \mathbb{E}X_i + 2^{-i} \sum_{\substack{\sigma, \sigma' \in S \\ \sigma \neq \sigma'}} \Pr[A(\sigma - \sigma') = \mathbf{0}] \ . \quad (7)$$

To move beyond this point we must make some assumptions about (the distribution of)  $A$ . One such assumption, of course, would be that for all  $\sigma - \sigma' = \tau \neq \mathbf{0}$ ,

$$\Pr[A\tau = \mathbf{0}] \leq 2^{-i} \ . \quad (8)$$

It is not hard to see that if (8) holds then:

- (a)  $R_i$  is an  $i$ -thinner.
- (b)  $\mathbb{E}X_i^2 \leq \mathbb{E}X_i + (\mathbb{E}X_i)^2$ . Thus, by the Paley-Zygmund inequality,  $\Pr[m_i \geq b_{i+c}] > 1 - 2^{-c}$ .
- (c) Taking  $c = 2$  and recalling (5) we see that (3), (4) are satisfied with  $\epsilon = 1/4$  (and we have proven Theorem 1).

The above viewpoint exposes how extraordinarily strict is the requirement of universality: it asks that an element  $\tau \in \Omega$  that has a single 1 should be no more likely to solve  $A\tau = \mathbf{0}$  than  $\tau = \mathbf{1}$ . Clearly, this can only be satisfied if the rows of  $A$  have very large expected mass. In [15] the universality requirement was dropped and the case where the entries of  $A$  are i.i.d. Bernoulli taking the value 1 with probability  $p \leq 1/2$  was analyzed. The bound derived for the contribution of each  $\sigma \in S$  to the sum in (7) under this scheme is dominated by its pairing with  $\sigma'$  forming a Hamming ball centered at  $\sigma$ . Note, though, that if  $R_i$  is an error-correcting code and  $\sigma \in R_i$ , then it is extremely unlikely that *any*  $\sigma'$  near  $\sigma$  will also be in  $R_i$ . Indeed, the most basic metric of the quality of an error-correcting code is its distance, i.e., the minimum distance of any two codewords. This “self-repulsive” property of error-correcting codes is our key insight in regards to their statistical properties.

### 5.1 LOW DENSITY PARITY CHECK CODES

In the basic LDPC construction, the (random) system of linear equations is represented as a bipartite graph with variables on the left and equations (checks) on the right, with adjacency denoting entailment, i.e., that the variable participates in the equation. To create a code with  $n$  variables, i.e., with codewords in  $\{0, 1\}^n$ , one first specifies the numbers  $\{\lambda_j\}$  and  $\{\phi_j\}$  of variables and equations, respectively, of each degree  $j$ . In the simplest case,  $\lambda_j = \phi_k = 0$  for all but one value of  $j$  and  $k$ , respectively, i.e., the graph is (bi-)regular. In general, with the degree sequences thus fixed, a random bipartite graph is chosen uniformly at random subject to the degree constraints. This uniformity implies that  $\Pr[A\tau = \mathbf{0}]$  depends only on the weight of  $\tau$ , i.e., its number of 1s, for every  $\tau \in \{0, 1\}^n$ .

An even better construction of LDPC codes than the above is the Progressive Edge Growth (PEG) construction [3]. Its main feature, relative to the standard LDPC construction, is that it tries to maximize the length of the shortest cycle (girth) of the resulting bipartite graph, as short cycles contribute significantly to the formation of small stopping sets. Motivated by these considerations we replaced the dense and sparse parity ensembles with PEG constructed LDPC codes. If  $N(w)$  is the number of codewords of weight  $w$  for a given code, then the probability in (8) is  $P(w) = N(w)/\binom{n}{w}$ . Ideally,  $P(w)$  would be constant for all  $w > 0$ , i.e., (8) would be an equality, which is precisely what happens when  $A \sim \text{Ber}(i \times n)$ . More generally, the flatter  $P(w)$  is, the better the statistical properties of  $R_i$ .

To demonstrate the superiority of PEG LDPC over the sparse ensemble we plot in Figure 3 the empirical value of  $\log P(w)$  for parity matrices of size  $20 \times 40$ , derived by exhaustively enumerating each code’s, roughly,  $2^{40/2} \approx 1$  million codewords (exhaustive enumeration was chosen because the number of codewords can have non-trivial fluctu-

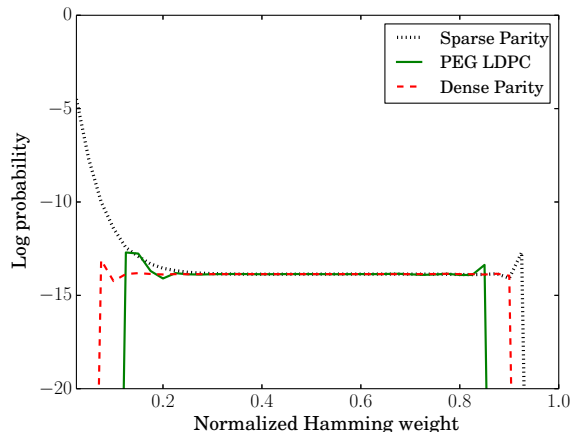

Figure 3: Empirical  $\log P(w)$  for  $w \in [1, 40]$  of dense parity ensemble (average 20 vars/equation), sparse parity ensemble (avg 8 vars/eq), and PEG LDPC (avg 8 vars/eq.)

ations for small  $n$ .) For the dense and sparse parity ensembles we generated 100 matrices each and report the mean; the PEG construction for LDPC is deterministic. We only considered codes with  $n = 40$  variables, as exhaustive enumeration rapidly becomes intractable with  $n$ . Already, though, for  $n = 40$  the behavior is very stable and it is easy to prove that flatness increases as  $n$  grows.

As can be seen, for a wide range of  $w$  both the sparse parity ensemble and the LDPC ensemble match  $P(w)$  perfectly (the fact that dense parity itself is not flat for  $w \notin [3, 36]$  is a finite-size effect). Crucially, though, for small  $w$  there is a big difference, with the sparse parity ensemble containing many more codewords (note that the vertical axis is logarithmic). The over-representation of low-weight codewords causes nearby pairs in  $S \subseteq \Omega$  to contribute disproportionately to the sum in (7), potentially causing the variance of  $X_i$  to blow up if  $S$  is clustered, e.g., if  $S$  is a cube. No such blowup occurs for the PEG codes even for such small  $n$ , witnessing their very good statistical properties. As the study of the codeword weight distribution function of LDPC codes greatly exceeds the scope of this work, we leave a formal proof that thinning by LDPC codes give rise to small-variance estimators as future work.

We claimed earlier that LDPC codes should be far preferable to random parity matrices. To that end we plot the performance of CPLEX on the Ising grid in Figure 4. The only difference between the three plots is in the parity matrix  $A$  used to define  $R_i = A\sigma + b$ . The collapse of CPLEX beyond a certain number of constraints was already pointed out in Figure 1. For LDPC PEG codes no such collapse occurs and CPLEX remains competitive with LocalSolver and random affine maps until  $i \approx 40$  even with a time-out at small as 30 seconds. In contrast, as demonstrated in Figure 5, LocalSolver, unaware of the variable/product

Figure 4:  $10 \times 10$  Ising grid with  $C = 1.0$  and  $F = 0.1$ . *Experiment:* for  $i \in [0, 100]$ , generate  $R_i$  via an  $i \times 100$  parity matrix chosen from 3 different ensembles (see legend); seek  $\max_{\sigma \in R_i} f(\sigma)$  for 30 seconds using CPLEX. *Plot:* for each  $i$  and each ensemble repeat the experiment 10 times and report the binary logarithm of the median value found. (As a yardstick, we also plot the values found by Local Solver when  $R_i$  is a random affine subspace.)

structure of  $\Omega$  (and the factorization of  $f$  over  $\{\psi_\alpha\}$ ) does not “feel” the difference between different parity check matrices, consistent with our hypothesis that it is the presence (and exploitation) of “safe” decoding moves that causes the dramatic improvement in the performance of CPLEX.

## 6 BRANCH-AND-BOUND

Our last observation is that not all  $\hat{b}_i$  are equally important (or even necessary) for an accurate estimate  $\hat{Z}$ . For instance, if  $f(\sigma) \in \{0, 1\}$ , it suffices to find the boundary  $k$  such that  $b_i = 1$  for  $i \leq k$  and  $b_i = 0$  for  $i > k$ . Using binary search we can do this by solving only  $\log n$ , instead of  $n$ , optimization problems as in (2).

To generalize let  $I = \{i_0, i_1, i_2, \dots, i_s\}$  be the set of quantiles estimated so far, where  $0 = i_0 < i_1 < \dots < i_s = n$ . Now define

$$U_I = b_0 + \sum_{j=0}^{s-1} b_{i_j} \left( \sum_{i=i_j}^{i_{j+1}-1} 2^i \right)$$

$$L_I = b_0 + \sum_{j=0}^{s-1} b_{i_{j+1}} \left( \sum_{i=i_j}^{i_{j+1}-1} 2^i \right).$$

By construction,  $U_I \geq U \geq Z \geq L \geq L_I$ . Let  $\hat{U}_I$  and  $\hat{L}_I$  be the estimated counterparts, of  $U_I, L_I$ , respectively, with  $\hat{b}_i$  in place of  $b_i$ . To identify the next quantile to estimate we consider the successive pairs  $(i_\ell, i_{\ell+1})$  in  $I$  and for each such pair  $(i_\ell, i_{\ell+1}) = (i, j)$  we define

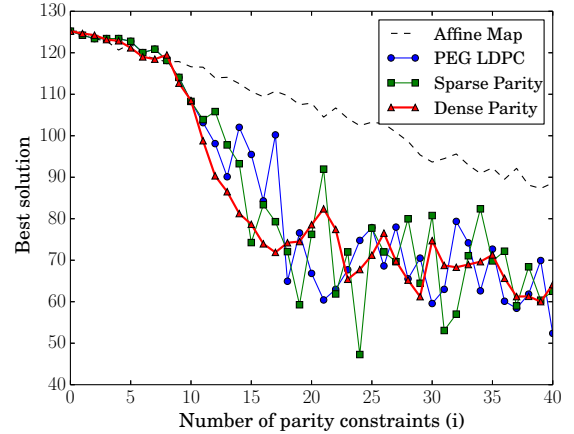

Figure 5:  $10 \times 10$  Ising grid with  $C = 1.0$  and  $F = 0.1$ . *Experiment:* for  $i \in [0, 40]$ , generate  $R_i$  via an  $i \times 100$  parity matrix chosen from 3 different ensembles, or as a random affine subspace (see legend); seek  $\max_{\sigma \in R_i} f(\sigma)$  for 30 seconds using LocalSolver. *Plot:* for each  $i$  and method repeat the experiment 10 times and report the binary logarithm of the median value found.

$\text{Gap}(i, j) = (\hat{b}_i - \hat{b}_j) \sum_{q=i}^j 2^q$ . At each iteration, we chose the pair  $(i, j)$  with maximum gap and estimate  $b_k$ , where  $k = \lfloor \frac{i+j}{2} \rfloor$ . Once the ratio  $\hat{U}_I / \hat{L}_I$  drops below the desired accuracy threshold, the process can stop early (see Table 6 for some indicative results).

---

### Algorithm 1 Branch-and-Bound

---

- 1:  $\hat{b}_0 \leftarrow \text{ESTIMATE}(b_0)$
  - 2:  $\hat{b}_n \leftarrow \text{ESTIMATE}(b_n)$
  - 3:  $I \leftarrow \{0, n\}$
  - 4:  $\hat{U}_I \leftarrow \hat{b}_0 2^n$
  - 5:  $\hat{L}_I \leftarrow \hat{b}_n 2^n$
  - 6: **while**  $(\hat{U}_I > \hat{L}_I \cdot \text{Tolerance})$  **do**
  - 7:     Find successive  $i, j \in I$  maximizing  $\text{Gap}(i, j)$
  - 8:      $k \leftarrow \lfloor (i + j) / 2 \rfloor$
  - 9:      $\hat{b}_k \leftarrow \text{Estimate}(b_k)$
  - 10:     $I \leftarrow I \cup \{k\}$
  - 11:    Compute  $\hat{U}_I, \hat{L}_I$
  - 12: **end while**
  - 13: **Return**  $(\hat{U}_I + \hat{L}_I) / 2$
- 

The benefit of branch and bound is universal, i.e., independent of the  $\{b_i\}$  estimation method. For example, over 24 problems on Ising grids it yielded a 7x average speedup.

| $C$ ( $F = 0.1$ ) | 0.25 | 0.5 | 1.0 | 1.5 | 2 | 2.5 | 3  |
|-------------------|------|-----|-----|-----|---|-----|----|
| Speedup (x)       | 11   | 5   | 3   | 7   | 9 | 11  | 12 |

Table 1: Speedup by Branch and Bound

## 7 EXPERIMENTS

The ferromagnetic Ising grid is a canonical spin glass model. Binary variables (spins)  $x_i \in \{\pm 1\}$  are placed on the vertices of a  $\sqrt{n} \times \sqrt{n}$  grid  $(V, E)$  and have nearest-neighbor interactions and a local (to each spin) field. Thus,

$$f(x) = \prod_{i \in V} \psi_i(x_i) \prod_{(i,j) \in E} \psi_{i,j}(x_i, x_j) , \quad (9)$$

with  $\psi_i(x_i) = \exp(F_i x_i)$  and  $\psi_{i,j}(x_i, x_j) = \exp(C_{i,j} x_i x_j)$ , where the local fields  $F_i$  are i.i.d.  $U[-F, F]$  and the coupling strengths  $C_{i,j}$  are i.i.d.  $U[0, C]$ . (As  $C_{i,j} \geq 0$ , configurations where neighboring spins align are favored.)

The model has been widely used as a test case for partition function estimation [4][8][14][15] due to its flexibility: as  $C$  is increased, the dominant contribution to the partition function shifts from configurations with many unaligned neighbors to configurations with few unaligned neighbors. We focus on the particularly challenging setting  $C \approx 1$ . A side benefit of this choice (not unrelated to hardness) is that a wide range of quantiles contribute significantly to  $Z$ , thus exercising each method for a wide range of thinning.

### 7.1 THE ALGORITHMS

Given the complementary nature of thinning via parity matrices and thinning via affine subspaces, it is natural to combine our two ideas into one algorithm that uses LDPC parity check matrices for small  $i$  (“light” thinning) and random affine subspaces for large  $i$  (“heavy” thinning). To reduce the confounding factors we simply used parity matrices for  $i \in [1, 33]$  and affine subspaces for  $i \in [34, 100]$ .

Besides the junction-tree algorithm used to compute  $Z$  exactly, we also evaluated the Mean Field approximation, and Tree-Reweighted Belief Propagation (TRWBP) [6], providing a lower and an upper bound for the partition function, respectively. We use the libDAI [10] implementations of all three algorithms. The WISH algorithm is the CPLEX implementation by the authors of [14].

### 7.2 THE RESULTS

WISH is not competitive with our algorithm in certain settings, as indicated by Figure 6 (note that the vertical axis is logarithmic). For example, our algorithm achieves better accuracy with a 10-second timeout than WISH achieves with 360 seconds. When this difference in accuracy is combined with the Branch and Bound speedup, our algorithm is over 100x faster than WISH.

In Figure 7 we compare all four algorithms for  $F = 0.1$  and various values of  $C \in [0.25, 3.0]$ . Rather than comparing run times, which in order to be fair would require adapting the timeout of each algorithm to the difficulty it

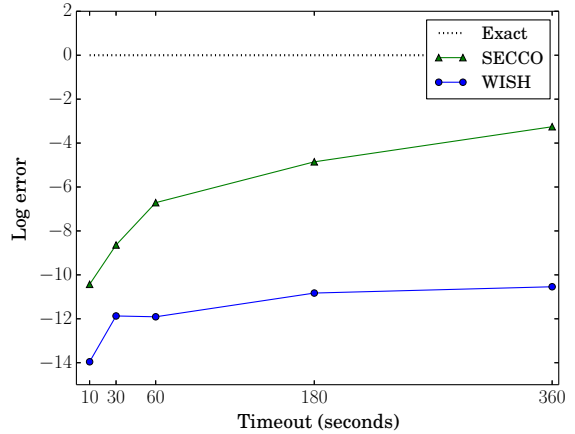

Figure 6:  $10 \times 10$  Ising grid with  $C = 1.0$  and  $F = 0.1$ . *Experiment:* run WISH and our algorithm with a timeout of  $t \in \{10, 30, 60, 180, 360\}$  seconds per instance to get an estimate  $\hat{Z}$  (see legend). *Plot:* report  $\log_2(\hat{Z}/Z)$ .

experiences, we have chosen the more transparent experiment of running each algorithm with the same timeout of 360 seconds across all instances and all  $i \in [n]$  and comparing the accuracy achieved in the final estimate of  $\hat{Z}$ .

The case of high coupling strengths is easy for both algorithms as the dominant contribution to  $Z$  comes from few configurations of high probability and, thus, only light thinning is performed. For  $C \in \{0.5, 0.75, 1.0\}$ , though, our algorithm outperforms WISH by a significant margin (the vertical axis is logarithmic).

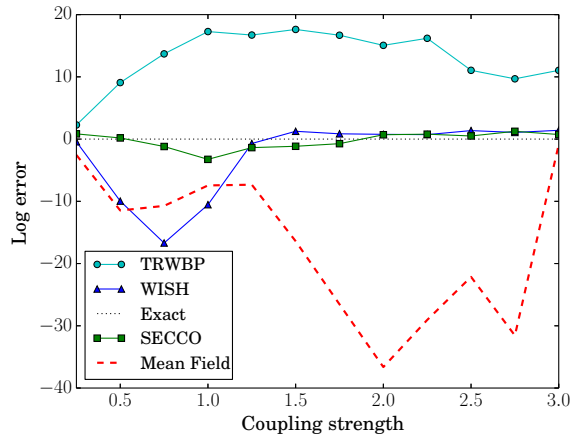

Figure 7:  $10 \times 10$  Ising grid with  $C \in [0.25, 3.0]$ ,  $F = 0.1$ . *Experiment:* for  $C \in \{0.25, 0.50, \dots, 3.0\}$ , determine  $Z$  and run four algorithms to get an estimate  $\hat{Z}$  (see legend). Mean Field and TRWBP are run to termination. WISH and our algorithm have a 360 second timeout for each instance. *Plot:* For  $C \in \{0.25, 0.50, \dots, 3.0\}$  report  $\log_2(\hat{Z}/Z)$ .

## Abstract

Sum-product networks (SPNs) are a recently developed class of deep probabilistic models where inference is tractable. We present two new structure learning algorithms for sum-product networks, in the generative and discriminative settings, that are based on recursively extracting rank-one submatrices from data. The proposed algorithms find the subSPNs that are the most coherent *jointly* in the instances and variables – that is, whose instances are most strongly correlated over the given variables.

Experimental results show that SPNs learned using the proposed generative algorithm have better likelihood and inference results – and also much faster – than previous approaches. Finally, we apply the discriminative SPN structure learning algorithm to handwritten digit recognition tasks, where it achieves state-of-the-art performance for an SPN.

## 1 INTRODUCTION

Sum-product networks (SPNs), introduced in Poon and Domingos [2011], provide compact, tractable representations of probability distributions. Layers of hidden variables are added to the model so long as they maintain compactness whilst keeping inference tractable.

In this work, we present a new SPN structure learning algorithm that constructs an SPN by identifying coherent subSPNs that are sought concurrently across both the instance and variable dimensions. The subSPN search procedure aims at compactly and tractably representing the data and is capable of splitting the data matrix across both dimensions at once, if this leads to a better data representation.

**Contribution.** We make two main contributions. The first is  $\text{SPN-SVD}$ , a new SPN structure learning algorithm

based on rank-one (rank-1) submatrix extraction. The problem of finding subSPNs is reformulated as a problem of finding approximate rank-1 submatrices of the data matrix. An important feature of the approach is that it splits the data along two dimensions (variables and instances) simultaneously when doing so optimises the objective. In contrast, previously developed approaches to learning the structure of SPNs split the data across one dimension only, at a time, without taking into consideration that such local improvement might drift the overall resulting SPN away from the optimal representation.

The second main contribution is an extension of our structure learning algorithm to the setting of *discriminative* learning [Gens and Domingos, 2012]. The discriminative structure learning algorithm,  $\text{DSPN-SVD}$ , first extracts the features that are the most dependent on the labels, where dependence is measured via the Hilbert-Schmidt Independence Criterion (HSIC), and then recursively applies  $\text{SPN-SVD}$ . To the best of our knowledge, it is the first structure learning algorithm designed for discriminatively training SPNs.

The performance of both algorithms is extensively evaluated. When evaluated on the Caltech-101 and Olivetti image datasets,  $\text{SPN-SVD}$  outperforms other SPN algorithms, with higher log-likelihood (LL) values and much faster performance. The discriminative structure learning algorithm achieves state-of-the-art performance on handwritten digit classification when compared with other SPN algorithms.

## 2 SUM-PRODUCT NETWORKS

SPNs are built by composing tractable distributions. A tractable distribution is a distribution whose partition function and mode can be computed in time  $O(1)$  [Gens and Domingos, 2013]. A tractable univariate distribution,  $D_X$ , is an SPN. SPNs provide a representation in which single tractable distributions of the form  $D_X$  are combined into a richer and more complex distribution, provided that the resulting distribution remains tractable.

An SPN is a rooted directed acyclic graph (DAG),  $Gr$ , whose leaves are univariate distributions, and whose internal nodes are sum and product nodes. Edges from a sum node to its children are assigned positive weights,  $W$ . Let  $Br(S)$  denote the branches (children) of  $S$ . The scope,  $sc$ , of a sum-product network,  $S(Gr, W)$ , is the set of variables that appear in the leaf nodes of the SPN [Poon and Domingos, 2011]. Sum nodes are denoted by  $Sum_i(Br_1 : w_1, Br_2 : w_2, \dots)$ , where  $Br_1, Br_2, \dots$  are the branches and  $w_1$  and  $w_2$  are their respective weights. Similarly, product nodes are denoted by  $Prd_i(Br_1, Br_2, \dots)$ .

The two composition rules used in SPNs are defined as follows. Firstly, a product,  $Prd$ , of SPNs,  $sub_1, \dots, sub_k$ , over disjoint scopes, is an SPN, rooted by  $Prd$ :

$$\forall sub_i, sub_j \in Br(Prd) : sc(sub_i) \cap sc(sub_j) = \phi \quad (1)$$

A decomposable SPN is one in which each product node satisfies Eq. (1).

Secondly, a positive weighted sum,  $Sum$ , of SPNs over the same scope is an SPN rooted by  $Sum$  [Gens and Domingos, 2013]:

$$\forall sub_i, sub_j \in Br(Sum) : sc(sub_i) = sc(sub_j) \quad (2)$$

A complete SPN is one in which each sum node satisfies Eq. (2). A sum node,  $Sum$ , can be thought of as the result of summing out a hidden variable. The sum of weights of all the branches of a sum node is always equal to 1 ( $\sum_{sub \in Br(Sum)} w_{sub} = 1$ ).

## 2.1 Related Work on Structure Learning

The emphasis in the SPN literature has recently shifted from learning parameters to learning the structure of models. Parameter learning algorithms assume a fixed structure and learn weights using either generative [Poon and Domingos, 2011] or discriminative [Gens and Domingos, 2012] training. A hard EM algorithm is used by Poon and Domingos [2011] to perform generative parameter learning on SPNs. Deep SPNs are learned successfully using hard EM with a *pre-defined* network structure. A discriminative parameter learning algorithm based on gradient descent was introduced in Gens and Domingos [2012].

The first algorithm to learn the structure of an SPN from data was proposed by Dennis and Ventura [2012]. The algorithm first clusters data instances and creates a corresponding sum node. Then, it clusters variables in a top-down approach, creating product nodes. There are three potential problems with the algorithm. The first is that any context-specific independences that appear after the first clustering are not taken into consideration because instances are not clustered after the first step. Secondly, the algorithm is based on a clustering method that ignores correlation between variables. It will therefore tend to place

dissimilar, but strongly correlated, variables in different clusters. Finally, the structure and weights are learned using two distinct methods.

A bottom-up approach, based on greedily merging small image regions into larger regions, was introduced in Peharz et al. [2013]. An online learning algorithm was proposed by Lee et al. [2013], where the problem was cast as an online clustering problem. They develop an incremental SPN structure learning algorithm based on dynamically modifying the number of clusters based on incoming data.

The most prominent general SPN structure learning algorithm was proposed by Gens and Domingos [2013]. It applies a recursive top-down approach which, at each step, checks whether variables can be split into approximately independent subsets – in which case a product node is constructed. Otherwise, the current instances are clustered, and a sum node is returned with weights proportional to the number of instances in each cluster. The algorithm greedily optimises the log-likelihood and overcomes several limitations in Dennis and Ventura [2012]. However, it only searches locally for the ideal splitting candidate at each step, see discussion of Table 1 below.

To the best of our knowledge, the most recent algorithm for general SPN structure learning was proposed in Rooshenas and Lowd [2014]. The authors adapt a method based on mixture modelling and arithmetic circuit learning. It does not only apply local modifications in the search of an optimal model as arithmetic circuit learning could lead to global changes. However, a global search over the data is neither systemic nor guaranteed.

Peharz et al. [2014] learn the structure of a restricted class of SPNs, where each sum node can have no more than one branch with a non-zero output for a certain input. Nath and Domingos [2014] develop an algorithm that learns the structure of relational SPNs.

Our focus is on learning the structure of general SPNs in both the generative and discriminative settings.

## 3 LEARNING THE STRUCTURE OF AN SPN

Previous SPN structure learning algorithms cluster instances without ensuring that the clustering respects context-specific independences (independences that hold only among instances of a specific context or cluster). In contrast, our proposed algorithm (*SPN-SVD*) concurrently checks the data matrix across both the instance and variable dimensions, looking for coherent subSPNs in the form of rank-1 submatrices.

**Motivating Example.** It is useful to consider a simple example in detail, so as to understand how *SPN-SVD* differs from *SPN-Gens*. Tables 1 & 2 contrast the steps

taken by SPN-SVD and SPN-Gens [Gens and Domingos, 2013]. Table 1(A) shows the data matrix, which consists of 6 instances with 4 variables each. SPN-Gens clusters the data into 2 clusters, as shown in Table 1(B) and in Figure 1. In the example, the cluster of elements with value 18 is split.

Table 1: SPN-Gens on an Example Data Matrix. Rows are instances and columns are variables.

Figure 1: The SPN Structure Learned from Table 1 by SPN-Gens.

SPN-SVD deals with the same data quite differently, as shown in Table 2. The algorithm simultaneously searches over instances and variables and therefore immediately identifies the submatrix with all entries equal to 18, chooses it as a rank-1 submatrix. The algorithm then decomposes the original matrix into three components and acts recursively on each.

The crucial difference between the two algorithms is that SPN-SVD identifies the submatrix of entries with value 18 as an “atom” in the data, resulting in a graph structure that captures an important feature of the data, whereas SPN-Gens does not. Quantitatively, the final LL value for SPN-Gens is  $-2$  whereas for SPN-SVD it is  $-1.39$ .

Table 2: SPN-SVD Applied to the Matrix from Table 1.

|    |    |    |    |    |    |    |    |
|----|----|----|----|----|----|----|----|
| 40 | 40 | 40 | 40 | 40 | 40 | 40 | 40 |
| 40 | 40 | 40 | 40 | 40 | 40 | 40 | 40 |
| 40 | 18 | 18 | 40 | 40 | 40 | 18 | 18 |
| 20 | 18 | 18 | 20 | 20 | 18 | 18 | 20 |
| 20 | 20 | 20 | 20 | 20 | 20 | 20 | 20 |
| 20 | 20 | 20 | 20 | 20 | 20 | 20 | 20 |

Figure 2: The SPN Structure Learned from Table 1 by SPN-SVD.

In essence, SPN-SVD and SPN-Gens are motivated by two different extreme cases.

SPN-Gens is inspired by the observation that if variables are independent, then they can be decomposed into separate (branches or) leaves of an SPN product node.

In contrast, SPN-SVD is inspired by a complementary observation: if a subset of variables is perfectly correlated over a subset of data, then it forms a rank-1 submatrix. These rank-1 submatrices are the “atoms” out of which SPN-SVD builds an SPN. Whereas SPN-Gens searches for independencies; SPN-SVD searches for correlated components.

Searching for rank-1 submatrices instead of independent variables has three potential advantages. Firstly, correlations are easier to estimate than independence. Secondly, the search for rank-1 submatrices occurs jointly over variables and instances, whereas clustering and identifying independencies are two unrelated procedures. Thirdly, extracting correlated submatrices reduces redundant compu-

tations, resulting in a faster algorithm, see Lemma 1 below.

### 3.1 Extracting a Rank-1 Submatrix

The main subroutine of SPN-SVD is a rank-1 extraction algorithm based on singular value decomposition (SVD). The approach derives from an algorithm for nonnegative matrix factorization (NMF) developed in Biggs et al. [2008a].

Let  $X \in \mathbb{R}^{m \times n}$  denote a data matrix containing  $m$  instances and  $n$  variables. We denote by  $X_{i\bullet}$  the  $i^{\text{th}}$  row of the matrix, corresponding to the  $i^{\text{th}}$  instance of the data, and by  $X_{\bullet j}$  the  $j^{\text{th}}$  column of the matrix, corresponding to the  $j^{\text{th}}$  variable.

In the generative training case, assume the labels, if provided, are included in  $X$ . We introduce the notation  $X_{(M,N)}$  to refer to the *submatrix* of  $X$  consisting of rows  $M \subset \{1, \dots, m\}$  and columns  $N \subset \{1, \dots, n\}$ .

The algorithm extracts the submatrix of the data matrix  $X$  that is closest to having rank-1, denoted by  $B_1$ , by maximising

$$B_1 := \operatorname{argmax}_{X_{(M,N)}} \|X_{(M,N)}\|_F^2 - \gamma \|X_{(M,N)} - \sigma uv^\top\|_F^2, \quad (3)$$

where  $\sigma$  is the maximum singular value of the submatrix  $X_{(M,N)}$  and  $u \in \mathbb{R}^m, v \in \mathbb{R}^n$  are the dominant singular vectors of  $X_{(M,N)}$ , and  $\|\bullet\|_F$  is the Frobenius norm. Recall that the Frobenius norm is the root sum of the squared singular values.

The second term in Eq. (3) thus encourages the optimization to find a submatrix that is close to rank-1. The first term ensures the submatrix is biased towards having large singular values;  $\gamma$  controls the penalty incurred as  $X_{(M,N)}$  deviates from being rank-1.

Algorithm 1 details the subroutine, `extractR1`, used to extract approximate rank-1 submatrices. For fixed  $M$  and  $N$ , `extractR1` exactly coincides with the SVD power method. However, instead of fixing  $M$  and  $N$ , the inner loop searches for the submatrix with the closest rank-1 approximation. Lines 6 and 8 show a heuristic used to solve the NP-hard problem defined in Eq. (3) [Biggs et al., 2008a]. The criterion in lines 6 and 8 of Algorithm 1 decides whether or not to include one column or row separately. This makes the subroutine parallelisable and highly scalable in terms of memory and processing power. `extractR1` computes the *dominant* singular vectors of a *submatrix*, which are less prone to perturbations by noise than the full matrix [Biggs et al., 2008b].

### 3.2 Generative SPN Structure Learning Algorithm (SPN-SVD)

SPN-SVD recursively extracts ‘‘atomic’’ submatrices from the input matrix. Each extraction breaks the input ma-

---

#### Algorithm 1 Function `extractR1(X)`

---

**Input:**  $X \in \mathbb{R}^{m \times n}, \gamma > 1$

**Output:**  $[M, N, Stop]$

- 1: Select  $j_0 \in \{1, \dots, n\}$  to maximise  $\|X_{(:,j_0)}\|_F$
  - 2:  $M = \{1, 2, \dots, m\}, N = \{j_0\}$
  - 3:  $u = X_{(:,j_0)}$
  - 4: **repeat**
  - 5:    $v = X_{(M,:)} \cdot \frac{u(M)}{\|u(M)\|_F}$
  - 6:    $N = \{j : \gamma v(j)^2 - \|X_{(M,j)}\|_F^2 > 0\}$
  - 7:    $u = X_{(:,N)} \cdot \frac{v(N)}{\|v(N)\|_F}$
  - 8:    $M = \{i : \gamma u(i)^2 - \|X_{(i,N)}\|_F^2 > 0\}$
  - 9: **until**  $M, N, u, v$  do not change
  - 10: **if**  $X_{(M,N)} = X$  or  $(|M| = 0$  and  $|N| = 0)$  **then**
  - 11:    $Stop = true$
  - 12: **else**
  - 13:    $Stop = false$
  - 14: **end if**
- 

trix into three pieces, which are glued together as sum and product nodes.

Algorithm 2 details the main steps of SPN-SVD. Rows are instances and columns are variables. Each variable is divided by its standard deviation before extracting rank-1 submatrices. The normalised values are used in the subroutine `extractR1` only, and are not returned or updated in the matrix. Normalisation helps discover correlated sets of variables.

Given an input matrix, subroutine `extractR1` recursively extracts an approximate rank-1 submatrix  $B_1$ . The matrix is then split into three components: the submatrix  $B_1$ , submatrix  $B_2$  consisting of other variables on the same instances as  $B_1$ , and finally submatrix  $B_3$  consisting of the remaining instances.

The optimization in (3) ensures that variables in  $B_1$  are maximally correlated and the remaining variables, captured by  $B_2$ , are largely uncorrelated with  $B_1$ . The algorithm therefore combines  $B_1$  and  $B_2$  via a product node

$$Prd(B_1, B_2).$$

Finally, the remaining *instances*, captured by  $B_3$ , are added via a sum node

$$Sum(B_3 : w_1, Prd(B_1, B_2) : w_2),$$

where  $w_2 = \frac{|M|}{m}$  and  $w_1 = 1 - w_2$ .

The algorithm proceeds recursively by feeding  $B_1, B_2$  and  $B_3$  back into the algorithm as input matrices until one of three base cases is reached:

1. *The input matrix contains a single variable:*

The remaining vector represents a univariate distribution and a leaf node is created (line 2).

---

**Algorithm 2** Function SPN-SVD( $A$ )

---

**Input:**  $A \in \mathbb{R}^{m \times n}, \gamma > 1$

**Output:** Sum-product network  $S$  representing  $A$

- 1: **if** #columns( $A$ ) = 1 **then**
  - 2:   **return** univariate distribution on variable.
  - 3: **else if** #rows( $A$ ) = 1 **then**
  - 4:   **return** return  $Prd$ (variables in  $A$ ).
  - 5: **end if**
  - 6:  $[M, N, Stop] = \text{extractR1}(A, \gamma)$
  - 7: Set  $B_1 = A_{(M, N)}$ ,  $B_2 = A_{(M, N^c)}$  and  $B_3 = A_{(M^c, \{1 \dots n\})}$
  - 8: **if**  $Stop = \text{true}$  **then**
  - 9:   **return** multivariate distribution  $MVLN(A)$
  - 10: **else**
  - 11:   Construct  $Prd(B_1, B_2)$
  - 12:   Call SPN-SVD( $B_1$ ) and SPN-SVD( $B_2$ )
  - 13:   Construct
- $$Sum \left( B_3 : \frac{m - |M|}{m}, Prd(B_1, B_2) : \frac{|M|}{m} \right)$$
- 14:   Call SPN-SVD( $B_3$ )
  - 15: **end if**
- 

2. *The input matrix contains a single instance:*

All variables are independent and a product node is created (line 4). Its leaves are the relevant variables.

3. *The entire input matrix is extracted:*

The variables in  $A$  are highly correlated since  $A$  has rank-1. The algorithm therefore constructs a sum node with a branch per instance in  $A$ , followed by product nodes over the variables. We refer to the node as a *multivariate leaf node* or *MVLN*.

More precisely, if  $A \in \mathbb{R}^{M \times N}$  and  $B_1 \equiv A$  then for each instance  $j$  form product node

$$r_j := Prd_j(A_{j1}, \dots, A_{jN}).$$

Combine the product nodes by summing over instances:

$$MVLN(A) := Sum(r_1 : w, \dots, r_M : w), \quad (4)$$

where  $w = \frac{1}{|M|}$ .

Variables in a rank-1 submatrix cannot be independent. SPN-SVD achieves significant speedups by avoiding redundant searches for independencies and returning MVLNs. In contrast, when SPN-Gens encounters a rank-1 submatrix, it recursively searches for independencies and clusters across its subsets, which leads to a slower implementation and also an SPN with a more complicated structure. The speedup from using MVLNs is reported in the experimental results below.

A commonly used assumption is that data is clustered in strongly correlated groups. For example, algorithms such as the group Lasso seeks solutions where groups of variables are zero together [Bach, 2008]. The following simple Lemma illustrates how large MVLNs arise in the more general setting where groups of variables receive the same, or even approximately the same, values.

**Lemma 1.** *Let  $X \in \mathbb{R}^{m \times n}$  be a data matrix consisting of  $m$  instances. Suppose that  $X$  contains a group of instances  $G \subset \{1, \dots, m\}$  with similarity pattern  $\mathbf{K}_G = \{k | X_{ik} = X_{jk} \text{ for all } i, j \in G\}$ . Then SPN-SVD will find a multivariate leaf node satisfying*

$$|MVLN| \geq |\mathbf{K}_G| \cdot |G|.$$

*Proof.* The result follows immediately since the algorithm will either find the MVLN corresponding to the group, or a larger MVLN.  $\square$

An interesting question, deferred to future work, is to characterise the *collections* of groups with similarity patterns that are best suited to the SPN-SVD algorithm. It is also worth investigating how robustly MVLNs are extracted in the presence of noise.

### 3.3 Discriminative SPN Structure Learning Algorithm (DSPN-SVD)

Finally, we consider the setting of discriminative learning, where the algorithm is provided with labeled data. Discriminative learning models the conditional distribution  $P(Y|X)$ , rather than the joint distribution  $P(X, Y)$ . Discriminative SPNs combine the flexibility of selecting/extracting relevant features, with the tractability and representational prowess of SPNs. They can achieve high classification or regression accuracy by selecting variables that are dependent on  $Y$ . They were first introduced by Gens and Domingos [2012], where parameters were learned on a pre-defined structure.

We propose a new discriminative SPN structure learning algorithm, referred to as DSPN-SVD. We assume the labels are discrete, and belong to the set  $\mathcal{C} = \{1, \dots, l\}$ . The algorithm extracts features  $Z$  from the input matrix,  $X$ , that are maximally correlated (in a suitable sense) with the labels  $Y$ . The algorithm then applies SPN-SVD to the learned features to construct a collection of generative SPNs, one per conditional distribution  $P(Z|Y = j)$  for  $j \in \mathcal{C}$ , that are combined by a single sum-node.

Extracting  $Z$  requires a measure of dependence between variables. We use the Hilbert-Schmidt independence criterion (HSIC), which we briefly recall [Gretton et al., 2005].

Let  $k(x, x')$  and  $l(y, y')$  be kernels on the input space  $\mathcal{X}$  and the label space  $\mathcal{Y}$ , with corresponding feature maps  $\phi :$

$\mathcal{X} \rightarrow \mathcal{F}$  and  $\psi : \mathcal{Y} \rightarrow \mathcal{G}$  respectively. The Hilbert-Schmidt Independence Criterion is

$$HSIC(k, l, P_{XY}) := \|C_{xy}\|_F, \text{ where}$$

$$C_{xy} := \mathbf{E}_{(x,y) \sim P} [(\phi(x) - \mu_x) \otimes (\psi(y) - \mu_y)]$$

is the cross-covariance operator [Fukumizu et al., 2004]. We apply the HSIC for supervised feature selection following Song et al. [2007].

Let  $\Pi := \{W \in \mathbb{R}^{n \times d} : \langle W_{\bullet i}, W_{\bullet j} \rangle = \delta_{ij}\}$  denote the set of orthogonal projections from  $\mathbb{R}^n = \mathcal{X}$  to  $\mathbb{R}^d$ . Given the standard dot product  $\langle \bullet, \bullet \rangle$  on  $\mathbb{R}^d$ , each projection induces a kernel  $K_W(x, y) := \langle Wx, Wy \rangle$  on  $\mathcal{X}$ .

Let  $L(y, y') = \delta_{y, y'}$  be the Kronecker kernel, which is 1 if  $y = y'$  and 0 otherwise. The Kronecker kernel is suitable for the categorical variable,  $Y \in \mathcal{C}$ , because it expresses precisely whether or not two labels are equal. It is easy to extend to real-valued or structured labels by employing more sophisticated kernels.

Let  $X \in \mathbb{R}^{m \times n}$  be a data matrix with labels  $Y \in \mathcal{Y}^m$ , yielding empirical distribution  $\hat{P}_{XY}$ . Construct the centering matrix  $H = (Id_m - m^{-1}11^\top)$  and empirical Kronecker kernel  $L_{ij} = \delta_{y_i = y_j}$ .

**Lemma 2.** Let  $V \in \mathbb{R}^{n \times d}$  be the top  $d$  eigenvectors of

$$\chi := X^\top H L H X \quad (5)$$

Then  $V$  maximizes the Hilbert-Schmidt dependence:

$$V = \operatorname{argmax}_{W \in \Pi} HSIC(K_W, L, \hat{P}_{XY}).$$

*Proof.* The vectors  $V_{\bullet j}$ ,  $j = 1, \dots, d$ , are the eigenvectors of  $\chi$ . They therefore maximize the trace

$$\operatorname{argmax}_V \operatorname{tr}(V^\top X^\top H L H X V)$$

Since  $\operatorname{tr}(AB) = \operatorname{tr}(BA)$ , the objective can be rewritten as:

$$\operatorname{argmax}_V \operatorname{tr}(H X V V^\top X^\top H L) \quad (6)$$

Following Barshan et al. [2011], let  $K = X V V^\top X^\top$ . The objective in Eq. (6) is then

$$\operatorname{tr}(H K H L),$$

which is the HSIC [Gretton et al., 2005].  $\square$

The higher the HSIC value, the stronger the dependence between the projected representation of the data  $Z = X V$  and  $Y$ , and thus the more useful the representation is for discriminative learning.

---

### Algorithm 3 Function DSPN-SVD

---

**Input:**  $X \in \mathbb{R}^{m \times n}, Y \in \mathcal{Y}^m, \gamma > 1, d > 1$

**Output:** Sum-product network  $S$  representing  $Y|X$

- 1: Construct kernel matrix  $L_{ij} = (\delta_{y_i = y_j})_{i,j=1}^m$  and centering matrix  $H = (Id_m - m^{-1}11^\top)$ .
  - 2: Compute the  $d$  eigenvectors  $V \in \mathbb{R}^{n \times d}$  of  $\chi = X^\top H L H X$  with the largest eigenvalues.
  - 3: Set feature matrix  $Z_{m \times d} \leftarrow X_{m \times n} \cdot V_{n \times d}$
  - 4: Construct sum node  $Sum_1(Br_j : w_j)$ , where  $Br_j$  contains all instances with label  $j$ , and weight  $w_j = \frac{m}{\#instances \text{ labeled } j}$ .
  - 5: **for** label  $j$  in  $\mathcal{Y}$  **do**
  - 6:   SPN-SVD( $Br_j, \gamma$ )
  - 7: **end for**
- 

After extracting the features  $Z$ , there are two remaining steps. The first step constructs the base node for the discriminative SPN as a sum node that separates instances belonging to different labels. Nodes in the sum are weighted by the number of instances. The resulting network is thus automatically biased towards more common labels. The second step applies the generative SPN-SVD algorithm to each branch of the sum node using the extracted features in  $Z$ .

The main steps of DSPN-SVD are shown in Algorithm 3.

Figure 3 shows an example with 2 labels and 3 variables. As shown in the tables at the top of the figure, the  $X$  variables are replaced by a more suitable representation,  $Z$ . The base sum node then places instances of each label on separate branches, where each branch's subSPN is in turn learned by SPN-SVD. A simplified example of the feature extraction process is shown in Figure 4. Since the first two features convey no information about the labels, extracting only the third feature,  $Z = X_{\bullet 3}$ , maximises the HSIC.

## 4 EXPERIMENTS

### 4.1 Generatively Trained SPNs

Our main evaluation of SPN-SVD is based on comparing its accuracy and speed to other SPN structure learning algorithms. Following prior work on structure learning [Gens and Domingos, 2013, Rooshenas and Lowd, 2014], we report accuracy in terms of the test-set log-likelihood (LL) and query conditional log-likelihood (CLL). These values are obtained from experiments on the Caltech-101 dataset [Fei-Fei et al., 2004], the Olivetti face dataset [Salakhutdinov and Hinton, 2009], and 20 binary datasets. Caltech-101 is one of the most commonly used image datasets. It contains images divided into 101 categories, e.g. airplanes, cameras and faces. Each object category contains from 40 to 800 images. Images in Caltech-101 are  $64 \times 64$  pixels. The Olivetti dataset contains 400 face images of  $64 \times 64$

Figure 3: The Discriminative SPN Prior to Running SPN-SVD on Each Sum Node Branch.

Figure 4: An Example of  $X$ ,  $Y$  and  $Z$  where  $m = 4, n = 3, d = 1$ .  $Z = XV = X[0 \ 0 \ 1]^T$ .

pixels. Importantly, these datasets are not binary, in contrast to previous datasets used for SPN structure learning. The datasets are discrete-valued. Extending to the continuous case is straightforward. 60% of the instances of each object category are used for training, 10% for validation (needed mainly for WinMine) and 30% for testing.

**Accuracy.** For Caltech-101, values of LL and inference are displayed as average values across all object categories, as well as averages for some of the individual object categories, while only the grand average is displayed for Olivetti. By “average”, we mean that the LL values displayed represent their respective summation of LL values divided by the number of test instances. Univariate leaf distributions are multinomials with Laplace smoothing (add 0.1).

We compared SPN-SVD with four algorithms: (1) SPN-Gens [Gens and Domingos, 2013], with code available online; (2) ID-SPN [Rooshenas and Lowd, 2014] by the Libra toolkit; (3) SPN-Dennis [Dennis and Ven-

tura, 2012], which was implemented via algorithms 1, 2 & 3 of Dennis and Ventura [2012]; (4) Bayesian network structure learning with the WinMine toolkit [Chickering, 2002], which was chosen because it can express context-specific independence.

Table 3 shows the test-set LL values obtained for 18 example object categories from Caltech-101, the whole Caltech-101 dataset and the Olivetti face dataset using the SPN-SVD, SPN-Gens, ID-SPN, SPN-Dennis algorithms and WinMine. The greater the LL, the better. The total number of instances (training + test + validation) in each category or dataset is shown in Table 3. Bold red signifies that an algorithm is significantly better than competitors on a category, whereas bold black indicates that an algorithm is better than competitors on a category. Significant results are identified using a paired t-test (performed in the log scale) with  $p = 0.05$ . Out of the 101 Caltech-101 categories, SPN-Gens is significantly better than its competitors in 5 categories, WinMine in 9 categories, ID-SPN in 12 categories while SPN-SVD is significantly better in 42 categories, 9 of which are shown in Table 3.

**Training time.** An important advantage of SPN-SVD is its rapid training time. SPN-SVD took 2.5 hours with 1 CPU to build the SPN and calculate the test-set LL values for Caltech-101 and Olivetti. In contrast, SPN-Gens took 13.5 hours, ID-SPN took 12 hours, and SPN-Dennis took 7.5 hours to perform the same task. WinMine took 2.5 hours to build the Bayesian network and calculate LL values.

Per the discussion of Lemma 1, we expect that larger *MVLNs* lead to larger reductions in run-time. Our experiments show a 3-fold speedup when comparing SPN-SVD’s performance with and without *MVLNs*. Returning *MVLNs* thus accounts for most of the 4.5-fold speedup of SPN-SVD compared to SPN-Gens.

Another major advantage of SPN-SVD is that it has few tuning parameters. The generative algorithm has one parameter,  $\gamma$ , which controls the penalty for deviating from rank-1, whereas DSPN-SVD has a  $2^{nd}$  parameter:  $d$ , the number of extracted features. In comparison, ID-SPN, for example, has:  $L_1$  prior parameters  $C^{ji}$ , split penalty  $SP^{ji}$ , maximum edges  $ME^{ji}$  for each AC node, cluster penalty, standard deviation of the Gaussian priors, and the number of main iterations [Rooshenas and Lowd, 2014].

**Queries.** Next, we investigate the accuracy and speed of queries. Queries are generated following Gens and Domingos [2013]. Experiments are performed with a range of query and evidence variables, see Table 4. A number of instances are selected randomly from the test-set of each object category or dataset, and then queries  $P(Q = q|E = e)$  are created by randomly picking proportions of the variables. The average CLL  $\log P(Q = q|E = e)$  is com-

Table 3: Test-set LL and Learning Time. Results are shown for 18 Caltech-101 Categories, Caltech-101 & Olivetti. Bold red signifies that an algorithm significantly outperforms the rest.

puted and normalised by the number of query variables following Gens and Domingos [2013]. Table 4 shows the results, for varied proportions of evidence and query variables, in the form of the average CLL for both SPN-SVD and SPN-Gens.

Both SPN-SVD and SPN-GENS achieve average dataset CLL values that are significantly higher than the results obtained by SPN-Dennis, ID-SPN and the conditional marginal likelihood (CMLL) values of WinMine. The latter three results are therefore not reported to save space. Similarly, we only show queries of 5 object categories, rather than 18, along with the average CLL of the whole Caltech-101 and Olivetti datasets.

Across all proportions of object categories, there are 84 categories in which SPN-SVD significantly outperforms SPN-Gens, and 18 where the converse occurs. As inference is linear in the number of edges of an SPN, there is not a major difference between average query time for SPN-SVD and SPN-Gens.

**Image completion.** To confirm that the LL values are visually meaningful, an image completion task was applied to a select few images from Caltech-101. Two images are shown in Figure 5, taken from one of the face categories of Caltech-101, referred to as Faces-easy. The left half of each test image is inferred after building an SPN using training images from the same faces category. In each case, the right half of the test image is given as evidence and the left half is regarded as query variables, and inference is performed by the SPN. The top part of Figure 5 displays the original images and the bottom shows the images inferred

by SPN-SVD.

**Binary datasets.** In Table 5, we report the test-set LL values of SPN-SVD, SPN-Gens and ID-SPN (LL values of SPN-Dennis are significantly lower) on 20 binary datasets used in Gens and Domingos [2013], Rooshenas and Lowd [2014]. The number of instances in a binary dataset ranges from 2k to 388k, and the number of variables ranges from 16 to 1556 [Gens and Domingos, 2013]. Out of the 20 datasets, SPN-SVD outperforms the alternatives in 7 datasets, whereas ID-SPN outperforms the rest in 6 datasets. Significant results are identified using a paired t-test with  $p = 0.05$ .

The results on discrete and binary datasets indicate that SPN-SVD achieves, by far, state-of-the-art performance for an SPN on discrete datasets. This is where interpreting correlations makes a huge difference. SPN-SVD is also at par with SPN state-of-the-art on binary datasets.

## 4.2 Discriminatively Trained SPNs

We present results obtained by applying discriminative SPNs on two handwritten digit recognition datasets, USPS [Hull, 1994] and MNIST [LeCun et al., 1998]. USPS consists of 1100 images per digit for each of the 10 digits. Each image is  $16 \times 16$ . For each digit, 800 images are assigned to the training set and 300 to the test set. MNIST consists of 6000 training images per digit, each of size  $28 \times 28$ , and a test set of 1000 images per digit. Discriminative SPN structures were learned by DSPN-SVD in both cases. The number of extracted features  $d$  was chosen by cross-validation.

Table 4: Average CLL & Query Time. Results are normalised by number of query variables. Results are shown for 5 Caltech-101 categories, Caltech-101 & Olivetti. SVD refers to SPN-SVD, and Gens to SPN-Gens.

Table 6 shows the results for DSPN-SVD, SPN-SVD, SPN-Gens and ID-SPN. Apart from boosting algorithms, DSPN-SVD achieves higher accuracy than other algorithms on USPS, including C4.5 as reported in Demiriz et al. [2002]. As per MNIST, DSPN-SVD also achieves the highest accuracy for an SPN, and 2.2% less than the current overall state-of-the-art accuracy on MNIST (reported as 99.79% by Wan et al. [2013] and 99.77% by Ciresan et al. [2012]). The flexibility of extracting features and building a discriminative SPN tailored for the respective dataset makes DSPN-SVD superior to SPN-SVD, as well as SPN-Gens and ID-SPN on both USPS and MNIST.

Table 6: Classification of Handwritten Digits.

| Dataset | DSPN-SVD | SPN-SVD | SPN-Gens | ID-SPN |
|---------|----------|---------|----------|--------|
| USPS    | 92.4%    | 90.2%   | 79%      | 77.1%  |
| MNIST   | 97.6%    | 85%     | 81.8%    | 83.4%  |

Figure 5: Face Image Completions. The top row shows the original images; the bottom row shows images with the left half inferred using SPN-SVD.

## 5 CONCLUSION

State-of-the-art results when performing learning and inference on image datasets and digit classification indicate that the proposed SPN structure learning algorithms are effective.

Some important advantages of SPN-SVD over previously developed approaches are that it: (i) does not depend on local data splittings and instead globally splits the data based on rank-1 submatrix extraction; (ii) is based on correlations, which are easier to estimate than independences; and (iii) achieves considerable speedups by detecting large approximate rank-1 submatrices and avoiding redundant computations.

Interesting directions for future research include extending the discriminative setting to regression or structured-output learning by plugging more sophisticated kernels into the HSIC step, and enabling the SPN to model features optimised for different labels.

## Abstract

We report a novel network reconstruction method, which combines constraint-based and Bayesian frameworks to reliably reconstruct graphical models despite inherent sampling noise in finite observational datasets. The approach is based on an information theory result tracing back the existence of colliders in graphical models to negative conditional 3-point information between observed variables. In turn, this provides a confident assessment of structural independencies in causal graphs, based on the ranking of their most likely contributing nodes with (significantly) positive conditional 3-point information. Starting from a complete undirected graph, dispensable edges are progressively pruned by iteratively “taking off” the most likely positive conditional 3-point information from the 2-point (mutual) information between each pair of nodes. The resulting network skeleton is then partially directed by orienting and propagating edge directions, based on the sign and magnitude of the conditional 3-point information of unshielded triples. This “3off2” network reconstruction approach is shown to outperform constraint-based, search-and-score and earlier hybrid methods on a range of benchmark networks.

## 1 INTRODUCTION

The prospect of learning the direction of causal dependencies from mere correlations in observational data has long defied practical implementations (Reichenbach, 1956). The fact that causal relationships can, to some extent, be inferred from nontemporal statistical data is now known to hinge on the unique statistical imprint of colliders in causal graphical models, provided that certain assumptions are made about the underlying process of data generation, such as its faithfulness to a tree structure (Rebane

and Pearl, 1988) or a directed acyclic graph model (Spirtes, Glymour, and Scheines, 2000; Pearl, 2009).

These early findings led to the developments of two types of network reconstruction approaches; on the one hand, search and score methods (Cooper and Herskovits, 1992; Heckerman, Geiger, and Chickering, 1995; Chickering, 2002) need heuristic strategies, such as hill-climbing algorithms, to sample network space, on the other hand, constraint-based methods, such as the PC (Spirtes and Glymour, 1991) and IC (Pearl and Verma, 1991) algorithms, rely on the identification of structural independencies, that correspond to edges to be removed from the underlying network (Spirtes, Glymour, and Scheines, 2000; Pearl, 2009). Yet, early errors in removing edges from the complete graph often lead to the accumulation of compensatory errors later on in the pruning process. Hence, despite recent, more stable implementations intending to overcome order-dependency in the pruning process (Colombo and Maathuis, 2014), constraint-based methods are not robust to sampling noise in finite datasets.

In this paper, we present a more robust constrained-based method and corresponding 3off2 algorithm. It is directly inspired by the PC and IC algorithms but relies on a quantitative information theoretic framework to reliably uncover conditional independencies in finite datasets and subsequently orient and propagate edge directions between connected variables.

## 2 RESULTS

### 2.1 UNCOVERING CAUSALITY FROM A STABLE / FAITHFUL DISTRIBUTION

Consider a network  $\mathcal{G} = (V, E)$  and a *stable* (or *faithful*) distribution  $P(\mathbf{X})$  over  $V$ , implying that each structural independency (*i.e.* missing edge  $XY$  in  $\mathcal{G}$ ) corresponds to a vanishing conditional 2-point (mutual) information and reciprocally as,

$$(X \perp\!\!\!\perp Y | \{U_i\})_{\mathcal{G}} \iff (X \perp\!\!\!\perp Y | \{U_i\})_P \quad (1)$$

$$\iff I(X; Y | \{U_i\}) = 0 \quad (2)$$

Eq. 1 assumes, in particular, that  $P(\mathbf{X})$  is a theoretical distribution, defined by a formal expression of its variables  $\mathbf{X} = \{X, Y, U_1, U_2, \dots\}$ . Note, however, that no such expression is known *a priori*, in general, and  $P(\mathbf{X})$  must typically be *estimated* from the available data. In principle, an infinite amount of data would be necessary to infer an ‘exact’ *stable* distribution  $P(\mathbf{X})$  consistent with Eq. 1. In the following, we will first assume that such an infinite amount of data is available and distributed as a stable  $P(\mathbf{X})$  to establish how causality can be inferred statistically from conditional 2-point and 3-point information. We will then consider the more realistic situation for which  $P(\mathbf{X})$  is not known exactly and must be estimated from a finite amount of data.

Let us first recall the *generic decomposition* of a conditional 2-point (or mutual) information  $I(X; Y | \{U_i\})$  by the introduction of a third node  $Z$  and the conditional 3-point information  $I(X; Y; Z | \{U_i\})$ ,

$$I(X; Y | \{U_i\}) = I(X; Y; Z | \{U_i\}) + I(X; Y | \{U_i\}, Z) \quad (3)$$

This relation can be taken as the definition of conditional 3-point information  $I(X; Y; Z | \{U_i\})$  which is in fact symmetric in  $X, Y$  and  $Z$ ,

$$\begin{aligned} I(X; Y; Z | \{U_i\}) &= I(X; Y | \{U_i\}) - I(X; Y | \{U_i\}, Z) \\ &= I(X; Z | \{U_i\}) - I(X; Z | \{U_i\}, Y) \\ &= I(Y; Z | \{U_i\}) - I(Y; Z | \{U_i\}, X) \end{aligned}$$

Note that Eq. 3 is always valid, regardless of any assumption on the underlying graphical model and of the amount of data available to estimate conditional 2-point and 3-point information terms. Eq. 3 will be used to prove the following lemmas and propositions, which trace back the origin of necessary causal relationships in a graphical model to the existence of a negative conditional 3-point information between *three* variables  $\{X, Y, Z\}$ ,  $I(X; Y; Z | \{U_i\}) < 0$ , where  $\{U_i\}$  accounts for a structural independency between two of them, *e.g.*  $I(X; Y | \{U_i\}) = 0$  (see Theorem 4).

**Lemma 1.** *Given a stable distribution  $P(\mathbf{X})$  on  $V$ ,  $\forall X, Y \in V$  not adjacent in  $\mathcal{G}$ ,  $\exists \{U_i\} \subseteq V_{\setminus \{X, Y\}}$  s.t.  $I(X; Y | \{U_i\}) = 0$  and  $\forall Z \neq X, Y, \{U_i\}$ ,  $I(X; Y; Z | \{U_i\}) \leq 0$ .*

**Proof.** If  $X, Y \in V$  are not adjacent in  $\mathcal{G}$ , this corresponds to a structural independency, *i.e.*  $\exists \{U_i\} \subseteq V_{\setminus \{X, Y\}}$  s.t.  $I(X; Y | \{U_i\}) = 0$ . Then  $\forall Z \neq X, Y, \{U_i\}$  Eq. 3 implies  $I(X; Y; Z | \{U_i\}) = -I(X; Y | \{U_i\}, Z) \leq 0$ , as conditional mutual information is always positive.  $\square$

**Corollary 2 (3-point contribution).**  $\forall X, Y, Z \in V$  and  $\forall \{U_i\} \subseteq V_{\setminus \{X, Y, Z\}}$  s.t.  $I(X; Y; Z | \{U_i\}) > 0$ , then  $I(X; Y | \{U_i\}) > 0$  (as well as  $I(X; Z | \{U_i\}) > 0$  and  $I(Y; Z | \{U_i\}) > 0$  by symmetry of  $I(X; Y; Z | \{U_i\})$ ).

Corollary 2, which is a direct consequence of Eq. 3 and the positivity of mutual information, will be the ba-

sis of the 3off2 causal network reconstruction algorithm, which iteratively ‘takes off’ 3-point information from 2-point information, as  $I(X; Y | \{U_i\}) - I(X; Y; Z | \{U_i\}) = I(X; Y | \{U_i\}, Z)$ , and update  $\{U_i\} \leftarrow \{U_i\} + Z$  as long as there remains some  $Z \in V$  with (significantly) positive conditional 3-point information  $I(X; Y; Z | \{U_i\}) > 0$ .

**Lemma 3 (vanishing conditional 2-point and 3-point information in undirected networks).** *If  $\mathcal{G}$  is an undirected (Markov) network,  $\forall X, Y \in V$  and  $\forall \{U_i\} \subseteq V_{\setminus \{X, Y\}}$  s.t.  $I(X; Y | \{U_i\}) = 0$ , then  $\forall Z \neq X, Y, \{U_i\}$ ,  $I(X; Y; Z | \{U_i\}) = 0$ .*

**Proof.** If  $\mathcal{G}$  is a Markov network,  $\forall X, Y \in V$  and  $\forall \{U_i\} \subseteq V_{\setminus \{X, Y\}}$  s.t.  $I(X; Y | \{U_i\}) = 0$ , then  $\forall Z \neq X, Y, \{U_i\}$ ,  $I(X; Y | \{U_i\}, Z) = 0$  as conditioning observation cannot induce correlations in Markov networks (Koller and Friedman, 2009). This implies that  $I(X; Y; Z | \{U_i\}) = 0$  through Eq. 3.  $\square$

Note, however, that the converse of Lemma 3 is not true. Namely, (partially) directed networks can also have vanishing conditional 3-point information associated to all their structural independencies. In particular, tree-like bayesian networks without colliders (*i.e.* without v-structures,  $X \rightarrow Z \leftarrow Y$ ) present only vanishing 3-point information associated to their structural independencies, *i.e.*  $I(X; Y; Z | \{U_i\}) = 0$ ,  $\forall X, Y, Z, \{U_i\} \in V$  s.t.  $I(X; Y | \{U_i\}) = 0$ . However, such a directed network must be Markov equivalent to an undirected network corresponding to the same structural independencies but lacking any trace of causal relationships (*i.e.* no directed edges). The probability distributions faithful to such directed networks do not contain evidence of obligate causality; *i.e.* no directed edges can be unambiguously oriented.

The following Theorem 4 establishes the existence of negative conditional 3-point information as statistical evidence of obligate causality in graphical models. For the purpose of generality in this section, we do not exclude the possibility that unobserved ‘latent’ variables might mediate the causal relationships among observed variables. However, this requires dissociating the labelling of the two endpoints of each edges. Let us first introduce three different endpoint marks associated to such edges in mixed graphs: they are the tail ( $-$ ), the head ( $>$ ) and the unspecified ( $\circ$ ) endpoint marks. In addition, we will use the asterisk symbol ( $*$ ) as a wild card denoting any of the three marks.

**Theorem 4 (negative conditional 3-point information as statistical evidence of causality).** *If  $\exists X, Y, Z \in V$  and  $\{U_i\} \subseteq V_{\setminus \{X, Y, Z\}}$  s.t.  $I(X; Y | \{U_i\}) = 0$  and  $I(X; Y; Z | \{U_i\}) < 0$  then,  $\mathcal{G}$  is (partially) directed, *i.e.* some variables in  $\mathcal{G}$  are causally linked, either directly or indirectly through other variables, including possibly unknown, ‘latent’ variables unobserved in  $\mathcal{G}$ .*

**Proof.** Theorem 4 is the contrapositive of Lemma 3, with the additional use of Lemma 1.  $\square$

**Proposition 5 (origin of causality at unshielded triples with negative conditional 3-point information).**

For all unshielded triple,  $X * - \circ Z \circ - * Y$ ,  $\exists \{U_i\} \subseteq V_{\setminus \{X, Y\}}$  s.t.  $I(X; Y | \{U_i\}) = 0$ , if  $Z \notin \{U_i\}$  then  $I(X; Y; Z | \{U_i\}) < 0$  and the unshielded triple should be oriented as  $X * \rightarrow Z \leftarrow * Y$ .

**Proof.** If  $I(X; Y | \{U_i\}) = 0$  with  $Z \notin \{U_i\}$ , the unshielded triple has to be a collider and  $I(X; Y | \{U_i\}, Z) > 0$ , by faithfulness, hence,  $I(X; Y; Z | \{U_i\}) < 0$  by Eq. 3.  $\square$

Hence, the origin of causality manifests itself in the form of colliders or v-structures in graphical models which reveal ‘genuine’ causations ( $X \rightarrow Z$  or  $Y \rightarrow Z$ ) or, alternatively, ‘possible’ causations ( $X \circ \rightarrow Z$  or  $Y \circ \rightarrow Z$ ), provided that the corresponding correlations are not due to unobserved ‘latent’ variables  $L$  or  $L'$  as,  $X \leftarrow - L - \rightarrow Z$  or  $Y \leftarrow - L' - \rightarrow Z$ .

Following the rationale of constraint-based approaches, it is then possible to ‘propagate’ further the orientations downstream of colliders, through positive (conditional) 3-point information, if one assumes that the underlying distribution  $P(\mathbf{X})$  is faithful to an *ancestral graph*  $\mathcal{G}$  on  $V$ . An *ancestral graph* is a mixed graph, that is, with three types of edges, undirected ( $-$ ), directed ( $\leftarrow$  or  $\rightarrow$ ) or bidirectional ( $\leftrightarrow$ ), but with *i.*) no directed cycle, *ii.*) no almost directed cycle (including one bidirectional edge) and *iii.*) no undirected edge with incoming arrowhead (such as  $X * \rightarrow Z - Y$ ). In particular, Directed Acyclic Graphs (DAG) are subclasses of ancestral graphs (*i.e.* without undirected nor bidirectional edges).

**Proposition 6 (‘propagation’ of causality at unshielded triples with positive conditional 3-pt information).**

Given a distribution  $P(\mathbf{X})$  faithful to an ancestral graph  $\mathcal{G}$  on  $V$ , for all unshielded triple with already one converging orientation,  $X * \rightarrow Z \circ - * Y$ ,  $\exists \{U_i\} \subseteq V_{\setminus \{X, Y\}}$  s.t.  $I(X; Y | \{U_i\}) = 0$ , if  $Z \in \{U_i\}$  then  $I(X; Y; Z | \{U_i\} \setminus Z) > 0$  and the first orientation should be ‘propagated’ to the second edge as  $X * \rightarrow Z \rightarrow Y$ .

**Proof.** If  $I(X; Y | \{U_i\}) = 0$  with  $Z \in \{U_i\}$ , the unshielded triple cannot be a collider and, since  $\mathcal{G}$  is assumed to be an ancestral graph, the edge  $Z - Y$  cannot be an undirected edge either. Hence, it has to be a directed edge,  $Z \rightarrow Y$  and  $I(X; Y; Z | \{U_i\} \setminus Z) > 0$  by faithfulness and Eq. 3.  $\square$

Note that the propagation rule of Proposition 6 can be applied iteratively to successive unshielded triples corresponding to positive conditional 3-point information. Yet, all arrowhead orientations can be ultimately traced back to a negative conditional 3-point information, Theorem 4 and

Proposition 5.

**2.2 ROBUST RECONSTRUCTION OF CAUSAL GRAPHS FROM FINITE DATASETS**

We now turn to the more practically relevant situation of finite datasets consisting of  $N$  independent data points. The associated sampling noise will intrinsically limit the accuracy of causal network reconstruction. In particular, conditional independencies cannot be exactly achieved ( $I(X; Y | \{U_i\}) = 0$ ) but can be reliably established using statistical criteria that depend on the number of data points  $N$ .

Given  $N$  independent datapoints from the available data  $\mathcal{D}$ , let us introduce the maximum likelihood,  $\mathcal{L}_{\mathcal{D}|\mathcal{G}}$ , that they might have been generated by the graphical model  $\mathcal{G}$  (Sanov, 1957),

$$\mathcal{L}_{\mathcal{D}|\mathcal{G}} = \frac{e^{-NH(\mathcal{G}, \mathcal{D})}}{Z(\mathcal{G}, \mathcal{D})} = \frac{e^{N \sum_{\{x_i\}} p(\{x_i\}) \log(q(\{x_i\}))}}{Z(\mathcal{G}, \mathcal{D})} \quad (4)$$

where  $H(\mathcal{G}, \mathcal{D}) = -\sum_{\{x_i\}} p(\{x_i\}) \log(q(\{x_i\}))$  is the cross entropy between the ‘true’ probability distribution  $p(\{x_i\})$  of the data  $\mathcal{D}$  and the theoretical probability distribution  $q(\{x_i\})$  of the model  $\mathcal{G}$  and  $Z(\mathcal{G}, \mathcal{D})$  is a data- and model-dependent factor ensuring proper normalization condition. The structural constraints of the model  $\mathcal{G}$  can be included *a priori* in the factorization form of the theoretical probability distribution,  $q(\{x_i\})$ . In particular, if we assume a Bayesian network as underlying graphical model,  $q(\{x_i\})$  factorizes as  $q(\{x_i\}) = \prod_i p(x_i | \text{pa}_{x_i})$ , where  $\{\text{pa}_{x_i}\}$  denote the values of the parents of node  $X_i$ ,  $\{\text{Pa}_{X_i}\}$ , and leads to the following maximum likelihood expression,

$$\mathcal{L}_{\mathcal{D}|\mathcal{G}} = \frac{e^{-N \sum_i H(X_i | \{\text{Pa}_{X_i}\})}}{Z(\mathcal{G}, \mathcal{D})} \quad (5)$$

The model  $\mathcal{G}$  can then be compared to the alternative model  $\mathcal{G}_{\setminus X \rightarrow Y}$  with one additional missing edge  $X \rightarrow Y$  using the maximum likelihood ratio,

$$\frac{\mathcal{L}_{\mathcal{D}|\mathcal{G}_{\setminus X \rightarrow Y}}}{\mathcal{L}_{\mathcal{D}|\mathcal{G}}} = e^{-NI(X; Y | \{\text{Pa}_Y \setminus X\})} \frac{Z(\mathcal{G}, \mathcal{D})}{Z(\mathcal{G}_{\setminus X \rightarrow Y}, \mathcal{D})} \quad (6)$$

where  $I(X; Y | \{\text{Pa}_Y \setminus X\}) = H(Y | \{\text{Pa}_Y \setminus X\}) - H(Y | \{\text{Pa}_Y\})$ . However, Eq. 6 cannot be used as such to learn the underlying graphical model, as it assumes that the order between the nodes and their parents is already known (see however (de Campos, 2006)). Yet, following the rationale of constraint-based approaches, Eq. 6 can be reformulated by replacing the parent nodes with an unknown separation set  $\{U_i\}$  to be learnt simultaneously with the missing edge candidate  $XY$ ,

$$\frac{\mathcal{L}_{\mathcal{G}_{\setminus XY | \{U_i\}}}}{\mathcal{L}_{\mathcal{G}}} = e^{-NI(X; Y | \{U_i\}) + k_{X; Y | \{U_i\}}} \quad (7)$$

$$k_{X; Y | \{U_i\}} = \log \left( Z(\mathcal{G}, \mathcal{D}) / Z(\mathcal{G}_{\setminus XY | \{U_i\}}, \mathcal{D}) \right)$$

where the factor  $k_{X;Y|\{U_i\}} > 0$  tends to limit the complexity of the models by favoring fewer edges. Namely, the condition,  $I(X;Y|\{U_i\}) < k_{X;Y|\{U_i\}}/N$ , implies that simpler models compatible with the structural independency,  $X \perp\!\!\!\perp Y|\{U_i\}$ , are more likely than model  $\mathcal{G}$ , given the finite available dataset. This replaces the ‘perfect’ conditional independency condition,  $I(X;Y|\{U_i\}) = 0$ , valid in the limit of an infinite dataset,  $N \rightarrow \infty$ . A common complexity criteria in model selection is the Bayesian Information Criteria (BIC) or Minimal Description Length (MDL) criteria (Rissanen, 1978; Hansen and Yu, 2001),

$$k_{X;Y|\{U_i\}}^{\text{MDL}} = \frac{1}{2}(r_x - 1)(r_y - 1) \prod_i r_{u_i} \log N \quad (8)$$

where  $r_x, r_y$  and  $r_{u_i}$  are the number of levels of the corresponding variables. The MDL complexity, Eq. 8, is simply related to the normalisation constant reached in the asymptotic limit of a large dataset  $N \rightarrow \infty$  (Laplace approximation). However, this limit distribution is only reached for very large datasets in practice. Alternatively, the normalisation of the maximum likelihood can also be done over all possible datasets including the same number of data points to yield a (universal) Normalized Maximum Likelihood (NML) criteria (Shtarkov, 1987; Rissanen and Tabus, 2005) and its decomposable (Kontkanen and Myllymäki, 2007; Roos et al., 2008) and  $XY$ -symmetric version,  $k_{X;Y|\{U_i\}}^{\text{NML}}$ , defined in the Supplementary Methods.

Then, instead of exploring the combinatorics of sepset composition  $\{U_i\}$  for each missing edge candidate  $XY$  as in traditional constraint-based approaches, we propose that Eq. 7 can be used to iteratively extend a *likely* sepset using the maximum likelihood ratios between two successive sepset candidates, *i.e.* between the already ascertained  $\{U_i\}$  and the possible extended  $\{U_i\} + Z$ , as,

$$\frac{\mathcal{L}_{\mathcal{D}|\mathcal{G}_{\setminus XY|\{U_i\},Z}}}{\mathcal{L}_{\mathcal{D}|\mathcal{G}_{\setminus XY|\{U_i\}}}} = e^{NI(X;Y;Z|\{U_i\}) + k_{X;Y;Z|\{U_i\}}} \quad (9)$$

using Eq. 3 for  $I(X;Y;Z|\{U_i\})$  and introducing a similar 3-point complexity conditioned on  $\{U_i\}$  as,

$$k_{X;Y;Z|\{U_i\}} = k_{X;Y|\{U_i\},Z} - k_{X;Y|\{U_i\}} \quad (10)$$

where  $k_{X;Y;Z|\{U_i\}} \geq 0$ , unlike 3-point information,  $I(X;Y;Z|\{U_i\})$  which can be positive or negative.

Introducing also the shifted 2-point and 3-point information for finite datasets as,

$$\begin{aligned} I'(X;Y|\{U_i\}) &= I(X;Y|\{U_i\}) - \frac{k_{X;Y|\{U_i\}}}{N} \\ I'(X;Y;Z|\{U_i\}) &= I(X;Y;Z|\{U_i\}) + \frac{k_{X;Y;Z|\{U_i\}}}{N} \end{aligned}$$

leads to maximum likelihood ratios equivalent to Eq. 7 and

Eq. 9,

$$\frac{\mathcal{L}_{\mathcal{D}|\mathcal{G}_{\setminus XY|\{U_i\}}}}{\mathcal{L}_{\mathcal{D}|\mathcal{G}}} = e^{-NI'(X;Y|\{U_i\})} \quad (11)$$

$$\frac{\mathcal{L}_{\mathcal{D}|\mathcal{G}_{\setminus XY|\{U_i\},Z}}}{\mathcal{L}_{\mathcal{D}|\mathcal{G}_{\setminus XY|\{U_i\}}}} = e^{NI'(X;Y;Z|\{U_i\})} \quad (12)$$

As will become apparent in the following discussion, learning, iteratively, the most likely edge to be removed  $XY$  and its corresponding separation set  $\{U_i\}$  will imply to simultaneously minimize 2-point information (Eq. 11) while maximizing 3-point information (Eq. 12).

We start the discussion with 3-point information, Eq. 12. The sign and magnitude of shifted conditional 3-point information  $I'(X;Y;Z|\{U_i\})$  determine the probability that  $Z$  should be included in or excluded from the sepset candidate  $\{U_i\}$ ,

- If  $I'(X;Y;Z|\{U_i\}) > 0$ ,  $Z$  is more likely to be included in  $\{U_i\}$  with probability,

$$\begin{aligned} P_{\text{nv}}(X;Y;Z|\{U_i\}) &= \frac{\mathcal{L}_{\mathcal{D}|\mathcal{G}_{\setminus XY|\{U_i\},Z}}}{\mathcal{L}_{\mathcal{D}|\mathcal{G}_{\setminus XY|\{U_i\}}} + \mathcal{L}_{\mathcal{D}|\mathcal{G}_{\setminus XY|\{U_i\},Z}}} \\ &= \frac{1}{1 + e^{-NI'(X;Y;Z|\{U_i\})}} \quad (13) \end{aligned}$$

- If  $I'(X;Y;Z|\{U_i\}) < 0$ ,  $Z$  is more likely to be excluded from  $\{U_i\}$ , suggesting obligatory causal relationships in the form of a v-structure or collider between  $X, Y, Z$  with probability,

$$\begin{aligned} P_{\text{v}}(X;Y;Z|\{U_i\}) &= 1 - P_{\text{nv}}(X;Y;Z|\{U_i\}) \\ &= \frac{1}{1 + e^{NI'(X;Y;Z|\{U_i\})}} \quad (14) \end{aligned}$$

But, in the case  $I'(X;Y;Z|\{U_i\}) > 0$ , Eq. 12 can also be interpreted as quantifying the likelihood increase that the edge  $XY$  should be removed from the model by extending the candidate sepset from  $\{U_i\}$  to  $\{U_i\} + Z$ , *i.e.*  $\mathcal{L}_{\mathcal{D}|\mathcal{G}_{\setminus XY|\{U_i\},Z}} = \mathcal{L}_{\mathcal{D}|\mathcal{G}_{\setminus XY|\{U_i\}}} \times \exp(NI'(X;Y;Z|\{U_i\}))$ , with  $\exp(NI'(X;Y;Z|\{U_i\})) > 1$ . Yet, as the 3-point information,  $I'(X;Y;Z|\{U_i\})$ , is actually symmetric with respect to the variables,  $X, Y$  and  $Z$ , the factor  $\exp(NI'(X;Y;Z|\{U_i\})) > 1$  provides in fact the same likelihood increase for the removal of the three edges  $XY, XZ$  and  $ZY$ , conditioned on the same initial set of nodes  $\{U_i\}$ , namely,

$$\begin{aligned} \frac{\mathcal{L}_{\mathcal{D}|\mathcal{G}_{\setminus XY|\{U_i\},Z}}}{\mathcal{L}_{\mathcal{D}|\mathcal{G}_{\setminus XY|\{U_i\}}}} &= \frac{\mathcal{L}_{\mathcal{D}|\mathcal{G}_{\setminus XZ|\{U_i\},Y}}}{\mathcal{L}_{\mathcal{D}|\mathcal{G}_{\setminus XZ|\{U_i\}}}} = \frac{\mathcal{L}_{\mathcal{D}|\mathcal{G}_{\setminus ZY|\{U_i\},X}}}{\mathcal{L}_{\mathcal{D}|\mathcal{G}_{\setminus ZY|\{U_i\}}}} \\ &= e^{NI'(X;Y;Z|\{U_i\})} \end{aligned}$$

However, despite this symmetry of 3-point information,  $I'(X; Y; Z|\{U_i\})$ , the likelihoods that the edges  $XY$ ,  $XZ$  and  $ZY$  should be removed are not the same, as they depend on different 2-point information,  $I'(X; Y|\{U_i\})$ ,  $I'(X; Z|\{U_i\})$  and  $I'(Z; Y|\{U_i\})$ , Eq. 11. In particular, the likelihood ratio between the removals of the alternative edges  $XY$  and  $XZ$  is given by,

$$\frac{\mathcal{L}_{\mathcal{D}|G_{\setminus XY|\{U_i\}, Z}}}{\mathcal{L}_{\mathcal{D}|G_{\setminus XZ|\{U_i\}, Y}}} = \frac{\mathcal{L}_{\mathcal{D}|G_{\setminus XY|\{U_i\}}}}{\mathcal{L}_{\mathcal{D}|G_{\setminus XZ|\{U_i\}}}} = \frac{e^{-NI'(X; Y|\{U_i\})}}{e^{-NI'(X; Z|\{U_i\})}} \quad (15)$$

and similarly between edges  $XY$  and  $ZY$ .

Hence, for  $XY$  to be the most likely edge to be removed conditioned on the sepset  $\{U_i\} + Z$ , not only  $Z$  should contribute through  $I'(X; Y; Z|\{U_i\}) > 0$  with probability  $P_{nv}(X; Y; Z|\{U_i\})$  (Eq. 13), but  $XY$  must also correspond to the ‘weakest’ edge of  $XY$ ,  $XZ$  and  $ZY$  conditioned on  $\{U_i\}$ , as given by the lowest conditioned 2-point information, Eq. 15. Note that removing the edge  $XY$  with the lowest conditional 2-point information is consistent, as expected, with the Data Processing Inequality,  $I(X; Y|\{U_i\}) \leq \min(I(X; Z|\{U_i\}), I(Z; Y|\{U_i\}))$ , in the limit of large datasets. However, quite frequently,  $XZ$  or  $ZY$  might also have low conditional 2-point information, so that the edge removal associated with the symmetric contribution  $I(X; Y; Z|\{U_i\})$  will only be consistent with the Data Processing Inequality (DPI) with probability,

$$\begin{aligned} P_{dpi}(XY; Z|\{U_i\}) &= \\ &= \frac{\mathcal{L}_{\mathcal{D}|G_{\setminus XY|\{U_i\}}}}{\mathcal{L}_{\mathcal{D}|G_{\setminus XY|\{U_i\}}} + \mathcal{L}_{\mathcal{D}|G_{\setminus XZ|\{U_i\}}} + \mathcal{L}_{\mathcal{D}|G_{\setminus ZY|\{U_i\}}}} \\ &= \frac{1}{1 + \frac{e^{-NI'(X; Z|\{U_i\})}}{e^{-NI'(X; Y|\{U_i\})}} + \frac{e^{-NI'(Z; Y|\{U_i\})}}{e^{-NI'(X; Y|\{U_i\})}}} \quad (16) \end{aligned}$$

In practice, taking into account this DPI-consistency probability  $P_{dpi}(XY; Z|\{U_i\})$ , as detailed below, significantly improves the results obtained by relying solely on the ‘non-structure’ probability  $P_{nv}(X; Y; Z|\{U_i\})$ . Conversely, the DPI-consistency probability  $P_{dpi}(XY; Z|\{U_i\})$  is not sufficient on its own to uncover causal relationships between variables, which require to compute 3-point information  $I(X; Y; Z|\{U_i\})$  and the probability  $P_{nv}(X; Y; Z|\{U_i\})$  (see Proposition 7 and Proposition 8, below).

To optimize the likelihood that the edge  $XY$  can be accounted for by the additional contribution of  $Z$  conditioned on previously selected  $\{U_i\}$ , we propose to combine the maximum of 3-point information (Eq. 13) and the minimum of 2-point information (Eq. 16) by defining the score  $S_{lb}(Z; XY|\{U_i\})$  as the lower bound of  $P_{nv}(X; Y; Z|\{U_i\})$  and  $P_{dpi}(XY; Z|\{U_i\})$ , since both conditions need to be fulfilled to warrant that edge  $XY$  is likely to be absent from

the model  $\mathcal{G}$ ,

$$\begin{aligned} S_{lb}(Z; XY|\{U_i\}) &= \\ &= \min \left[ P_{nv}(X; Y; Z|\{U_i\}), P_{dpi}(XY; Z|\{U_i\}) \right] \end{aligned}$$

Hence, the pair of nodes  $XY$  with the most likely contribution from a third node  $Z$  and likely to be absent from the model can be ordered according to their rank  $R(XY; Z|\{U_i\})$  defined as,

$$R(XY; Z|\{U_i\}) = \max_Z (S_{lb}(Z; XY|\{U_i\})) \quad (17)$$

Then,  $Z$  can be iteratively added to the set of contributing nodes (*i.e.*  $\{U_i\} \leftarrow \{U_i\} + Z$ ) of the top edge  $XY = \operatorname{argmax}_{XY} R(XY; Z|\{U_i\})$  to progressively recover the most significant indirect contributions to all pairwise mutual information in a causal graph.

Implementing this local optimization scheme, the 3off2 algorithm eventually learns the network skeleton by collecting the nodes of the separation sets one-by-one, instead of exploring the full combinatorics of sepset composition without any likelihood guidance. Indeed, the 3off2 scheme amounts to identify  $\{U_i\}$  by ‘‘taking off’’ iteratively the ‘‘most likely’’ conditional 3-point information from each 2-point information as,

$$\begin{aligned} I(X; Y|\{U_i\}_n) &= I(X; Y) - I(X; Y; U_1) \\ &\quad - I(X; Y; U_2|U_1) - \dots \\ &\quad - I(X; Y; U_n|\{U_i\}_{n-1}) \end{aligned}$$

or equivalently between the shifted 2-point and 3-point information terms,

$$\begin{aligned} I'(X; Y|\{U_i\}_n) &= I'(X; Y) - I'(X; Y; U_1) \\ &\quad - I'(X; Y; U_2|U_1) - \dots \\ &\quad - I'(X; Y; U_n|\{U_i\}_{n-1}) \end{aligned}$$

This leads to the following Algorithm 1 for the reconstruction of the graph skeleton using the 3off2 scheme. Note, in particular, that the 3off2 scheme to reconstruct graph skeleton is solely based on identifying structural independencies, which can also be applied to graphical models for undirected Markov networks.

Then, given the skeleton obtained from Algorithm 1, Eqs. 13 and 14 lead to the following Proposition 7 and Proposition 8 for the orientation and propagation rules of unshielded triples, which are equivalent to Proposition 5 and Proposition 6 but for underlying DAG models (assuming no latent variables) and for finite datasets with the corresponding probabilities for the initiation/propagation of orientations.

**Proposition 7 (Significantly negative conditional 3-point information as robust statistical evidence of causality in finite datasets).**

Assuming that the underlying graphical model is a DAG  $\mathcal{G}$  on  $V$ ,  $\forall X, Y, Z \in V$  and  $\forall \{U_i\} \subseteq V \setminus \{X, Y, Z\}$  s.t.  $I'(X; Y|\{U_i\}) < 0$  (i.e. no  $XY$  edge) and  $I'(X; Y; Z|\{U_i\}) < 0$  then,

- i. if  $X, Y, Z$  form an unshielded triple,  $X \circ\text{-}\circ Z \circ\text{-}\circ Y$ , then it should be oriented as  $X \rightarrow Z \leftarrow Y$ , with probabilities,

$$P_{X \rightarrow Z}^\circ = P_{Y \rightarrow Z}^\circ = \frac{1 + e^{NI'(X; Y; Z|\{U_i\})}}{1 + 3e^{NI'(X; Y; Z|\{U_i\})}}$$

- ii. similarly, if  $X, Y, Z$  form an unshielded triple,

with one already known converging arrow,  $X \rightarrow Z \circ\text{-}\circ Y$ , with probability  $P_{X \rightarrow Z} > P_{X \rightarrow Z}^\circ$ , then the second edge should be oriented to form a  $v$ -structure,  $X \rightarrow Z \leftarrow Y$ , with probability,

$$P_{Y \rightarrow Z} = P_{X \rightarrow Z} \left( \frac{1}{1 + e^{NI'(X; Y; Z|\{U_i\})}} - \frac{1}{2} \right) + \frac{1}{2}$$

**Proof.** The implications (i.) and (ii.) rely on Eq. 14 to estimate the probability that the two edges form a collider. We start proving (ii.) using the probability decomposition formula:

$$\begin{aligned} P_{Y \rightarrow Z} &= P_{X \rightarrow Z} \frac{P_{X \rightarrow Z \leftarrow Y}}{P_{X \rightarrow Z \leftarrow Y} + P_{X \rightarrow Z \rightarrow Y}} \\ &\quad + (1 - P_{X \rightarrow Z}) \frac{P_{X \leftarrow Z \leftarrow Y}}{P_{X \leftarrow Z \leftarrow Y} + P_{X \leftarrow Z \rightarrow Y}} \\ &= P_{X \rightarrow Z} \left( \frac{1}{1 + e^{NI'(X; Y; Z|\{U_i\})}} - \frac{1}{2} \right) + \frac{1}{2} \end{aligned}$$

which also leads to (i.) if one assumes  $P_{X \rightarrow Z} = P_{Y \rightarrow Z}$  by symmetry in absence of prior information on these orientations.  $\square$

Following the rationale of constraint-based approaches, it is then possible to ‘propagate’ further the orientations downstream of colliders, using Eq. 13 for positive (conditional) 3-point information. For simplicity and consistency, we only implement the propagation of orientation based on likelihood ratios, which can be quantified for finite datasets as proposed in the following Proposition 8. In particular, we do not extend the propagation rules (Meek, 1995) to enforce acyclic constraints that are necessary to have a complete reconstruction of the Markov equivalent class of the underlying DAG model.

**Proposition 8 (robust ‘propagation’ of causality at unshielded triples with significantly positive conditional 3-pt information).**

Assuming that the underlying graphical model is a DAG  $\mathcal{G}$  on  $V$ ,  $\forall X, Y, Z \in V$  and  $\forall \{U_i\} \subseteq V \setminus \{X, Y, Z\}$  s.t.  $I'(X; Y|\{U_i\}, Z) < 0$  (i.e. no  $XY$  edge) and  $I'(X; Y; Z|\{U_i\}) > 0$ , then if  $X, Y, Z$  form an unshielded triple with one already known converging orientation,  $X \rightarrow Z \circ\text{-}\ast Y$ , with probability  $P_{X \rightarrow Z} > 1/2$ , this orientation should be ‘propagated’ to the second edge as  $X \rightarrow Z \rightarrow Y$ , with probability,

$$P_{Z \rightarrow Y} = P_{X \rightarrow Z} \left( \frac{1}{1 + e^{-NI'(X; Y; Z|\{U_i\})}} - \frac{1}{2} \right) + \frac{1}{2}$$

**Proof.** This results is shown using the probability decom-

position formula,

$$\begin{aligned}
P_{Z \rightarrow Y} &= P_{X \rightarrow Z} \frac{P_{X \rightarrow Z \rightarrow Y}}{P_{X \rightarrow Z \leftarrow Y} + P_{X \rightarrow Z \rightarrow Y}} \\
&\quad + (1 - P_{X \rightarrow Z}) \frac{P_{X \leftarrow Z \rightarrow Y}}{P_{X \leftarrow Z \leftarrow Y} + P_{X \leftarrow Z \rightarrow Y}} \\
&= P_{X \rightarrow Z} \left( \frac{1}{1 + e^{-NI'(X;Y;Z|\{U_i\})}} - \frac{1}{2} \right) + \frac{1}{2}
\end{aligned}$$

□

Proposition 7 and Proposition 8 lead to the following Algorithm 2 for the orientation of unshielded triples of the graph skeleton obtained from Algorithm 1.

---

**Algorithm 2:** 3off2 Orientation / Propagation Step

---

**In:** Graph skeleton from Algorithm 1 and corresponding conditional 3-point information  $I'(X; Y; Z|\{U_i\})$ .

**Out:** Partially oriented causal graph  $\mathcal{G}$  with edge orientation probabilities.

**3off2 Orientation / Propagation Step**

**sort** list of unshielded triples,  $\mathcal{L}_c = \{\langle X, Z, Y \rangle_{X \neq Y}\}$ , in decreasing order of their orientation/propagation probability initialized at 1/2 and computed from:

- (i.) Proposition 7, if  $I'(X; Y; Z|\{U_i\}) < 0$ , or
- (ii.) Proposition 8, if  $I'(X; Y; Z|\{U_i\}) > 0$

**repeat**

Take  $\langle X, Z, Y \rangle_{X \neq Y} \in \mathcal{L}_c$  with highest orientation / propagation probability  $> 1/2$ .

**if**  $I'(X; Y; Z|\{U_i\}) < 0$  **then**

**Orient**/propagate edge direction(s) to form a **v-structure**  $X \rightarrow Z \leftarrow Y$  with probabilities  $P_{X \rightarrow Z}$  and  $P_{Y \rightarrow Z}$  given by **Proposition 7**.

**else**

**Propagate** second edge direction to form a **non-v-structure**  $X \rightarrow Z \rightarrow Y$  assigning probability  $P_{Z \rightarrow Y}$  from **Proposition 8**.

**end**

Apply new orientation(s) and **sort** remaining list of unshielded triples  $\mathcal{L}_c \leftarrow \mathcal{L}_c \setminus \langle X, Z, Y \rangle_{X \neq Y}$  after **updating propagation probabilities**.

**until** no additional orient./propa. probability  $> 1/2$  ;

## 2.3 APPLICATIONS TO CAUSAL GRAPH BENCHMARKS

We have tested the 3off2 method on a range of benchmark networks of 50 nodes with up to 160 edges generated with the causal modeling tool Tetrad IV (<http://www.phil.cmu.edu/tetrad>). The average connectivity  $\langle k \rangle$  of these benchmark networks ranges between 1.6 to 6.4, and the average maximal in/out-degree between 3.2 to 8.8 (see Table S1 for a detailed description). The evaluation metrics are the Precision,  $Prec = TP/(TP + FP)$ , the Recall,  $Rec = TP/(TP + FN)$  and the  $F$ -score  $= 2Prec.Rec/(Prec + Rec)$ . However, in order to take into account the orientation/non-orientation of edges in the predicted networks and compare them with the CPDAG of the benchmark graphs, we define orientation-dependent counts as,  $TP' = TP - TP_{\text{misorient}}$  and  $FP' = FP + TP_{\text{misorient}}$ , where  $TP_{\text{misorient}}$  corresponds to all true positive edges of the skeleton with different orientation/non-orientation status as in the CPDAG reference.

The first methods used for comparison with 3off2 are the PC-stable algorithm (Colombo and Maathuis, 2014) with conservative (Ramsey, Spirtes, and Zhang, 2006) or majority orientation rules, implemented in the `pcalg` package (Kalisch et al., 2012; Kalisch and Bühlmann, 2008) and the hybrid method MMHC combining constraint-based skeleton and Bayesian orientation (Tsamardinos, Brown, and Aliferis, 2006), implemented in the `bnlearn` package (Scutari, 2010). Figs. 1-5 give the average CPDAG comparison results over 100 dataset replicates from 5 different benchmark networks (Table S1). The causal graphical models predicted by the 3off2 method are obtained using either the MDL/BIC or the NML complexities (see Supplementary Methods). Figs. S1-S6 provide additional results on the prediction of the network skeletons and execution times. The PC and MMHC results are shown, Figs. 1-5, for an independence test parameter  $\alpha = 0.1$ , as reducing  $\alpha$  tends to worsen the CPDAG F-score for benchmark networks with  $\langle k \rangle \geq 2.4$  (Figs. S7-S18). All in all, we found that 3off2 outperforms PC-stable on all tested datasets, Figs. 1-5, and to a lesser extent, MMHC especially on less sparse networks,  $\langle k \rangle \geq 2.4$ , Figs. 2-5.

Additional comparisons were obtained with Bayesian inference implemented in the `bnlearn` package (Scutari, 2010), using AIC, BDe and BIC/MDL scores and hill-climbing heuristics with 30 to 100 random restarts, Figs. S19-S30. 3off2 reaches equivalent or significantly better F-scores than Bayesian hill-climbing on relatively sparse benchmark networks,  $\langle k \rangle \leq 4.8$  (Figs. S19 & S23). In particular, 3off2 with MDL scores reaches one of the best F-scores on sparse networks (Figs. S19 & S20) and eventually better F-scores on large datasets for less sparse networks when combined to NML complexity (Figs. S21 & S22). For somewhat denser networks

( $\langle k \rangle \simeq 5$ ), the 3off2 F-score appears slightly lower than for Bayesian inference methods, Fig. S23, although it eventually becomes equivalent for large datasets ( $N \geq 1000$ ).

On denser networks ( $\langle k \rangle \geq 5 - 6$ ), Bayesian inference exhibits better F-scores than 3off2, in particular with AIC score, Fig. S24. However, the good performance with AIC strongly relies on its high Recall (but low Precision), due to its very small penalty term on large datasets, which makes it favor more complex networks (Figs. S24) but perform very poorly on sparse graphs (Figs. S19-S21). By contrast, the reconstruction of dense networks is impeded with the 3off2 scheme, as it is not always possible to uncover structural independencies,  $I(X; Y | \{U_{ij}\}_n) \simeq 0$ , in dense graphs through an ordered set  $\{U_{ij}\}_n$  with only positive conditional 3-point information,  $I'(X; Y; U_k | \{U_{ij}\}_{k-1}) > 0$ . Indeed in complex graphs, there are typically many indirect paths  $X \rightarrow U_j \rightarrow Y$  between unconnected node pairs  $(X, Y)$ . At the beginning of the pruning process, this is prone to suggest likely v-structures  $X \rightarrow Y \leftarrow U_j$ , instead of the correct non-v-structures,  $X \rightarrow U_j \rightarrow Y$  (for instance if  $I(X; U_j) \ll I(X; Y)$ ,  $I(X; U_j) \ll I(U_j; Y)$  and  $I(X; U_j) - I(X; U_j | Y) = I(X; Y; U_j) < 0$ , for all  $j$ ). Such elimination of *FN* edge  $X \rightarrow U_j$  and conservation of *FP*  $X \rightarrow Y$  tend to decrease both Precision and Recall, although 3off2 remains significantly more robust than PC and MMHC, Fig. 5. Besides, for most practical applications on real life data, interpretable causal models should remain relatively sparse and avoid to display multiple indirect paths between unconnected nodes.

Finally, 3off2 running times on these benchmark networks are similar to MMHC and Bayesian hill-climbing heuristic methods (with 100 restarts) and 10 to 100 times faster than PC for large datasets, Figs. S1-S30.

### 3 DISCUSSION

In this paper, we propose to combine constraint-based and score-based frameworks to improve network reconstruction. Earlier hybrid methods, including MMHC, have also attempted to exploit the best of these two types of inference approaches by combining the robustness of Bayesian scores with the attractive conceptual features of constraint-based approaches (Dash and Druzdzel, 1999; Tsamardinos, Brown, and Aliferis, 2006; Cano, Gomez-Olmedo, and Moral, 2008; Claassen and Heskes, 2012). In particular, (Dash and Druzdzel, 1999) have proposed to exploit an intrinsic weakness of the PC algorithm, its sensitivity to the order in which conditional independencies are tested on finite data, to rank these different order-dependent PC predictions with Bayesian scores. More recently, (Claassen and Heskes, 2012) have also combined constraint-based and Bayesian approaches to improve the reliability of causal inference. They proposed to use Bayesian scores to directly assess the reliability of conditional independen-

Figure 1: CPDAG comparison between 3off2, PC-stable and MMHC. 50 node, 40 edge benchmark networks generated using Tetrad.  $\langle k \rangle = 1.6$ ,  $\langle k_{\max}^{in} \rangle = 3.2$ ,  $\langle k_{\max}^{out} \rangle = 3.6$ . PC-stable benchmarks were tested up to  $N=10,000$  due to their sharp increase in execution time, see Figs. S7-S12.

Figure 2: CPDAG comparison between 3off2, PC-stable and MMHC. 50 node, 60 edge benchmark networks generated using Tetrad.  $\langle k \rangle = 2.4$ ,  $\langle k_{\max}^{in} \rangle = 4.6$ ,  $\langle k_{\max}^{out} \rangle = 3.6$ . PC-stable benchmarks were tested up to  $N=10,000$  due to their sharp increase in execution time, see Figs. S7-S12.

Figure 3: CPDAG comparison between 3off2, PC-stable and MMHC. 50 node, 80 edge benchmark networks generated using Tetrads.  $\langle k \rangle = 3.2$ ,  $\langle k_{\max}^{\text{in}} \rangle = 4.8$ ,  $\langle k_{\max}^{\text{out}} \rangle = 5.6$ . PC-stable benchmarks were tested up to  $N=10,000$  due to their sharp increase in execution time, see Figs. S7-S12.

Figure 4: CPDAG comparison between 3off2, PC-stable and MMHC. 50 node, 120 edge benchmark networks generated using Tetrads.  $\langle k \rangle = 4.8$ ,  $\langle k_{\max}^{\text{in}} \rangle = 8.8$ ,  $\langle k_{\max}^{\text{out}} \rangle = 7.2$ . PC-stable benchmarks were tested up to  $N=10,000$  due to their sharp increase in execution time, see Figs. S7-S12.

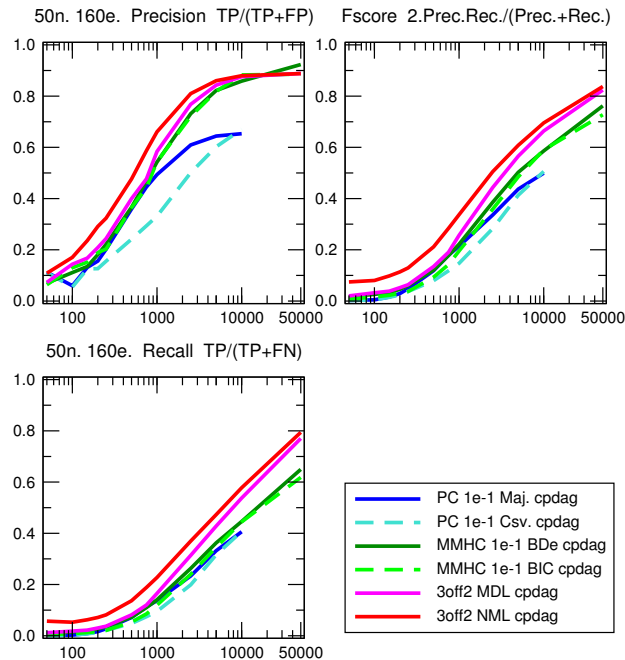

Figure 5: CPDAG comparison between 3off2, PC-stable and MMHC. 50 node, 160 edge benchmark networks generated using Tetrads.  $\langle k \rangle = 6.4$ ,  $\langle k_{\max}^{\text{in}} \rangle = 8.6$ ,  $\langle k_{\max}^{\text{out}} \rangle = 8.6$ . PC-stable benchmarks were tested up to  $N=10,000$  due to their sharp increase in execution time, see Figs. S7-S12.

cies by *summing* the likelihoods over compatible graphs. By contrast, we propose to use Bayesian scores to progressively uncover the best supported conditional independencies, by iteratively “taking off” the most likely indirect contributions of conditional 3-point information from every 2-point (mutual) information of the causal graph. In addition, using likelihood ratios (Eqs. 11 & 12) instead of likelihood sums (Claassen and Heskes, 2012) circumvents the need to score conditional independencies over a potentially intractable number of compatible graphs.

All in all, we found that 3off2 outperforms constraint-based, search-and-score and earlier hybrid methods on a range of benchmark networks, while displaying similar running times as hill-climbing heuristic methods.

## Abstract

The key for effective interaction in many multi-agent applications is to reason explicitly about the behaviour of other agents, in the form of a *hypothesised* behaviour. While there exist several methods for the construction of a behavioural hypothesis, there is currently no universal theory which would allow an agent to contemplate the correctness of a hypothesis. In this work, we present a novel algorithm which decides this question in the form of a frequentist hypothesis test. The algorithm allows for multiple metrics in the construction of the test statistic and learns its distribution during the interaction process, with asymptotic correctness guarantees. We present results from a comprehensive set of experiments, demonstrating that the algorithm achieves high accuracy and scalability at low computational costs.

## 1 INTRODUCTION

A common difficulty in many multiagent systems is the fact that the behaviour of other agents may be initially unknown. Important examples include adaptive user interfaces, robotic elderly assistance, and electronic markets. Often, the key for effective interaction in such systems is to reason explicitly about the behaviour of other agents, typically in the form of a *hypothesised* behaviour which makes predictions about future actions based on a given interaction history.

A number of methods have been studied for the construction of behavioural hypotheses. One method is to use opponent modelling techniques to learn a behaviour from the interaction history. Two well-known examples include fictitious play (Brown, 1951) and case-based reasoning (Gilboa and Schmeidler, 2001), as well as their many variants. Another method is to maintain a set of possible action policies, called types, over which a posterior belief is computed based on the interaction history (Albrecht and Ramamoorthy, 2014; Gmytrasiewicz and Doshi, 2005). The hypothesis is then

obtained by using the posterior to mix the types. Related methods have been studied in the plan recognition literature (Carberry, 2001; Charniak and Goldman, 1993).

The learned behaviours (or models) of these methods can be viewed as hypotheses because they are eventually either true or false (subject to the various assumptions they are based on), and because they are *testable*. Thus, the following is a natural question: given an interaction history  $H$  and a hypothesis  $\pi^*$  for the behaviour of an agent, does the agent indeed behave according to  $\pi^*$ ? There are several ways in which an answer to this question could be utilised. For instance, if we persistently reject the hypothesis  $\pi^*$ , we may construct an alternative hypothesis or resort to some default plan of action (such as a “maximin” strategy).

Unfortunately, the above methods for hypothesis construction do not provide an answer to this question. Some opponent modelling methods use goodness-of-fit measures (e.g. those that rely on maximum likelihood estimation), but these measures describe how well the model fits the data (i.e. interaction history) and not necessarily if the model is correct. Similarly, the posterior belief in the type-based approach quantifies the relative likelihood of types (relative to a set of alternative types) but not the *correctness* of types.

To illustrate the source of difficulty, consider the below excerpt of an interaction process between two agents which can choose from three actions. The columns show, respectively, the current time  $t$  of the interaction, the actions chosen by the agents at time  $t$ , and agent 1’s hypothesised probabilities with which agent 2 would choose its actions at time  $t$ , based on the prior interaction history.

| $t$ | $(a_1^t, a_2^t)$ | $\pi_2^*$    |
|-----|------------------|--------------|
| 1   | (1, 2)           | (.3, .1, .6) |
| 2   | (3, 1)           | (.2, .3, .5) |
| 3   | (2, 3)           | (.7, .1, .2) |
| 4   | (2, 3)           | (.0, .4, .6) |
| 5   | (1, 2)           | (.4, .2, .4) |

Assuming that the process continues in this fashion, and without any restrictions on the behaviour of agent 2, how

should agent 1 decide whether or not to reject its hypothesis about the behaviour of agent 2?

A natural way to address this question is to compute some kind of *score* from the information given in the above table, and to compare this score with some manually chosen rejecting threshold. A prominent example of such a score is the empirical frequency distribution (Conitzer and Sandholm, 2007; Foster and Young, 2003). While the simplicity of this method is appealing, there are two significant problems: (1) it is far from trivial to devise a scoring scheme that reliably quantifies “correctness” of hypotheses (for instance, an empirical frequency distribution taken over all past actions would be insufficient in the above example since the hypothesised action distributions are changing), and (2) it is unclear how one should choose the threshold parameter for any given scoring scheme.

In this work, we present an efficient algorithm which decides this question in the form of a frequentist hypothesis test. The algorithm addresses (1) by allowing for multiple scoring criteria in the construction of the test statistic, with the intent of obtaining an overall more reliable scoring scheme. The distribution of the test statistic is then learned during the interaction process, and we show that the learning is asymptotically correct. Finally, analogous to standard frequentist testing, the hypothesis is rejected at a given point in time if the resulting  $p$ -value is below some “significance level”. This eliminates (2) by providing a uniform semantic for rejection that is invariant to the employed scoring scheme. We present a comprehensive set of experiments, demonstrating that our algorithm achieves high accuracy and scalability at low computational costs.

Of course, there is a long-standing debate on the role of statistical hypothesis tests and quantities such as  $p$ -values (e.g. Gelman and Shalizi, 2013; Berger and Sellke, 1987; Cox, 1977). The usual consensus is that  $p$ -values should be combined with other forms of evidence to reach a final conclusion (Fisher, 1935), and this is the view we adopt as well. In this sense, our method may be used as part of a larger machinery to decide the truth of a hypothesis.

## 2 RELATED WORK

In addition to the related works mentioned in the previous section, there are a number of other related research areas:

There exists a large body of literature on what is often referred to as *model criticism* (e.g. Bayarri and Berger, 2000; Meng, 1994; Rubin, 1984; Box, 1980). Model criticism attempts to answer the following question: given a data set  $D$  and model  $M$ , could  $D$  have been generated by  $M$ ? This is analogous to our question, in which  $D$  is a sequence of observed actions of some agent and  $M$  is a hypothesised behaviour for that agent. However, in contrast to our work, model criticism usually assumes that the data are indepen-

dent and identically distributed, which is not the case in the interactive settings we consider.

A related problem, sometimes referred to as *identity testing*, is to test if a given sequence of data was generated by some given stochastic process (Ryabko and Ryabko, 2008; Basawa and Scott, 1977). Instead of independent and identical distributions, this line of work assumes other properties such as stationarity and ergodicity. Unfortunately, these assumptions are also unlikely in interaction processes, and the proposed solutions are very costly.

Model criticism and identity testing are not to be confused with *model selection*, in which two or more alternative models are under consideration (e.g. Vehtari and Ojanen, 2012). Similarly, we do not consider alternative hypotheses. However, our method can be applied individually to multiple hypotheses, or the hypotheses may be fused into a single hypothesis using a posterior belief (Albrecht and Ramamoorthy, 2014; Gmytrasiewicz and Doshi, 2005).

Another related problem is that of *model checking*, which attempts to verify that a given system (or model) satisfies certain formal properties (Clarke et al., 1999). Recently, Albrecht and Ramamoorthy (2014) applied the concept of probabilistic bisimulation (Larsen and Skou, 1991) to the question of “incorrect” hypotheses and showed that a certain form of optimality is preserved if a bisimulation relation exists. However, their work is not concerned with establishing whether or not a given behavioural hypothesis is correct, and their analysis is performed *before* any interaction.

Our method can be viewed as *passive* in the sense that it does not actively probe different aspects of the hypothesis, and we show in Section 5 that this can be a drawback. This is in contrast to methods such as (Carmel and Markovitch, 1999), which promote active exploration. However, this exploration comes at high computational costs and limits the structure of hypotheses, such as deterministic finite state machines. On the other hand, our method has low computational costs and leaves the structure of the hypothesis open.

## 3 PRELIMINARIES

We consider a sequential interaction process with  $m$  agents. The process begins at time  $t = 0$ . At each time  $t$ , each agent  $i \in \{1, \dots, m\}$  receives a signal  $s_i^t$  and chooses an action  $a_i^t$  from a finite set of actions  $A_i$ . (Agents choose actions simultaneously.) The process continues in this fashion indefinitely or until some termination criterion is satisfied.

The signal  $s_i^t$  specifies information that agent  $i$  receives at time  $t$  and may in general be the result of a random variable over past actions and signals. For example,  $s_i^t$  may be a discrete system state and its dynamics may be described by some stochastic transition function. Note that we allow for asymmetric information (i.e.  $s_i^t \neq s_j^t$ ). For example,  $s_i^t$  may include a private payoff for agent  $i$ . In this work, we leave

the precise structure and dynamics of  $s_i^t$  open.

We assume that each agent  $i$  can choose actions  $a_i^t$  based on the entire interaction history  $H_i^t = (s_i^0, a^0, s_i^1, a^1, \dots, s_i^t)$ , where  $a^\tau = (a_1^\tau, \dots, a_m^\tau)$  is the tuple of actions taken by the agents at time  $\tau$ . Formally, each agent  $i$  has a *behaviour*  $\pi_i$  which assigns a probability distribution over actions  $A_i$  given a history  $H_i^t$ , denoted  $\pi_i(H_i^t)$ . We use  $\Pi_i$  to denote the infinite and uncountable space of all such behaviours. Note that a behaviour may implement any kind of logic, and it is useful to think of it as a black-box programme.

Given two agents  $i$  and  $j$ , we use  $\Pi_j^i$  to denote  $i$ 's *hypothesis space* for  $j$ 's behaviours. The difference between  $\Pi_j^i$  and  $\Pi_j$  is that  $\pi_j^* \in \Pi_j^i$  are defined over  $H_i^t$  while  $\pi_j \in \Pi_j$  are defined over  $H_j^t$ . Since we allow for asymmetric information, any information that is contained in  $s_j^t$  but not in  $s_i^t$ , denoted  $s_{j-i}^t$ , becomes part of the hypothesis space  $\Pi_j^i$ . For example, if  $s_{j-i}^t$  contains a private payoff for  $j$ ,  $i$  can hypothesise a payoff as part of its hypothesis for  $j$ 's behaviour.

Defining a behavioural hypothesis  $\pi_j^* \in \Pi_j^i$  as a function  $\pi_j^*(H_i^t)$  has two implicit assumptions: firstly, it assumes knowledge of  $A_j$ , and secondly, it assumes that the information in  $s_{j-i}^t$  is a (deterministic) function of  $H_i^t$ . If, on the other hand, we allowed  $s_{j-i}^t$  to be stochastic (i.e. a random variable over the interaction history), we would in addition have to hypothesise the random outcome of  $s_{j-i}^t$ . In other words,  $\pi_j^*(H_i^t)$  would itself be a random variable, which is outside the scope of this work.

## 4 A METHOD FOR BEHAVIOURAL HYPOTHESIS TESTING

Let  $i$  denote our agent and let  $j$  denote another agent. Moreover, let  $\pi_j^* \in \Pi_j^i$  denote our hypothesis for  $j$ 's behaviour and let  $\pi_j \in \Pi_j$  denote  $j$ 's true behaviour. The central question we ask is if  $\pi_j^* = \pi_j$ ?

Unfortunately, since we do not know  $\pi_j$ , we cannot directly answer this question. However, at each time  $t$ , we know  $j$ 's past actions  $\mathbf{a}_j^t = (a_j^0, \dots, a_j^{t-1})$  which were generated by  $\pi_j$ . If we use  $\pi_j^*$  to generate a vector  $\hat{\mathbf{a}}_j^t = (\hat{a}_j^0, \dots, \hat{a}_j^{t-1})$ , where  $\hat{a}_j^\tau$  is sampled using  $\pi_j^*(H_i^\tau)$ , we can formulate the related two-sample problem of whether  $\mathbf{a}_j^t$  and  $\hat{\mathbf{a}}_j^t$  were generated from the same behaviour, namely  $\pi_j^*$ .

In this section, we propose a general and efficient algorithm to decide this problem. At its core, the algorithm computes a frequentist  $p$ -value

$$p = P\left(|T(\hat{\mathbf{a}}_j^t, \hat{\mathbf{a}}_j^t)| \geq |T(\mathbf{a}_j^t, \hat{\mathbf{a}}_j^t)|\right) \quad (1)$$

where  $\hat{\mathbf{a}}_j^t \sim \delta^t(\pi_j^*) = (\pi_j^*(H_i^0), \dots, \pi_j^*(H_i^{t-1}))$ . The value of  $p$  corresponds to the probability with which we expect to observe a test statistic at least as extreme as  $T(\mathbf{a}_j^t, \hat{\mathbf{a}}_j^t)$ , under the null-hypothesis  $\pi_j^* = \pi_j$ . Thus, we reject  $\pi_j^*$  if  $p$  is below some ‘‘significance level’’  $\alpha$ .

---

### Algorithm 1

---

- 1: **Input:** history  $H_i^t$  (including observed action  $a_j^{t-1}$ )
  - 2: **Output:**  $p$ -value (reject  $\pi_j^*$  if  $p$  below some threshold  $\alpha$ )
  - 3: **Parameters:** hypothesis  $\pi_j^*$ ; score functions  $z_1, \dots, z_K$ ;  $N > 0$
  - 4: // Expand action vectors
  - 5: Set  $\mathbf{a}_j^t \leftarrow \langle \mathbf{a}_j^{t-1}, a_j^{t-1} \rangle$
  - 6: Sample  $\hat{a}_j^{t-1} \sim \pi_j^*(H_i^{t-1})$ ; set  $\hat{\mathbf{a}}_j^t \leftarrow \langle \hat{\mathbf{a}}_j^{t-1}, \hat{a}_j^{t-1} \rangle$
  - 7: **for**  $n = 1, \dots, N$  **do**
  - 8:   Sample  $\tilde{a}_j^{t-1} \sim \pi_j^*(H_i^{t-1})$ ; set  $\tilde{\mathbf{a}}_j^{t,n} \leftarrow \langle \tilde{\mathbf{a}}_j^{t-1,n}, \tilde{a}_j^{t-1} \rangle$
  - 9: // Fit skew-normal distribution  $f$
  - 10: **if** update parameters? **then**
  - 11:   Compute  $D \leftarrow \{T(\tilde{\mathbf{a}}_j^{t,n}, \hat{\mathbf{a}}_j^t) \mid n = 1, \dots, N\}$
  - 12:   Fit  $\xi, \omega, \beta$  to  $D$ , e.g. using (12)
  - 13:   Find mode  $\mu$  from  $\xi, \omega, \beta$
  - 14: // Compute  $p$ -value
  - 15:   Compute  $q \leftarrow T(\mathbf{a}_j^t, \hat{\mathbf{a}}_j^t)$  using (2)/(5)
  - 16: **return**  $p \leftarrow f(q \mid \xi, \omega, \beta) / f(\mu \mid \xi, \omega, \beta)$
- 

In the following subsections, we describe the test statistic  $T$  and its asymptotic properties, and how our algorithm learns the distribution of  $T(\tilde{\mathbf{a}}_j^t, \hat{\mathbf{a}}_j^t)$ . A summary of the algorithm is given in Algorithm 1.

#### 4.1 TEST STATISTIC

We follow the general approach outlined in Section 1 by which we compute a *score* from a vector of actions and their hypothesised distributions. Formally, we define a *score function* as  $z : (A_j)^t \times \Delta(A_j)^t \rightarrow \mathbb{R}$ , where  $\Delta(A_j)$  is the set of all probability distributions over  $A_j$ . Thus,  $z(\mathbf{a}_j^t, \delta^t(\pi_j^*))$  is the score for observed actions  $\mathbf{a}_j^t$  and hypothesised distributions  $\delta^t(\pi_j^*)$ , and we sometimes abbreviate this to  $z(\mathbf{a}_j^t, \pi_j^*)$ . We use  $Z$  to denote the space of all score functions.

Given a score function  $z$ , we define the test statistic  $T$  as

$$T(\tilde{\mathbf{a}}_j^t, \hat{\mathbf{a}}_j^t) = \frac{1}{t} \sum_{\tau=1}^t T_\tau(\tilde{\mathbf{a}}_j^\tau, \hat{\mathbf{a}}_j^\tau) \quad (2)$$

$$T_\tau(\tilde{\mathbf{a}}_j^\tau, \hat{\mathbf{a}}_j^\tau) = z(\tilde{\mathbf{a}}_j^\tau, \pi_j^*) - z(\hat{\mathbf{a}}_j^\tau, \pi_j^*) \quad (3)$$

where  $\tilde{\mathbf{a}}_j^\tau$  and  $\hat{\mathbf{a}}_j^\tau$  are the  $\tau$ -prefixes of  $\tilde{\mathbf{a}}_j^t$  and  $\hat{\mathbf{a}}_j^t$ , respectively.

In this work, we assume that  $z$  is provided by the user. While formally unnecessary (in the sense that our analysis does not require it), we find it a useful design guideline to interpret a score as a kind of likelihood, such that higher scores suggest higher likelihood of  $\pi_j^*$  being correct. Under this interpretation, a minimum requirement for  $z$  should be that it is *consistent*, such that, for any  $t > 0$  and  $\pi_j^* \in \Pi_j^i$ ,

$$\pi_j^* \in \Pi^z = \arg \max_{\pi_j^* \in \Pi_j^i} \mathbb{E}_{\mathbf{a}_j^t \sim \delta^t(\pi_j^*)} [z(\mathbf{a}_j^t, \pi_j^*)] \quad (4)$$

where  $\mathbb{E}_\eta$  denotes the expectation under  $\eta$ . This ensures

that if the null-hypothesis  $\pi_j^* = \pi_j$  is true, then the score  $z(\mathbf{a}_j^t, \pi_j^*)$  is maximised on expectation.

Ideally, we would like a score function  $z$  which is *perfect* in that it is consistent and  $|\Pi^z| = 1$ . This means that  $\pi_j^*$  can maximise  $z(\mathbf{a}_j^t, \pi_j^*)$  (where  $\mathbf{a}_j^t \sim \delta^t(\pi_j)$ ) *only* if  $\pi_j^* = \pi_j$ . Unfortunately, it is unclear if such a score function exists for the general case and how it should look. Even if we restrict the behaviours agents may exhibit, it can still be difficult to find a perfect score function. On the other hand, it is a relatively simple task to specify a small set of score functions  $z_1, \dots, z_K$  which are consistent but imperfect. (Examples are given in Section 5.) Given that these score functions are consistent, we know that the cardinality  $|\cap_k \Pi^{z_k}|$  can only monotonically decrease. Therefore, it seems a reasonable approach to combine multiple imperfect score functions in an attempt to approximate a perfect score function.

Of course, we could simply define  $z$  as a linear (or otherwise) combination of  $z_1, \dots, z_K$ . However, this approach is at risk of losing information from the individual scores, e.g. due to commutativity and other properties of the combination. Thus, we instead propose to compare the scores individually. Given score functions  $z_1, \dots, z_K \in Z$  which are all bounded by the same interval  $[a, b] \subset \mathbb{R}$ , we redefine  $T_\tau$  to

$$T_\tau(\tilde{\mathbf{a}}_j^\tau, \hat{\mathbf{a}}_j^\tau) = \sum_{k=1}^K w_k (z_k(\tilde{\mathbf{a}}_j^\tau, \pi_j^*) - z_k(\hat{\mathbf{a}}_j^\tau, \pi_j^*)) \quad (5)$$

where  $w_k \in \mathbb{R}$  is a weight for score function  $z_k$ . In this work, we set  $w_k = \frac{1}{K}$ . (We also experiment with alternative weighting schemes in Section 5.) However, we believe that  $w_k$  may serve as an interface for useful modifications of our algorithm. For example, Yue et al. (2010) compute weights to increase the power of their specific hypothesis tests.

## 4.2 ASYMPTOTIC PROPERTIES

The vectors  $\mathbf{a}_j^t$  and  $\hat{\mathbf{a}}_j^t$  are constructed iteratively. That is, at time  $t$ , we observe agent  $j$ 's past action  $a_j^{t-1}$ , which was generated from  $\pi_j(H_j^{t-1})$ , and set  $\mathbf{a}_j^t = \langle \mathbf{a}_j^{t-1}, a_j^{t-1} \rangle$ . At the same time, we sample an action  $\hat{a}_j^{t-1}$  using  $\pi_j^*(H_i^{t-1})$  and set  $\hat{\mathbf{a}}_j^t = \langle \hat{\mathbf{a}}_j^{t-1}, \hat{a}_j^{t-1} \rangle$ . Assuming the null-hypothesis  $\pi_j^* = \pi_j$ , will  $T(\mathbf{a}_j^t, \hat{\mathbf{a}}_j^t)$  converge in the process?

Unfortunately,  $T$  might not converge. This may seem surprising at first glance given that  $a_j^{t-1}, \hat{a}_j^{t-1}$  have the same distribution  $\pi_j(H_j^{t-1}) = \pi_j^*(H_i^{t-1})$ , since  $\mathbb{E}_{x,y \sim \psi} [x - y] = 0$  for any distribution  $\psi$ . However, there is a subtle but important difference: while  $a_j^{t-1}, \hat{a}_j^{t-1}$  have the same distribution,  $z_k(\mathbf{a}_j^t, \pi_j^*)$  and  $z_k(\hat{\mathbf{a}}_j^t, \pi_j^*)$  may have arbitrarily different distributions. This is because these scores may depend on the entire prefix vectors  $\mathbf{a}_j^{t-1}$  and  $\hat{\mathbf{a}}_j^{t-1}$ , respectively, which means that their distributions may be different if  $\mathbf{a}_j^{t-1} \neq \hat{\mathbf{a}}_j^{t-1}$ . Fortunately, our algorithm does not require  $T$  to converge because it learns the distribution of  $T$  during the interaction process, as we will discuss in Section 4.3.

Interestingly, while  $T$  may not converge, it can be shown that the fluctuation of  $T$  is eventually normally distributed, for any set of score functions  $z_1, \dots, z_K$  with bound  $[a, b]$ . Formally, let  $\mathbb{E}[T_\tau(\mathbf{a}_j^\tau, \hat{\mathbf{a}}_j^\tau)]$  and  $\text{Var}[T_\tau(\mathbf{a}_j^\tau, \hat{\mathbf{a}}_j^\tau)]$  denote the finite expectation and variance of  $T_\tau(\mathbf{a}_j^\tau, \hat{\mathbf{a}}_j^\tau)$ , where it is irrelevant if  $\mathbf{a}_j^\tau, \hat{\mathbf{a}}_j^\tau$  are sampled directly from  $\delta^\tau(\pi_j^*)$  or generated iteratively as prescribed above. Furthermore, let  $\sigma_t^2 = \sum_{\tau=1}^t \text{Var}[T_\tau(\mathbf{a}_j^\tau, \hat{\mathbf{a}}_j^\tau)]$  denote the cumulative variance. Then, the standardised stochastic sum

$$\frac{1}{\sigma_t} \sum_{\tau=1}^t T_\tau(\mathbf{a}_j^\tau, \hat{\mathbf{a}}_j^\tau) - \mathbb{E}[T_\tau(\mathbf{a}_j^\tau, \hat{\mathbf{a}}_j^\tau)] \quad (6)$$

will converge in distribution to the standard normal distribution as  $t \rightarrow \infty$ . Thus,  $T$  is normally distributed as well.

To see this, first recall that the standard central limit theorem requires the random variables  $T_\tau$  to be independent and identically distributed. In our case,  $T_\tau$  are independent in that the random outcome of  $T_\tau$  has no effect on the outcome of  $T_{\tau'}$ . However,  $T_\tau$  and  $T_{\tau'}$  depend on different action sequences, and may therefore have different distributions. Hence, we have to show an additional property, commonly known as *Lyapunov's condition* (e.g. Fischer, 2010), which states that there exists a positive integer  $d$  such that

$$\lim_{t \rightarrow \infty} \frac{\hat{\sigma}_t^{2+d}}{\sigma_t^{2+d}} = 0, \text{ with} \quad (7)$$

$$\hat{\sigma}_t^{2+d} = \sum_{\tau=1}^t \mathbb{E} \left[ |T_\tau(\mathbf{a}_j^\tau, \hat{\mathbf{a}}_j^\tau) - \mathbb{E}[T_\tau(\mathbf{a}_j^\tau, \hat{\mathbf{a}}_j^\tau)]|^{2+d} \right]. \quad (8)$$

Since  $z_k$  are bounded, we know that  $T_\tau$  are bounded. Hence, the summands in (8) are uniformly bounded, say by  $U$  for brevity. Setting  $d = 1$ , we obtain

$$\lim_{t \rightarrow \infty} \frac{\hat{\sigma}_t^3}{\sigma_t^3} \leq \frac{U \hat{\sigma}_t^2}{\sigma_t^3} = \frac{U}{\sigma_t} \quad (9)$$

The last part goes to zero if  $\sigma_t \rightarrow \infty$ , and hence Lyapunov's condition holds. If, on the other hand,  $\sigma_t$  converges, then this means that the variance of  $T_\tau$  is zero from some point onward (or that it has an appropriate convergence to zero). In this case,  $\pi_j^*$  will prescribe deterministic action choices for agent  $j$ , and a statistical analysis is no longer necessary.

## 4.3 LEARNING THE TEST DISTRIBUTION

Given that  $T$  is eventually normal, it may seem reasonable to compute (1) using a normal distribution whose parameters are fitted during the interaction. However, this fails to recognise that the distribution of  $T$  is shaped *gradually* over an extended time period, and that the fluctuation around  $T$  can be heavily skewed in either direction until convergence to a normal distribution emerges. Thus, a normal distribution may be a poor fit during this shaping period.

What is needed is a distribution which can represent any normal distribution, and which is flexible enough to faithfully

represent the gradual shaping. One distribution which has these properties is the *skew-normal distribution* (Azzalini, 1985; O’Hagan and Leonard, 1976). Given the PDF  $\phi$  and CDF  $\Phi$  of the standard normal distribution, the skew-normal PDF is defined as

$$f(x | \xi, \omega, \beta) = \frac{2}{\omega} \phi\left(\frac{x - \xi}{\omega}\right) \Phi\left(\beta \left(\frac{x - \xi}{\omega}\right)\right) \quad (10)$$

where  $\xi \in \mathbb{R}$  is the location parameter,  $\omega \in \mathbb{R}^+$  is the scale parameter, and  $\beta \in \mathbb{R}$  is the shape parameter. Note that this reduces to the normal PDF for  $\beta = 0$ , in which case  $\xi$  and  $\omega$  correspond to the mean and standard deviation, respectively. Hence, the normal distribution is a sub-class of the skew-normal distribution.

Our algorithm learns the shifting parameters of  $f$  during the interaction process, using a simple but effective sampling procedure. Essentially, we use  $\pi_j^*$  to iteratively generate  $N$  additional action vectors  $\hat{\mathbf{a}}_j^{t,1}, \dots, \hat{\mathbf{a}}_j^{t,N}$  in the exact same way as  $\hat{\mathbf{a}}_j^t$ . The vectors  $\hat{\mathbf{a}}_j^{t,n}$  are then mapped into data points

$$D = \left\{ T(\hat{\mathbf{a}}_j^{t,n}, \hat{\mathbf{a}}_j^t) \mid n = 1, \dots, N \right\} \quad (11)$$

which are used to estimate the parameters  $\xi, \omega, \beta$  by minimising the negative log-likelihood

$$N \log(\omega) - \sum_{x \in D} \log \phi\left(\frac{x - \xi}{\omega}\right) + \log \Phi\left(\beta \left(\frac{x - \xi}{\omega}\right)\right) \quad (12)$$

whilst ensuring that  $\omega$  is positive. An alternative is the method-of-moments estimator, which can also be used to obtain initial values for (12). Note that it is usually unnecessary to estimate the parameters at every point in time. Rather, it seems reasonable to update the parameters less frequently as the amount of evidence (i.e. observed actions) grows.

Given the asymmetry of the skew-normal distribution, the semantics of “as extreme as” in (1) may no longer be obvious (e.g. is this with respect to the mean or mode?). In addition, the usual tail-area calculation of the  $p$ -value requires the CDF, but there is no closed form for the skew-normal CDF and approximating it is rather cumbersome. To circumvent these issues, we approximate the  $p$ -value as

$$p \approx \frac{f(T(\hat{\mathbf{a}}_j^t, \hat{\mathbf{a}}_j^t) | \xi, \omega, \beta)}{f(\mu | \xi, \omega, \beta)} \quad (13)$$

where  $\mu$  is the mode of the fitted skew-normal distribution. This avoids the asymmetry issue and is easier to compute.

## 5 EXPERIMENTS

We conducted a comprehensive set of experiments to investigate the accuracy (correct and incorrect rejection), scalability (with number of actions), and sampling complexity of

our algorithm. The following three score functions and their combinations were used:

$$z_1(\mathbf{a}_j^t, \pi_j^*) = \frac{1}{t} \sum_{\tau=0}^{t-1} \frac{\pi_j^*(H_i^\tau)[a_j^\tau]}{\max_{a_j \in A_j} \pi_j^*(H_i^\tau)[a_j]}$$

$$z_2(\mathbf{a}_j^t, \pi_j^*) = \frac{1}{t} \sum_{\tau=0}^{t-1} 1 - \mathbb{E}_{\pi_j^*(H_i^\tau)}^{a_j \sim} |\pi_j^*(H_i^\tau)[a_j^\tau] - \pi_j^*(H_i^\tau)[a_j]|$$

$$z_3(\mathbf{a}_j^t, \pi_j^*) = \sum_{a_j \in A_j} \min \left[ \frac{1}{t} \sum_{\tau=0}^{t-1} [a_j^\tau = a_j]_1, \frac{1}{t} \sum_{\tau=0}^{t-1} \pi_j^*(H_i^\tau)[a_j] \right]$$

where  $[b]_1 = 1$  if  $b$  is true and 0 otherwise. Note that  $z_1, z_3$  are generally consistent (cf. Section 4.1), while  $z_2$  is consistent for  $|A_j| = 2$  but not necessarily for  $|A_j| > 2$ . Furthermore,  $z_1, z_2, z_3$  are all imperfect. The score function  $z_3$  is based on the empirical frequency distribution (cf. Section 1).

The parameters of the test distribution (cf. Section 4.3) were estimated less frequently as  $t$  increased. The first estimation was performed at time  $t = 1$  (i.e. after observing one action). After estimating the parameters at time  $t$ , we waited  $\lfloor \sqrt{t} \rfloor - 1$  time steps until the parameters were re-fitted. Throughout our experiments, we used a significance level of  $\alpha = 0.01$  (i.e. reject  $\pi_j^*$  if the  $p$ -value is below 0.01).

### 5.1 RANDOM BEHAVIOURS

In the first set of experiments, the behaviour spaces  $\Pi_i, \Pi_j$  and hypothesis space  $\Pi_j^i$  were restricted to “random” behaviours. Each random behaviour is defined by a sequence of random probability distributions over  $A_j$ . The distributions are created by drawing uniform random numbers from  $(0, 1)$  for each action  $a_j \in A_j$ , and subsequent normalisation so that the values sum up to 1.

Random behaviours are a good baseline for our experiments because they are usually hard to distinguish. This is due to the fact that the entire set  $A_j$  is always in the support of the behaviours, and since they do not react to any past actions. These properties mean that there is little structure in the interaction that can be used to distinguish behaviours.

We simulated 1000 interaction processes, each lasting 10000 time steps. In each process, we randomly sampled behaviours  $\pi_i \in \Pi_i, \pi_j \in \Pi_j$  to control agents  $i$  and  $j$ , respectively. In half of these processes, we used a correct hypothesis  $\pi_j^* = \pi_j$ . In the other half, we sampled a random hypothesis  $\pi_j^* \in \Pi_j^i$  with  $\pi_j^* \neq \pi_j$ . We repeated each set of simulations for  $|A_j| = 2, 10, 20$  (with  $|A_i| = |A_j|$ ) and  $N = 10, 50, 100$  (cf. Section 4.3).

#### 5.1.1 Accuracy & Scalability

Figure 1 shows the average accuracy of our algorithm (for  $N = 50$ ), by which we mean the average percentage of time steps in which the algorithm made correct decisions (i.e. no reject if  $\pi_j^* = \pi_j$ ; reject if  $\pi_j^* \neq \pi_j$ ). The x-axis shows

Figure 1: Average accuracy with random behaviours, for  $N = 50$  and  $|A_j| = 2, 10, 20$ . Results averaged over 500 processes with 10000 time steps, for  $\pi_j^* = \pi_j$  and  $\pi_j^* \neq \pi_j$  each. X-axis shows score functions  $z_k$  used in test statistic.

Figure 2: Average  $p$ -values with random behaviours, for  $N = 50$  and  $\pi_j^* \neq \pi_j$  (i.e. hypothesis wrong). Results averaged over 500 processes. Legend shows score functions  $z_k$  used in test statistic.

the combination of score functions used to compute the test statistic (e.g. [1 2] means that we combined  $z_1, z_2$ ).

The results show that our algorithm achieved excellent accuracy, often bordering the 100% mark. They also show that the algorithm scaled well with the number of actions, with no degradation in accuracy. However, there were two exceptions to these observations: Firstly, using  $z_3$  resulted in very poor accuracy for  $\pi_j^* \neq \pi_j$ . Secondly, the combination of  $z_2, z_3$  scaled badly for  $\pi_j^* \neq \pi_j$ .

The reason for both of these exceptions is that  $z_3$  is not a good scoring scheme for random behaviours. The function  $z_3$  quantifies a similarity between the empirical frequency distribution and the averaged hypothesised distributions. For random behaviours (as defined in this work), both of these distributions will converge to the uniform distribution. Thus, under  $z_3$ , any two random behaviours will eventually be the same, which explains the low accuracy for  $\pi_j^* \neq \pi_j$ .

As can be seen in Figure 1, the inadequacy of  $z_3$  is solved when adding any of the other score functions  $z_1, z_2$ . These functions add discriminative information to the test statistic, which technically means that the cardinality  $|\Pi^z|$  in (4) is reduced. However, in the case of  $[z_2, z_3]$ , the converge is substantially slower for higher  $|A_j|$ , meaning that more evidence is needed until  $\pi_j^*$  can be rejected. Figure 2 shows how a higher number of actions affects the average convergence rate of  $p$ -values computed with  $z_2, z_3$ .

In addition to the score functions  $z_k$ , a central aspect for the convergence of  $p$ -values are the corresponding weights

$w_k$  (cf. (5)). As mentioned in Section 4.1, we use uniform weights  $w_k = \frac{1}{K}$ . However, to show that the weighting is not trivial matter, we repeated our experiments with four alternative weighting schemes: Let  $z_k^T = z_k(\hat{\mathbf{a}}_j^T, \pi_j^*) - z_k(\hat{\mathbf{a}}_j^T, \pi_j^*)$  denote the summands in (5). The weighting schemes `truemax`/`truemin` assign  $w_k = 1$  for the first  $k$  that maximises/minimises  $|z_k^T|$ , and 0 otherwise. Similarly, the weighting schemes `max`/`min` assign  $w_k = 1$  for the first  $k$  that maximises/minimises  $z_k^T$ , and 0 otherwise.

Figures 3 and 4 show the results for `truemax` and `truemin`. As can be seen in the figures, `truemax` is very similar to uniform weights while `truemin` improves the convergence for  $[z_2, z_3]$  but compromises elsewhere. The results for `max` and `min` are very similar to those of `truemin` and `truemax`, respectively, hence we omit them.

Finally, we recomputed all accuracies using a more lenient significance level of  $\alpha = 0.05$ . As could be expected, this marginally decreased and increased (i.e. by a few percentage points) the accuracy for  $\pi_j^* = \pi_j$  and  $\pi_j^* \neq \pi_j$ , respectively. Overall, however, the results were very similar to those obtained with  $\alpha = 0.01$ .

### 5.1.2 Sampling Complexity

Recall that  $N$  specifies the number of sampled action vectors  $\tilde{\mathbf{a}}_j^{t,n}$  used to learn the distribution of the test statistic (cf. Section 4.3). In the previous section, we reported results for  $N = 50$ . In this section, we investigate differences in accuracy for  $N = 10, 50, 100$ .

Figure 3: Average accuracy with random behaviours, for  $N = 50$  and  $|A_j| = 2, 10, 20$ . X-axis shows score functions  $z_k$  used in test statistic. Weights  $w_k$  computed using `truemax` weighting.

Figure 4: Average accuracy with random behaviours, for  $N = 50$  and  $|A_j| = 2, 10, 20$ . X-axis shows score functions  $z_k$  used in test statistic. Weights  $w_k$  computed using `truemin` weighting.

Figures 5 and 6 show the differences for  $|A_j| = 2, 20$ , respectively. (The figure for  $|A_j| = 10$  was virtually the same as the one for  $|A_j| = 20$ , except with minor improvements in accuracy for the  $[z_2, z_3]$  cluster. Hence, we omit it here.) As can be seen, there were improvements of up to 10% from  $N = 10$  to  $N = 50$ , and no (or very marginal) improvements from  $N = 50$  to  $N = 100$ . This was observed for all  $|A_j| = 2, 10, 20$ , and all constellations of score functions. The fact that  $N = 50$  was sufficient even for  $|A_j| = 20$  is remarkable, since, under random behaviours, there are  $20^t$  possible action vectors to sample at any time  $t$ .

We also compared the learned skew-normal distributions and found that they fitted the data very well. Figures 7 and 8 show the histograms and fitted skew-normal distributions for two example processes after 1000 time steps. In Figure 8, we deliberately chose an example in which the learned distribution was maximally skewed for  $N = 10$ , which is a sign that  $N$  was too small. Nonetheless, in the majority of the processes, the learned distribution was only moderately skewed and our algorithm achieved an average accuracy of 90% even for  $N = 10$ . Moreover, if one wants to avoid maximally skewed distributions, one can simply restrict the parameter space when fitting the skew-normal (specifically, the shape parameter  $\beta$ ; cf. Section 4.3).

The flexibility of the skew-normal distribution was particularly useful in the early stages of the interaction, in which the test statistic typically does not follow a normal distribution. Figure 9 shows the test distribution for an example process after 10 time steps, using  $z_2$  for the test statistic and  $N = 100$  (the histogram was created using  $N = 10000$ ). The learned skew-normal approximated the true test distribution very closely. Note that, in such examples, the normal

Figure 9: True test distribution for  $z_2$  (histogram) and learned skew-normal distribution (red curve) after 10 time steps, with  $|A_j| = 10$  and  $N = 100$ .

and Student distributions do not produce good fits.

Our implementation of the algorithm performed all calculations as iterative updates (except for the skew-normal fitting). Hence, it used little (fixed) memory and had very low computation times. For example, using all three score functions and  $|A_j| = 20$ ,  $N = 100$ , one cycle in the algorithm (cf. Algorithm 1) took on average less than 1 millisecond without fitting the skew-normal parameters, and less than 10 milliseconds when fitting the skew-normal parameters (using an off-the-shelf Simplex-optimiser with default parameters). The times were measured using Matlab R2014a on a Unix machine with a 2.6 GHz Intel Core i5 processor.

## 5.2 ADAPTIVE BEHAVIOURS

We complemented the “structure-free” interaction of random behaviours by conducting analogous experiments with

Figure 5: Average accuracy with random behaviours, for  $|A_j| = 2$  and  $N = 10, 50, 100$ . Results averaged over 500 processes with 10000 time steps, for  $\pi_j^* = \pi_j$  and  $\pi_j^* \neq \pi_j$  each. X-axis shows score functions  $z_k$  used in test statistic.

Figure 6: Average accuracy with random behaviours, for  $|A_j| = 20$  and  $N = 10, 50, 100$ . Results averaged over 500 processes with 10000 time steps, for  $\pi_j^* = \pi_j$  and  $\pi_j^* \neq \pi_j$  each. X-axis shows score functions  $z_k$  used in test statistic.

three additional classes of behaviours. Specifically, we used a benchmark framework specified by Albrecht et al. (2015) which consists of 78 distinct  $2 \times 2$  matrix games and three methods to automatically generate sets of behaviours for any given game. The three behaviour classes are Leader-Follower-Trigger Agents (LFT), Co-Evolved Decision Trees (CDT), and Co-Evolved Neural Networks (CNN). These classes cover a broad spectrum of possible behaviours, including fully deterministic (CDT), fully stochastic (CNN), and hybrid (LFT) behaviours. Furthermore, all generated behaviours are *adaptive* to varying degrees (i.e. they adapt their action choices based on the other player’s choices). We refer to Albrecht et al. (2015) for a more detailed description of these classes (we used the same parameter settings).

The following experiments were performed for each behaviour class, using identical randomisation: For each of the 78 games, we simulated 10 interaction processes, each lasting 10000 time steps. For each process, we randomly sampled behaviours  $\pi_i \in \Pi_i, \pi_j \in \Pi_j$  to control agents  $i$  and  $j$ , respectively, where  $\Pi_i, \Pi_j$  (and  $\Pi_j^i$ ) were restricted to the same behaviour class. In half of these processes, we used a correct hypothesis  $\pi_j^* = \pi_j$ , and in the other half, we sampled a random hypothesis  $\pi_j^* \in \Pi_j^i$  with  $\pi_j^* \neq \pi_j$ . As before, we repeated each simulation for  $N = 10, 50, 100$  and all constellations of score functions, but found that there were virtually no differences. Hence, in the following, we report results for  $N = 50$  and the  $[z_1, z_2, z_3]$  cluster.

Figure 10 shows the average accuracy achieved by our algorithm for all three behaviour classes. While the accuracy for  $\pi_j^* = \pi_j$  was generally good, the accuracy for  $\pi_j^* \neq \pi_j$  was mixed. Note that this was not merely due to the fact that the score functions were imperfect (cf. Section 4.1), since we

Figure 10: Average accuracy for behaviour classes LFT, CDT, CNN ( $N = 50$ ).  $\Pi_i$  and  $\Pi_j$  restricted to same class.

Figure 11: Average accuracy for behaviour classes LFT, CDT, CNN ( $N = 50$ ).  $\Pi_i$  set to random behaviours.

obtained the same results for all combinations. Rather, this reveals an inherent limitation of our approach, which is that *we do not actively probe aspects of the hypothesis  $\pi_j^*$* . In other words, our algorithm performs statistical hypothesis tests based only on evidence that was generated by  $\pi_i$ .

To illustrate this, it is useful to consider the tree structure of behaviours in the CDT class. Each node in a tree  $\pi_j$  corresponds to a past action taken by  $\pi_i$ . Depending on how  $\pi_i$  chooses actions, we may only ever see a subset of the

Figure 7: Example histograms and fitted skew-normal distributions (red curve) after 1000 time steps, for random behaviours with  $|A_j| = 10$  and  $N = 10, 50, 100$ . Using score function  $z_1$  in test statistic.

Figure 8: Example histograms and fitted skew-normal distributions (red curve) after 1000 time steps, for random behaviours with  $|A_j| = 10$  and  $N = 10, 50, 100$ . Using score functions  $z_1, z_2, z_3$  in test statistic.

entire tree that defines  $\pi_j$ . However, if our hypothesis  $\pi_j^*$  differs from  $\pi_j$  only in the unseen aspects of  $\pi_j$ , then there is no way for our algorithm to differentiate the two. Hence the asymmetry in accuracy for  $\pi_j^* = \pi_j$  and  $\pi_j^* \neq \pi_j$ . Note that this problem did not occur in random behaviours because, there, all aspects are eventually visible.

Following this observation, we repeated the same experiments but restricted  $\Pi_i$  to random behaviours, with the goal of exploring  $\pi_j^*$  more thoroughly. As shown in Figure 11, this led to significant improvements in accuracy, especially for the CDT class. Nonetheless, choosing actions purely randomly may not be a sufficient probing strategy, hence the accuracy for CNN was still relatively low. For CNN, this was further complicated by the fact that two neural networks  $\pi_j, \pi'_j$  may formally be different ( $\pi_j \neq \pi'_j$ ) but have essentially the same action probabilities (with extremely small differences). Hence, in such cases, we would require much more evidence to distinguish the behaviours.

## 6 CONCLUSION

We hold the view that if an intelligent agent is to interact effectively with other agents whose behaviours are unknown, it will have to hypothesise what these agents might be doing *and* contemplate the truth of its hypotheses, such that appropriate measures can be taken if they are deemed false. In this spirit, we presented a novel algorithm which decides this

question in the form of a frequentist hypothesis test. The algorithm can incorporate multiple statistical criteria into the test statistic and learns the test distribution during the interaction process, with asymptotic correctness guarantees. We presented results from a comprehensive set of experiments, showing that our algorithm achieved high accuracy and scalability at low computational costs.

There are several directions for future work: To bring some structure into the space of score functions, we introduced the concepts of consistency and perfection as minimal and ideal properties. However, more research is needed to understand precisely what properties a useful score function should satisfy, and whether the concept of perfection is feasible or even necessary in the general case. Furthermore, we used uniform weights to combine the computed scores into a test statistic, and we also experimented with alternative weighting schemes to show that the weighting can have a substantial effect on convergence rates. However, further research is required to understand the effect of weights on decision quality and convergence.

Finally, in this work, we assumed that the behaviour of the other agent ( $j$ ) could be described as a function of the information available to our agent ( $i$ ). An important extension would be to also account for information that cannot be deterministically derived from our observations, especially in the context of robotics where observations are often described as random variables.

## Abstract

We introduce *disciplined convex stochastic programming* (DCSP), a modeling framework that can significantly lower the barrier for modelers to specify and solve convex stochastic optimization problems, by allowing modelers to naturally express a wide variety of convex *stochastic programs* in a manner that reflects their underlying mathematical representation. DCSP allows modelers to express expectations of arbitrary expressions, *partial optimizations*, and *chance constraints* across a wide variety of convex optimization problem families (*e.g.*, linear, quadratic, second order cone, and semidefinite programs). We illustrate DCSP’s expressivity through a number of sample implementations of problems drawn from the operations research, finance, and machine learning literatures.

## 1 INTRODUCTION

We introduce *disciplined convex stochastic programming* (DCSP), a modeling framework for specifying and solving convex *stochastic programs*: convex optimization problems that include random variables. DCSP builds on principles from stochastic optimization and convex analysis to allow modelers to naturally express a wide variety of stochastic programs in a manner that reflects their underlying mathematical representation. At a high level, DCSP enables modelers to specify — in a straightforward way — and solve convex optimization problems that include (1) expectations of arbitrary expressions, (2) *partial optimizations*, optimizations over (only) a subset of the optimization variables, which additionally pave the way for the specification of *multi-stage* stochastic programs (Sec. 2.1), and (3) *chance constraints*, constraints that are required to hold with high probability — these three building blocks can be used to express a wide variety of stochastic optimization problems.

Concurrently with this paper, we also make available an open source Python implementation of DCSP, which we refer to as `cvxstoc`<sup>1</sup>, that allows modelers to write and solve stochastic programs — we present a variety of examples of using `cvxstoc` to model stochastic optimization problems, drawn from the operations research, finance, and machine learning literatures, in Sec. 4.

**Related work** Although other frameworks for stochastic programming do exist ([24, 20, 11], and in Python mainly [26]), they often require significant effort from the modeler to manipulate the optimization problem into an amenable form, support a limited number of stochastic programming constructs (*e.g.*, [11] only supports chance constraints with uncertainty sets), and cannot express certain families of convex optimization problems; indeed, checking the convexity of and solving (convex) optimization problems in general is challenging. DCSP builds on (and extends) *disciplined convex programming* (DCP) [10], a recently introduced framework that makes it natural for modelers to express convex optimization problems, and additionally automates the tasks of verifying the convexity of these problems and translating them into conic form (see, *e.g.*, [8]). This means that DCSP can be used to express and solve a wide variety of stochastic convex optimization problems, including linear, quadratic, second order cone, and semidefinite programs. Probabilistic programming languages (*e.g.*, [9, 16, 13]) offer an alternative approach, but tend to focus on inference problems, and may not contain the features to capture traditional stochastic programming problem formulations; in contrast, convex modeling can be attractive because local solutions are global solutions, efficient solvers exist, and guarantees can often be obtained on the optimality of a solution obtained by a solver.

This paper is structured as follows. In Sec. 2, we review background on stochastic programming, DCP, and `cvxpy` (an open source Python implementation of DCP). In Sec. 3, we describe DCSP and `cvxstoc`’s syntax. In

---

<sup>1</sup>`cvxstoc` is available as an extension of the `cvxpy` Python package [7]: see <http://www.cvxpy.org>.

Sec. 4, we present a number of examples that illustrate our framework.

## 2 BACKGROUND

### 2.1 STOCHASTIC PROGRAMMING

A convex optimization problem has the form

$$\begin{aligned} & \text{minimize} && f_0(x) \\ & \text{subject to} && f_i(x) \leq 0, \quad i = 1, \dots, m, \\ & && h_i(x) = 0, \quad i = 1, \dots, p, \end{aligned}$$

where  $x \in \mathbf{R}^n$  is the optimization variable,  $f_0 : \mathbf{R}^n \rightarrow \mathbf{R}$  is a convex objective function,  $f_i : \mathbf{R}^n \rightarrow \mathbf{R}$ ,  $i = 1, \dots, m$  are convex inequality constraint functions, and  $h_i : \mathbf{R}^n \rightarrow \mathbf{R}$ ,  $i = 1, \dots, p$  are affine equality constraint functions.

A convex stochastic program has the form

$$\begin{aligned} & \text{minimize} && \mathbf{E} f_0(x, \omega) \\ & \text{subject to} && \mathbf{E} f_i(x, \omega) \leq 0, \quad i = 1, \dots, m \\ & && h_i(x) = 0, \quad i = 1, \dots, p, \end{aligned} \quad (1)$$

where  $f_i : \mathbf{R}^n \times \mathbf{R}^q \rightarrow \mathbf{R}$ ,  $i = 0, \dots, m$  are convex functions in  $x$  for each value of a random variable  $\omega \in \mathbf{R}^q$ , and  $h_i : \mathbf{R}^n \rightarrow \mathbf{R}$ ,  $i = 1, \dots, p$  are (deterministic) affine functions; since expectations preserve convexity, the objective and inequality constraint functions in (1) are (also) convex in  $x$ , making (1) a convex optimization problem.

**Two-stage stochastic programs** An important special case of (1) is a so-called *two-stage* stochastic program (also referred to as an optimization problem with *recourse*) [6]:

$$\begin{aligned} & \text{minimize} && f_0(x) + \mathbf{E} Q(x, \omega) \\ & \text{subject to} && f_i(x) \leq 0, \quad i = 1, \dots, m, \\ & && h_i(x) = 0, \quad i = 1, \dots, p, \end{aligned} \quad (2)$$

$$\text{where } Q(x, \omega) = \inf_y \{ \phi_0(x, y, \omega) : \phi_i(x, y, \omega) \leq 0, \psi_j(x, y) = 0, i = 1, \dots, s, j = 1, \dots, w \}$$

is the *second stage* problem,  $y \in \mathbf{R}^r$  is the second stage optimization variable,  $\phi_0 : \mathbf{R}^n \times \mathbf{R}^r \times \mathbf{R}^q \rightarrow \mathbf{R}$  is the second stage objective function, and is convex in  $(x, y)$  for each value of  $\omega$ ,  $\phi_i : \mathbf{R}^n \times \mathbf{R}^r \times \mathbf{R}^q \rightarrow \mathbf{R}$ ,  $i = 1, \dots, s$  are the second stage inequality constraint functions, also convex in  $(x, y)$  for each value of  $\omega$ , and  $\psi_i : \mathbf{R}^n \times \mathbf{R}^r \rightarrow \mathbf{R}$ ,  $i = 1, \dots, w$  are the second stage equality constraint functions, and are affine in  $(x, y)$ . That is,  $Q$  is itself the optimal value of another convex optimization problem, and is convex in  $x$  for each value of  $\omega$ .

Two-stage stochastic programs model the uncertain consequences (in the second stage) of here-and-now decision-making (in the first stage): *e.g.*, in a finance application, we may wish to decide which assets to purchase now, while (also) factoring in how the asset prices might fluctuate later.

**Chance-constrained problems** A *chance constraint* [5] is a constraint on the variable  $x$  of the form

$$\text{Prob}(f(x, \omega) \leq 0) \geq \eta,$$

where  $f$  is convex in  $x$  for each value of  $\omega$ , and  $\eta$  is typically a large probability (*e.g.*, 0.95); a *chance-constrained problem* is an optimization problem with one or more chance constraints. Chance constraints are typically non-convex, although effective convex approximations exist (see Sec. 3.3).

### 2.2 DISCIPLINED CONVEX PROGRAMMING

Disciplined convex programming (DCP) is a recently introduced modeling framework for specifying and solving convex optimization problems [10]. In a nutshell, DCP consists of a library of convex atomic functions, and a *convex rule-set* that prescribes how these atomic functions may be composed to express (more complex) convex optimization problems.

**Convex rule-set** Verifying the convexity of arbitrary expressions is challenging; DCP checks convexity using Thm. 2.1, which is equivalent to enforcing a set of rules.

**Theorem 2.1** ([10]). *Suppose  $f = h(g_1(x), \dots, g_k(x))$ , where  $h : \mathbf{R}^k \rightarrow \mathbf{R}$  is convex and  $g_i : \mathbf{R}^n \rightarrow \mathbf{R}$ ,  $i = 1, \dots, k$ , and one of the following holds for each  $i = 1, \dots, k$ :*

- $g_i$  is convex and  $h$  is nondecreasing in argument  $i$
- $g_i$  is concave and  $h$  is nonincreasing in argument  $i$
- $g_i$  is affine.

Then  $f$  is convex<sup>2</sup>.

Thm. 2.1 permits a wide variety of convex expressions: for example, the maximum eigenvalue of a symmetric matrix,  $\lambda_{\max}(2X - 4I)$ , where  $X \in \mathbf{S}^n$ , is recognized as convex. (On the other hand, as an example of a limitation of the rule-set, the expression  $(\sum_{i=1}^n x_i^2)^{1/2}$ , where  $x \in \mathbf{R}^n$ , is *not* recognized as convex, although it *is* recognized as convex once reformulated as  $\|x\|_2$ .)

**Library of atoms** Atomic convex functions<sup>3</sup> are specified in DCP in their epigraph form: for example, the (convex) function  $f(x) = \|x\|_1$  is specified as

$$\begin{aligned} & \text{minimize} && 1^T t \\ & \text{subject to} && -t \preceq x \preceq t, \end{aligned} \quad (3)$$

<sup>2</sup>A similar result holds for concave functions.

<sup>3</sup>See <http://www.cvxpy.org/en/latest/tutorial/functions/index.html> for a list of the convex atoms available in cvxpy.

where  $x, t \in \mathbf{R}^n$ . Thus, whenever a modeler writes the atom  $f(x) = \|x\|_1$ , DCP internally replaces it with (3), introduces the variable  $t$ , and can subsequently optimize over  $(x, t)$ .

**Disciplined convex programming** DCP certifies a problem’s convexity by constructing an abstract syntax tree for the objective and constraint functions, with atoms as internal nodes, and variables and constants as leaves, and then applying Thm. 2.1 recursively [10, 22].

### 2.3 cvxpy

cvxpy [7] is an open source Python DCP implementation; we briefly describe its syntax next.

Variables are declared simply in cvxpy as follows:

```
x = Variable()
x = NonNegative()
X = Semidefinite(n)
```

The first line declares  $x$  to be a variable in  $\mathbf{R}$ , the second declares  $x$  to be a variable in the nonnegative orthant  $\mathbf{R}_+$ , and the third declares  $X$  to be a  $(n \times n)$  matrix variable in the positive semidefinite cone  $\mathbf{S}_+^n$ .

Convex expressions are specified by composing convex atoms; for example, the log loss  $\sum_{i=1}^m \log(1 + \exp(-y_i(w^T x_i + b)))$  can be specified by using the simpler `log_sum_exp` atom as follows:

```
expr = [log_sum_exp(vstack(0, -y[i]*(w.T*x[i]+b)))
        for i in range(m)]
```

An objective is specified by instantiating a *sense* (i.e., `Minimize` or `Maximize`) with an expression:

```
obj = x.T*c
Minimize(obj)
```

Constraints are specified by forming a list of expressions:

```
constrs = [x >= 0, x.T*numpy.ones((n,1)) == 1, ...]
```

A convex optimization problem, then, is specified by instantiating a `Problem` with an objective and a list of constraints:

```
prob = Problem(Minimize(obj), constrs)
prob.solve()
```

The last line solves the optimization problem.

## 3 DISCIPLINED CONVEX STOCHASTIC PROGRAMMING

In this section we present the chief methodological contribution of the paper: the disciplined convex stochastic programming (DCSP) framework, along with an overview of

its implementation in the `cvxstoc` Python package. In a nutshell, DCSP consists of the addition of three operations to the disciplined convex programming (DCP) framework, which can be used to express a wide variety of convex stochastic programs: the ability to (1) compute (approximations to) expectations of arbitrary expressions, (2) handle *partial optimization*, and (3) compute (approximations to) chance constraints.

### 3.1 RANDOM VARIABLES AND EXPECTATIONS

**Random variables** The most fundamental operations in stochastic programs, and hence in DCSP, are the ability to specify random variables, and compute (approximations to) expectations of arbitrary expressions containing these random variables. As in Sec. 2, DCSP assumes that all expressions in a stochastic program are convex in the optimization variable(s) for each value of the random variable(s) — thus, from the point of view of DCSP, random variables do not affect the convexity of their parent expressions and can be regarded as equivalent to constants, thereby requiring no additions to the DCP convex rule-set. (Practically speaking, DCSP permits the specification of a variety of random variables; see Sec. 3.4.)

**Expectations** DCSP computes (approximations to) expectations of arbitrary expressions using simple Monte Carlo evaluation, i.e.,

$$\mathbf{E} f(x, \omega) \approx (1/N) \sum_{i=1}^N f(x, \omega_i),$$

where  $f$  is (again) assumed to be convex in the optimization variable  $x$  for each value of the random variable  $\omega$ , and  $\omega_i, i = 1, \dots, N$  are samples of  $\omega$ ; this approximation is referred to as the *sample average approximation* (SAA) in the stochastic programming literature, and methods that use it are often referred to as *scenario-based* methods. By the DCP rule-set, the nonnegative weighted sum of convex functions is a convex function; thus, the expectation operator applied to an expression that is convex in  $x$  returns an expression that is (also) convex in  $x$ .

The SAA is, of course, a very simple method for approximating an expectation, and much more involved methods for solving stochastic programs exist, but the clear advantage of this method is its simplicity: any random variable can be included in a stochastic program as long as we are able to draw samples of it. If  $\omega$  is a discrete random variable, then DCSP calculates its expectation exactly; otherwise, DCSP draws samples using Markov chain Monte Carlo (MCMC) methods<sup>4</sup> [15].

In the case of unconstrained stochastic programs, the SAA objective value is (naturally) an unbiased estimator of the

<sup>4</sup>We implement MCMC by leveraging the `PyMC` Python package [15].

true objective value,  $\mathbf{E} f_0(x, \omega)$ , with variance  $\propto 1/N$ , and an asymptotically normal distribution [21, chap. 5]. Thm. 3.1 additionally tells us that (roughly) both the optimal value and optimal set of a SAA converge almost surely to the optimal value and optimal set of the true problem.

**Theorem 3.1** ([21, Thm. 5.3]). *Define  $\hat{p}_N^*$ ,  $\hat{S}_N$  and  $p^*$ ,  $S$  as the optimal value and optimal set of a SAA with  $N$  samples and of the true problem, respectively, and let  $K \subset \mathbf{R}^n$  be a compact set. Suppose (a)  $S \subseteq K$  is nonempty, (b)  $\hat{S}_N \subseteq K$  is nonempty a.s., (c)  $f_0$  is finite and continuous on  $K$ , and (d)  $(1/N) \sum_{i=1}^N f_0(x, \omega_i) \xrightarrow{\text{a.s.}} f(x)$  (uniformly) for  $x \in K$ . Then  $\hat{p}_N^* \xrightarrow{\text{a.s.}} p^*$  and  $\sup_{x \in \hat{S}_N} \inf_{y \in S} \|x - y\|_2 \xrightarrow{\text{a.s.}} 0$ .*

$\hat{p}_N^*$  is also a downward biased estimator of  $p^*$ , although its bias decreases with  $N$  [21, Prop. 5.6]. In Sec. 3.4, we empirically investigate the quality of the SAA.

### 3.2 PARTIAL OPTIMIZATION

DCSP adds a new partial optimization atom to the DCP atom library, allowing modelers to express partial optimizations, *i.e.*, optimizations over (only) a subset of the optimization variables; this atom also forms the basis for specifying two-stage stochastic programs.

We start with the observation that partial optimization is a convex operation (see, *e.g.*, [4, page 87]): *i.e.*, if  $f$  is convex in  $(x, y)$  and  $C$  is a nonempty convex set, then

$$g(x) := \inf_y \{f(x, y) : (x, y) \in C\},$$

is convex in  $x$ .

Accordingly, DCSP specifies a new partial optimization atom that takes as input a convex optimization problem and returns (the epigraph form for) another convex atom, which complies with the DCP prescription for specifying atoms — this means that modelers can use partial optimizations in stochastic programs as they would other atoms. In particular, two-stage stochastic programs, *i.e.*, (2), can be naturally expressed using this atom; furthermore, the second stage optimization problem  $Q$  need not be in standard form (as required by other frameworks).

### 3.3 CHANCE CONSTRAINTS

DCSP computes conservative approximations to chance constraints, as they are typically nonconvex<sup>5</sup>; in particular, DCSP replaces

$$\mathbf{Prob}(f(x, \omega) \geq 0) \leq 1 - \eta, \quad (4)$$

<sup>5</sup>One notable exception is chance constraints involving affine functions of normal random variables, which can be expressed as a second order cone constraint (see, *e.g.*, [4, page 157]). However, we favor the approximate approach described in this section because it is substantially more general, and applies to any class of random variables.

with a convex upper bound derived as follows [3]. Suppose  $\phi : \mathbf{R} \rightarrow \mathbf{R}_+$  is a nonnegative, increasing convex function with  $\phi(0) = 1$ ; then  $\phi(z) \geq 1(z \geq 0)$ , where  $1(z \geq 0)$  equals 1 if  $z \geq 0$  and 0 otherwise, and so  $\phi(z/\alpha) \geq 1(z \geq 0)$ , for some variable  $\alpha \in \mathbf{R}_{++}$ . Thus

$$\mathbf{E} \phi(f(x, \omega)/\alpha) \geq \mathbf{Prob}(f(x, \omega) \geq 0),$$

and so

$$\begin{aligned} \alpha \mathbf{E} \phi(f(x, \omega)/\alpha) &\leq \alpha(1 - \eta) \\ \implies \mathbf{Prob}(f(x, \omega) \geq 0) &\leq 1 - \eta, \end{aligned} \quad (5)$$

*i.e.*, (5) is a conservative approximation to (4). Note that (5) is convex in  $(x, \alpha)$ : it is the perspective of the expectation of a convex increasing function,  $\phi$ , of a convex function,  $f$ .<sup>6</sup>

In (5),  $\alpha$  can be interpreted as modulating the “steepness” of the approximation; several choices of  $\phi$  are possible, and are analogous, *e.g.*, to different approximations to the zero-one loss common in machine learning. DCSP uses  $\phi(z) = \max\{0, z + 1\}$ , which roughly corresponds to a Markov-inequality type bound<sup>7</sup> on (4), and can also be interpreted as the *conditional value-at-risk* of  $f(x, \omega)$  [19]. Prop. 3.2 also tells us that this is the tightest possible choice of  $\phi$ .

Practically speaking, DCSP approximates (5) with its SAA (at which point all the benefits of DCP readily apply), then optimizes over  $(x, \alpha)$  to obtain the tightest possible bound; in Sec. 4.3, we empirically investigate the quality of these approximations.

**Proposition 3.2** ([14]). *Suppose  $\phi : \mathbf{R} \rightarrow \mathbf{R}_+$  is a nonnegative, increasing convex function and  $\phi(z) \geq 1(z \geq 0)$ ; then  $\exists \alpha \in \mathbf{R}_+$  such that  $\mathbf{E}(f(x, \omega)/\alpha + 1)_+ \leq \mathbf{E} \phi(f(x, \omega))$ .*

### 3.4 cvxstoc

Next, we briefly detail the syntax of `cvxstoc`; `cvxstoc` builds on `cvxpy`, and thus much of the usage is similar.

Random variables are specified simply in `cvxstoc` as follows:

```
omega = RandomVariableFactory().create_normal_rv(0,1)
```

Here, `omega` is a standard normal random variable. `cvxstoc` includes a `RandomVariableFactory` object to simplify the specification of common random variables; see Sec. 4 for examples of the specification of other random variables.

Expectations are specified by applying the `expectation` atom:

<sup>6</sup>Alternatively, the modeler can fix  $\alpha$ , in which case the bound is convex in  $(x, \eta)$  if desired.

<sup>7</sup>Alternatively, one could take  $\phi(z) = \exp z$ , which would be analogous to a Chernoff-type inequality.

```
result = expectation(exp(omega*x), m)
```

Here,  $\exp(\omega x)$  is the expression we wish to compute the expectation of, and  $m$  is the number of Monte Carlo samples to use when constructing the SAA.

Partial optimizations are specified by applying the `partial_optimize` atom:

```
atom = partial_optimize(prob, [y], [x])
```

The first argument here is a `Problem`, the second is a list of variables to optimize over, and the third is a list of variables to *not* optimize over.

Two-stage stochastic programs can, in turn, be specified as follows:

```
Q = partial_optimize(prob2, [y], [x])
probl = Problem(Minimize(f0 + expectation(Q(x),m)),
               constrs)
```

Here, `prob2` is the second stage problem, `y` is the second stage variable, `x` is the first stage variable, and `probl` is the first stage problem. Multi-stage stochastic programs can be specified by iterating this construction:

```
Q2 = partial_optimize(prob3, [z], [x,y])
prob2 = Problem(Minimize(phi0 + expectation(Q2(y),m)),
               constrs2)
Q1 = partial_optimize(prob2, [y], [x])
probl = Problem(Minimize(f0 + expectation(Q1(x),m)),
               constrs1)
```

Chance constraints are specified by instantiating the `prob` class and chaining it with an inequality:

```
prob(constr >= 0, m) <= 1-eta
```

Here, `constr` is a (stochastic) constraint, and `m` is the number of Monte Carlo samples to use.

### 3.4.1 Quality of the sample average approximation

Here, we investigate the quality of the SAA employed by `cvxstoc` in the special case of a (unconstrained) least squares problem

$$\underset{x}{\text{minimize}} \quad \mathbf{E} \|Ax - b\|_2^2, \quad (6)$$

where the entries of  $A \in \mathbf{R}^{m \times n} \sim \text{Normal}(\mu_1, \sigma_1^2)$ ,  $b \in \mathbf{R}^m \sim \text{Normal}(\mu_2, \sigma_2^2)$ , and  $x \in \mathbf{R}^n$ , in which case the objective has the analytic form

$$x^T \mathbf{E} A^T A x - 2 \mathbf{E} b^T A x + \mathbf{E} b^T b,$$

assuming we know the second moments of  $(A, b)$ . Fig. 1 plots the optimal value of the true problem (6) and a SAA to (6): we see that the SAA obtains reasonable accuracy after roughly 100 Monte Carlo samples.

**Figure 1:** The optimal values of the stochastic least squares problem (6) (red) and a SAA to (6) (blue) with 95% confidence intervals (light blue) vs. the number of Monte Carlo samples; in this case,  $m = 100, n = 50$ , although similar results hold across a variety of problem sizes.

## 4 EXAMPLES

At this point, we switch gears slightly and present several examples of stochastic programs along with their corresponding `cvxstoc` implementations<sup>8</sup>; the majority of these applications are well established or previously known, though we also include some formulations that are novel, to the best of our knowledge (namely, the precise formulation of the stochastic optimal power flow problem in Sec. 4.4, and the budgeted learning of a classifier in a cascade problem in Sec. 4.6).

### 4.1 YIELD-CONSTRAINED COST MINIMIZATION

We begin with a simple example from the operations research literature (see, *e.g.*, [4, page 107]). Consider the (general) problem of choosing the parameters  $x \in \mathbf{R}^n$  governing a manufacturing process so that our cost  $c^T x$ , where  $c \in \mathbf{R}^n$ , is minimized, while the parameters lie in a set of allowable values  $S$ ; we can model noise in the manufacturing process by expressing this constraint as  $\text{Prob}(x + \omega \in S) \geq \eta$ , where  $\omega \in \mathbf{R}^n$  is a random vector and  $\eta$  is a large probability (*e.g.*, 0.95), which is referred to as an  $\eta$ -yield constraint. Thus, we have the optimization problem

$$\begin{aligned} & \underset{x}{\text{minimize}} && c^T x \\ & \text{subject to} && \text{Prob}(x + \omega \in S) \geq \eta. \end{aligned}$$

<sup>8</sup>Due to space constraints, we present one of these examples in the supplementary material.

Note that if the distribution over  $\omega$  is log-concave and  $S$  is a convex set, then this constraint is convex in  $x$ . We can directly express the yield-constrained cost minimization problem using `cvxstoc`; an implementation is given in Listing 1 ( $S$  is taken to be an ellipsoid).

```
# Create problem data
n = 10
c = numpy.random.randn(n)
P, q, r = numpy.eye(n), numpy.random.randn(n), numpy.
    random.randn()
mu, Sigma = numpy.zeros(n), 0.1*numpy.eye(n)
omega = RandomVariableFactory().create_normal_rv(mu,
    Sigma)
m, eta = 100, 0.95

# Create and solve optimization problem
x = Variable(n)
yield_constr = prob(quad_form(x+omega,P)
    + (x+omega).T*q + r >= 0, m) <= 1-eta
p = Problem(Minimize(x.T*c), [yield_constr])
p.solve()
```

**Listing 1:** A `cvxstoc` implementation of the yield-constrained cost minimization problem.

## 4.2 THE NEWS VENDOR PROBLEM

The news vendor problem is a classic problem in the stochastic programming literature (see, e.g., [2, page 15]); in this problem, a vendor must decide how much newspaper to stock, so that profit is maximized while backorder and return fees (due to excess or insufficient demand, respectively) are minimized, in the face of uncertain demand.

Our optimization variables are the number of units of stocked newspaper  $x \in \mathbf{R}_+$ , the number of units purchased by customers  $y_1 \in \mathbf{R}_+$ , and the number of unpurchased (surplus) units that must be returned by the vendor  $y_2 \in \mathbf{R}_+$ . Our problem data are  $b, s, r \in \mathbf{R}_+$ , which denote the price to stock, sell, and return a unit of newspaper, respectively. Lastly, we let the random variable  $d \sim \text{Categorical}$  model the uncertain (newspaper) demand.

We can pose the news vendor problem as the following two-stage stochastic program:

$$\begin{aligned} & \underset{x}{\text{minimize}} && bx + \mathbf{E} Q(x) \\ & \text{subject to} && 0 \leq x \leq u, \end{aligned}$$

where  $Q(x) = \min_{y_1, y_2} -(sy_1 + ry_2)$

$$\begin{aligned} \text{s.t.} &&& y_1 + y_2 \leq x \\ &&& 0 \leq y_1 \leq d \\ &&& y_2 \geq 0. \end{aligned}$$

A `cvxstoc` implementation of the news vendor problem is given in Listing 2; in contrast, a PySP [26] implementation (see the supplementary material) required 111 lines spanning 6 files.

```
# Create problem data
b, s, r, u = 10, 25, 5, 150
d_probs = [0.3, 0.6, 0.1]
d_vals = [55, 139, 141]
```

```
d = RandomVariableFactory().create_categorical_rv(
    d_vals, d_probs)

# Create optimization variables
x = NonNegative()
y1, y2 = NonNegative(), NonNegative()

# Create second stage problem
obj = -s*y1 - r*y2
constrs = [y1+y2<=x, y1<=d]
p2 = Problem(Minimize(obj), constrs)
Q = partial_optimize(p2, [y1, y2], [x])

# Create and solve first stage problem
p1 = Problem(Minimize(b*x + expectation(Q(x), want_de=
    True)), [x<=u])
p1.solve()
```

**Listing 2:** A `cvxstoc` implementation of the news vendor problem.

We can also represent a stochastic program by means of an *influence diagram*, a directed acyclic graph, where circular nodes correspond to random variables, square nodes correspond to decision variables, diamond nodes correspond to costs, and edges flow from node  $x$  to node  $y$  iff the value of node  $y$  depends in some way on the value of node  $x$ ; Fig. 2 presents the influence diagram for the news vendor problem.

**Figure 2:** The influence diagram for the news vendor problem.

## 4.3 PORTFOLIO OPTIMIZATION

In portfolio optimization, we wish to maximize wealth while meeting certain restrictions on risk, in the face of uncertain asset prices; we can pose a standard portfolio optimization problem [12], subject to two kinds of risk constraints, as a stochastic program.

The risk constraints we consider here are the *value-at-risk* (VaR) (see, e.g., [25, chap. 29]) and *conditional value-at-risk* (CVaR) (e.g., [19], [23, page 286]); intuitively, VaR allows the modeler to control the probability of a loss (on asset sales) beyond a (modeler-defined) threshold, and is often nonconvex, while CVaR allows the modeler to control the expected value of such a loss, and is convex.

Our optimization variables are the allocation vector (across a set of  $n$  assets)  $x \in \mathbf{R}^n$ , and the CVaR  $\beta \in \mathbf{R}$ ; the prob-

lem data is the loss threshold  $u \in \mathbf{R}_+$ , and the vector of returns  $p \sim \text{Normal}(\bar{p}, \Sigma)$ .

We can pose a CVaR-constrained portfolio optimization problem as

$$\begin{aligned} & \underset{x, \beta}{\text{minimize}} && \mathbf{E} -p^T x \\ & \text{subject to} && \beta + 1/(1 - \eta) \mathbf{E}(-p^T x - \beta)_+ \leq u \quad (7) \\ & && \mathbf{1}^T x = 1, \quad x \succeq 0, \end{aligned}$$

where  $(z)_+ := \max\{0, z\}$ .

A `cvxstoc` implementation of the CVaR-constrained portfolio optimization problem is given in Listing 3.

```
# Create problem data
n = 10
pbar, Sigma = numpy.random.randn(n), numpy.eye(n)
p = RandomVariableFactory().create_normal_rv(pbar,
      ↪ Sigma)
u, eta, m = numpy.random.rand(), 0.95, 100

# Create optimization variables
x, beta = NonNegative(n), Variable()

# Create and solve optimization problem
cvar = expectation(pos(-x.T*p - beta), m)
cvar = beta + 1/(1-eta)*cvar
prob = Problem(Minimize(expectation(-x.T*p, m)),
      [x.T*numpy.ones((n,1)) == 1, cvar<=u])
prob.solve()
```

**Listing 3:** A `cvxstoc` implementation of the CVaR-constrained portfolio optimization problem.

We can also pose a VaR-constrained portfolio optimization problem as

$$\begin{aligned} & \underset{x}{\text{minimize}} && \mathbf{E} -p^T x \\ & \text{subject to} && \mathbf{Prob}(p^T x \leq 0) \leq 1 - \eta \quad (8) \\ & && \mathbf{1}^T x = 1, \quad x \succeq 0. \end{aligned}$$

As per Sec. 3.3, DCSP replaces the chance constraint in (8) with a sample average approximation (SAA) to a (more conservative) CVaR constraint (making (8) equivalent to (7)). We investigate the quality of this approximation in the special case where  $p \sim \text{Normal}(\bar{p}, \Sigma)$ , in which case both the VaR and CVaR constraints have analytic forms [18]: the VaR constraint can be expressed as

$$\bar{p}^T x \geq \Phi^{-1}(\eta) \|\Sigma^{1/2} x\|_2, \quad (9)$$

where  $\Phi^{-1}(\cdot)$  is the inverse standard normal cumulative distribution function, while the CVaR constraint can be expressed as

$$\bar{p}^T x \geq \exp\left(-(\Phi^{-1}(\eta))^2/2\right) / \left(\sqrt{2\pi}(1 - \eta) \|\Sigma^{1/2} x\|_2\right). \quad (10)$$

Fig. 3 plots the optimal value (*i.e.*, wealth) of the VaR-constrained portfolio optimization problem (8), the CVaR-constrained portfolio optimization problem (7), and a SAA to (7): we see that the wealth obtained by constraining VaR is indeed less conservative than by constraining CVaR. The

SAA also obtains reasonable accuracy after roughly 100 Monte Carlo samples. Fig. 4 plots the probability of a SAA to (7) vs. the number of Monte Carlo samples, and has a similar interpretation.

**Figure 3:** The optimal values (higher means more wealth) of the VaR-constrained portfolio optimization problem (8) (green), the CVaR-constrained portfolio optimization problem (7) (red), and a SAA to (7) (blue) with 95% confidence intervals (light blue) vs. the number of Monte Carlo samples; the problem size  $n = 50$ , although similar results hold across a variety of problem sizes.

#### 4.4 OPTIMAL POWER FLOW

Consider a network  $G = (\mathcal{V}, \mathcal{E})$ , with a set of vertices  $\mathcal{V}$  and a set of edges  $\mathcal{E}$ , that models an electrical grid: *i.e.*, a subset of the vertices  $\mathcal{G} \subseteq \mathcal{V}$  are *generators*, which produce power, the remaining vertices  $\mathcal{L} = \mathcal{V} \setminus \mathcal{G}$  are *loads*, which consume power, and an edge is drawn between a generator and a load if and only if there is a (physical) transmission line between them.

In the standard optimal power flow problem, we wish to minimize the total cost of generating power, while satisfying demand, subject to the topology of the network and per-generator capacity constraints. We often do not have complete control over all the generators in the grid, so we denote the subset of generators that we do have control over as  $\mathcal{G}_1$ , and also define  $\mathcal{G}_2 = \mathcal{G} \setminus \mathcal{G}_1$ ; we also define  $G = |\mathcal{G}|$ ,  $G_1 = |\mathcal{G}_1|$ ,  $G_2 = |\mathcal{G}_2|$ , and  $L = |\mathcal{L}|$ . We write the per-generator costs as  $c_{\mathcal{G}_1} \in \mathbf{R}^{G_1}$  and  $c_{\mathcal{G}_2} \in \mathbf{R}^{G_2}$ , and the per-generator lower and upper (respectively) limits as  $l$  and  $u \in \mathbf{R}^G$ .

The topology/demand constraints can be expressed as  $A p_{\text{lin}} = (p_{\mathcal{G}_1}, p_{\mathcal{G}_2}, p_{\mathcal{L}})$ , where  $A \in \mathbf{R}^{n \times E}$  is the incidence matrix for the (directed) graph  $G$ ,  $p_{\mathcal{G}_1} \in \mathbf{R}^{G_1}$  and  $p_{\mathcal{G}_2} \in \mathbf{R}^{G_2}$  are variables denoting (nonnegative) power generation,  $p_{\mathcal{L}} \in \mathbf{R}^L$  are constants denoting the (non-positive) power consumption at the loads, and  $p_{\text{lin}} \in \mathbf{R}^E$  are vari-

**Figure 4:** The probability of a SAA to (7) (blue) with 95% confidence intervals (light blue) and  $\beta$  (red) vs. the number of Monte Carlo samples; the problem size  $n = 50$ , although similar results hold across a variety of problem sizes.

ables denoting the power flowing through each edge.

Now, additionally consider the presence of a set of renewable generators (*e.g.*, wind farms), which we denote  $\mathcal{W}$ , whose (intermittent) generation an operator can either sell on the *spot market* [17], or use to power loads. We let  $W = |\mathcal{W}|$ , and model this situation with a random vector  $p_{\mathcal{W}} \in \mathbf{R}^W$ ,  $(p_{\mathcal{W}})_i \sim \text{LogNormal}(\mu_i, \sigma_i^2)$ ,  $i = 1, \dots, W$ .

We can cast this as the following optimization problem:

$$\text{minimize}_{p_{\mathcal{G}_1}} \mathbf{E} Q(p_{\mathcal{G}_1})$$

where

$$Q(p_{\mathcal{G}_1}) = \min_{p_{\mathcal{G}_2}, z, p_{\text{lin}}} \begin{bmatrix} c_{\mathcal{G}_1} \\ c_{\mathcal{G}_2} \end{bmatrix}^T \begin{bmatrix} p_{\mathcal{G}_1} \\ p_{\mathcal{G}_2} \end{bmatrix} + c_{\mathcal{W}}^T z$$

$$\text{s.t.} \quad A p_{\text{lin}} = \begin{bmatrix} p_{\mathcal{G}_1} \\ p_{\mathcal{G}_2} \\ p_{\mathcal{L}} \\ p_{\mathcal{W}} - z \end{bmatrix}$$

$$0 \preceq z \preceq p_{\mathcal{W}}$$

$$|p_{\text{lin}}| \preceq u_{\text{lin}}$$

$$l_{\mathcal{G}} \preceq \begin{bmatrix} p_{\mathcal{G}_1} \\ p_{\mathcal{G}_2} \end{bmatrix} \preceq u_{\mathcal{G}},$$

$c_{\mathcal{W}}$  is the (nonpositive) revenue obtained by selling renewable power,  $z \in \mathbf{R}^W$  is the decision vector for the renewable generators, and  $u_{\text{lin}}$  are the limits on the power flowing through each edge.

A `cvxstoc` implementation of the stochastic optimal power flow problem is given in Listing 4. We solved this problem on the IEEE 14 Bus Test Case, *i.e.*, with  $n = 14$ ,  $G_1 = 1$ ,  $G_2 = 1$ ,  $W = 1$ , and  $L = 10$ : Fig. 5 presents the results.

```
# Create optimization variables
p_g1, p_g2 = NonNegative(), NonNegative()
z = NonNegative(num_winds)
p_lines = Variable(E)
p_w = RandomVariable(pymc.Lognormal(name="p_w", mu=1,
tau=1, size=num_winds))

# Create second stage problem
p_g = vstack(p_g1, p_g2)
p = vstack(p_g1,
p_g2,
p[load_idxes[:-1]],
p_w-z,
p[load_idxes[-1]])
p2 = Problem(Minimize(p_g.T*c_g + z.T*c_w),
[A*p_lines == p, p_g<=u_gens, z<=p_w,
abs(p_lines)<=u_lines])
Q = partial_optimize(p2, [p_g2, z, p_lines], [p_g1])

# Create and solve first stage problem
p1 = Problem(Minimize(expectation(Q(p_g1), m)))
p1.solve()
```

**Listing 4:** A `cvxstoc` implementation of the optimal power flow problem.

**Figure 5:** The electrical grid and (optimal) power generation for the optimal power flow problem on the IEEE 14 Bus Test Case. Red vertices are generators: a positive number indicates the optimal power generation, while “sec. stg.” denotes an uncontrolled generator. The blue vertex is a (stochastic) renewable generator: its mean available (wind) power is shown above it. Other vertices are loads: their (nonpositive) demanded powers are shown above them.

#### 4.5 ROBUST SUPPORT VECTOR MACHINE

Consider the problem of learning a support vector machine (SVM) from a set of  $m$  data points  $\{(x_i, y_i)\}_{i=1}^m$ . Suppose we would like to (additionally) model the fact that our data collection process is noisy (in order to gain robustness in our solution), by incorporating the belief that (say)  $x_i \sim \text{Normal}(\mu_1, \Sigma_1)$  for all  $i$  where  $y_i = 1$  and  $x_i \sim \text{Normal}(\mu_2, \Sigma_2)$  for all  $i$  where  $y_i = -1$  into the learning process. We can thereby pose the following chance-constrained variant of the canonical (soft-margin)

SVM optimization problem [1]

$$\begin{aligned} & \underset{w, b, \xi_i}{\text{minimize}} && \|w\|_2^2 + C \sum_{i=1}^m \xi_i \\ & \text{subject to} && \text{Prob}(y_i(w^T x_i + b) \geq 1 - \xi_i) \geq \eta, \\ & && \xi_i \geq 0, \quad i = 1, \dots, m, \end{aligned}$$

where  $w \in \mathbf{R}^n$ ,  $b \in \mathbf{R}$ ,  $\xi_i \in \mathbf{R}_+$  for  $i = 1, \dots, m$ ,  $C$  is the regularization trade-off parameter, and  $\eta$  is a large probability (e.g., 0.95)<sup>9</sup>.

A `cvxstoc` implementation of the robust SVM problem is given in Listing 5.

```
w, b, xi = Variable(n), Variable(), NonNegative(m)

constr = []
Sigma = 0.1*numpy.eye(n)
for i in range(m):
    mu = numpy.array(X[i])[0]
    x = RandomVariableFactory().create_normal_rv(mu,
    ↪ Sigma)
    chance = prob(-y[i]*(w.T*x+b) >= (xi[i]-1), ns)
    constr += [chance <= eta]

p = Problem(Minimize(norm(w,2) + C*sum_entries(xi)),
            constr)
p.solve()
```

**Listing 5:** A `cvxstoc` implementation of the robust SVM problem.

## 4.6 BUDGETED LEARNING OF A CLASSIFIER IN A CASCADE

Suppose we are interested in learning a (single) classifier that is part of a system (cascade) of classifiers; *i.e.*, we are interested in estimating the parameters  $a \in \mathbf{R}^n$  and  $b \in \mathbf{R}$  of a first stage classifier, whose output is to be (somehow) combined with the output of a second stage classifier, before presenting the combined output to a user<sup>10</sup>.

If we knew the second stage classifier’s parameters, then our learning task would be trivial. Instead, we choose to model our uncertainty as follows: we assume that we *do* know the second stage classifier’s loss function, but remain uncertain of its feature representation. We can pose this as a two-stage stochastic program, where the expectation in the second stage is taken over all possible feature representations for the second stage classifier; for instance, if the cascade is being used for document classification, then we might posit that each possible feature representation in the second stage is a function of a sample of a word from a generative model (e.g., latent Dirichlet allocation).

We additionally assume that there is some overall test time budget on the cascade, which we express as an upper bound  $u \in \mathbf{R}_+$  on the quantity  $\|a\|_1 + \|c\|_1$ , where  $c \in \mathbf{R}^q$  are the parameters of the second stage classifier [27].

<sup>9</sup>We note that this formulation is quite fine-grained, in the sense that per-data point noise models/distributions, as well as mistake probabilities, may be specified.

<sup>10</sup>Such scenarios are common in web search: see, e.g., [27].

Concretely, we can write this optimization problem as

$$\begin{aligned} & \underset{a, b}{\text{minimize}} && L_1(a, b; \{x_i, y_i\}_{i=1}^m) + \mathbf{E} Q(a, b), \\ & \text{where } Q(a, b) = && \underset{c, d}{\min} L_2(c, d; \{z_i, w_i\}_{i=1}^p) \\ & && \text{s.t. } \|a\|_1 + \|c\|_1 \leq u, \end{aligned}$$

$\{(x_i, y_i)\}_{i=1}^m$  is the (fixed) training set of  $m$  points in  $\mathbf{R}^n$  for the first stage classifier, and  $\{(z_i, w_i)\}_{i=1}^p$  is the (stochastic) training set of  $p$  points in  $\mathbf{R}^q$  for the second stage classifier.

A `cvxstoc` implementation, where  $L_1$  and  $L_2$  are (both) taken to be the  $\ell_2$ -regularized log loss, is given in Listing 6.

```
# Create optimization variables
a, b = Variable(n), Variable()
c, d = Variable(q), Variable()

# Create second stage problem
obj2 = [log_sum_exp(vstack(0, -w[i]*(c.T*z[i]+d)))
        for i in range(p)]
budget = norm1(a) + norm1(c)
p2 = Problem(Minimize(sum(obj2) + C*norm(c,2)),
            [budget<=u])
Q = partial_optimize(p2, [c,d], [a,b])

# Create and solve first stage problem
obj1 = [log_sum_exp(vstack(0, -y[i]*(x[i]*a+b)))
        for i in range(m)]
p1 = Problem(Minimize(sum(obj1) + C*norm(a,2) +
            expectation(Q(a,b), ns)), [])
p1.solve()
```

**Listing 6:** A `cvxstoc` implementation of the budgeted learning of a classifier in a cascade problem.

## 5 CONCLUSION

We described disciplined convex stochastic programming (DCSP), a modeling framework that can significantly lower the barrier for modelers to specify and solve convex stochastic programs. We presented a number of sample implementations of stochastic programs that illustrated DCSP’s expressivity; in contrast, other frameworks often require significantly more effort from the modeler to express the problem and/or manipulate it into standard form, support a limited number of stochastic programming constructs, and cannot express certain families of convex optimization problems.

## Abstract

Affect Control Theory (ACT) is a mathematical model that makes accurate predictions about human behaviour across a wide range of settings. The predictions, which are derived from statistics about human actions and identities in real and laboratory environments, are shared *prescriptive* and *affective* behaviours that are believed to lead to solutions to everyday cooperative problems. A generalisation of ACT, called *BayesAct*, allows the principles of ACT to be used for human-interactive agents by combining a probabilistic version of the ACT dynamical model of affect with a utility function encoding external goals. Planning in *BayesAct*, which we address in this paper, then allows one to go beyond the affective prescription, and leads to the emergence of more complex interactions between “cognitive” and “affective” reasoning, such as deception leading to manipulation and altercasting. We use a continuous variant of a successful Monte-Carlo tree search planner (POMCP) that dynamically discretises the action and observation spaces while planning. We give demonstrations on two classic two-person social dilemmas.

## 1 INTRODUCTION

*BayesAct* [4, 20, 21, 22] is a partially-observable Markov decision process (POMDP) model of affective interactions between a human and an artificial agent. *BayesAct* is based upon a sociological theory called “Affect Control Theory” (ACT) [16], but generalises this theory by modeling affective states as probability distributions, and allowing decision-theoretic reasoning about affect. *BayesAct* posits that humans will strive to achieve consistency in shared affective cultural sentiments about events, and will seek to increase *alignment* (decrease *deflection*) with other agents (including artificial ones). Importantly, this need to align

implicitly defines an affective heuristic (a *prescription*<sup>1</sup>) for making decisions quickly within interactions. Agents with sufficient resources can do further planning beyond this prescription, possibly allowing them to manipulate other agents to achieve individual profit in collaborative games.

*BayesAct* arises from the symbolic interactionist tradition in sociology and proposes that humans learn and maintain a set of *shared* cultural affective *sentiments* about people, objects, behaviours, and about the dynamics of interpersonal events. Humans use a simple affective mapping to appraise individuals, situations, and events as sentiments in a three dimensional vector space of evaluation (good vs. bad), potency (strong vs. weak) and activity (active vs. inactive). These mappings can be measured, and the culturally shared consistency has repeatedly been demonstrated to be extremely robust in large cross-cultural studies [17, 29]. Many believe this consistency “gestalt” is a keystone of human intelligence. Humans use it to make predictions about what others will do, and to guide their own behaviour. The shared sentiments, and the resulting *affective ecosystem* of vector mappings, encodes a set of social prescriptions that, if followed by all members of a group, results in an equilibrium or *social order* [14] which is optimal for the group as a whole, rather than for individual members. Humans living at the equilibrium “feel” good and want to stay there. The evolutionary consequences of this individual need are beneficial for the species.

Nevertheless, humans are also a curious, crafty and devious bunch, and often use their cortical processing power to go beyond these prescriptions, finding individually beneficial strategies that are still culturally acceptable, but that are not perfectly normative. This delicate balance is maintained by evolution, as it is beneficial for the species to avoid foundering within a rigid set of rules. In this paper, starting from the principles of *BayesAct*, we investigate how planning beyond cultural prescriptions can result in deceptive or manipulative strategies in two-player social dilemma games. To handle the continuous state, action and observation spaces in *BayesAct*, we use a Monte-Carlo tree

---

<sup>1</sup>We prefer *prescription*, but also use *norm*, although the latter must not be mis-interpreted as logical rules (see Section 5).

search (MCTS) algorithm that dynamically clusters observations and actions, and samples actions from the *BayesAct* prescriptions as a distribution over the action space.

This paper makes two contributions. First, it describes how to use MCTS planning in *BayesAct*, and gives arguments for why this is an appropriate method. This idea was only hinted at in [22]. Second, it shows how this planning can lead to realistic and manipulative behaviours in the *prisoner’s dilemma* and *battle of the sexes* games.

## 2 BACKGROUND

### 2.1 Partially Observable Markov Decision Processes

A partially observable Markov decision process (POMDP) [1] is a stochastic control model that consists of a finite set  $\mathcal{S}$  of states; a finite set  $\mathcal{A}$  of actions; a stochastic transition model  $\Pr : \mathcal{S} \times \mathcal{A} \rightarrow \Delta(\mathcal{S})$ , with  $\Pr(s'|s, a)$  denoting the probability of moving from state  $s$  to  $s'$  when action  $a$  is taken, and  $\Delta(\mathcal{S})$  is a distribution over  $\mathcal{S}$ ; a finite observation set  $\Omega_s$ ; a stochastic observation model,  $\Pr(\omega_s|s)$ , denoting the probability of making observation  $\omega_s \in \Omega_s$  while the system is in state  $s$ ; and a reward assigning  $R(a, s')$  to a transition to  $s'$  induced by action  $a$ . A *policy* maps *belief states* (i.e., distributions over  $\mathcal{S}$ ) into actions, such that the expected discounted sum of rewards is (approximately) maximised. We use *factored* POMDPs in which the state is represented by the cross-product of a set of variables or features. POMDPs have been used as models for many human-interactive domains, including assistive technologies [19].

### 2.2 Affect Control Theory

Affect Control Theory (ACT) arises from work on the psychology and sociology of human social interaction [16]. ACT proposes that social perceptions, behaviours, and emotions are guided by a psychological need to minimize the differences between culturally shared fundamental affective sentiments about social situations and the transient impressions resulting from the interactions between elements within those situations. Fundamental sentiments,  $\mathbf{f}$ , are representations of social objects, such as interactants’ identities and behaviours, as vectors in a 3D affective space, hypothesised to be a universal organising principle of human socio-emotional experience [29]. The basis vectors of affective space are called Evaluation/valence, Potency/control, and Activity/arousal (EPA). EPA profiles of concepts can be measured with the *semantic differential*, a survey technique where respondents rate affective meanings of concepts on numerical scales with opposing adjectives at each end (e.g., good, nice vs. bad, awful for E, weak, little vs. strong, big for P, and calm, passive vs. exciting, active for A). Affect control theorists have compiled lexicons of a few thousand words along with average EPA ratings obtained from survey participants who are knowledgeable about their culture [17]. For example, most

English speakers agree that professors are about as nice as students (E), more powerful (P) and less active (A). The corresponding EPAs are [1.7, 1.8, 0.5] for professor and [1.8, 0.7, 1.2] for student<sup>2</sup>. In Japan, professor has the same P (1.8) but students are seen as less powerful (-0.21).

The three dimensions were found by Osgood to be extremely robust across time and cultures. More recently these three dimensions are also thought to be related directly to intrinsic reward [12]. That is, it seems that reward is assessed by humans along the same three dimensions: Evaluation roughly corresponds with expected value, Potency with risk (e.g. powerful things are more risky to deal with, because they do what they want and ignore you), and Activity corresponds roughly with uncertainty, increased risk, and decreased values (e.g. faster and more excited things are more risky and less likely to result in reward) [12]. Similarly, Scholl argues that the three dimensions are in correspondence with the major factors governing choice in social dilemmas [33]. Evaluation is a measure of affiliation or correspondence between outcomes: agents with similar goals will rate each other more positively. Potency is a measure of dependence: agents who can reach their goals independently of other agents are more powerful. Activity is a measure of the magnitude of dependence: agents with bigger payoffs will tend to be more active.

Social events can cause transient impressions,  $\tau$  (also three dimensional in EPA space) of identities and behaviours that may deviate from their corresponding fundamental sentiments,  $\mathbf{f}$ . ACT models this formation of impressions from events with a grammar of the form actor-behaviour-object. Consider for example a professor (actor) who yells (behaviour) at a student (object). Most would agree that this professor appears considerably less nice (E), a bit less potent (P), and certainly more aroused (A) than the cultural average of a professor. Such transient shifts in affective meaning caused by specific events are described with models of the form  $\tau' = M\mathcal{G}(\mathbf{f}', \tau)$ , where  $M$  is a matrix of statistically estimated prediction coefficients from empirical impression-formation studies and  $\mathcal{G}$  is a vector of polynomial features in  $\mathbf{f}'$  and  $\tau$ . In ACT, the weighted sum of squared Euclidean distances between fundamental sentiments and transient impressions is called *deflection*, and is hypothesised to correspond to an aversive state of mind that humans seek to avoid. This *affect control principle* allows ACT to compute *prescriptive* actions for humans: those that minimize the deflection. Emotions in ACT are computed as a function of the difference between fundamentals and transients [16], and are thought to be communicative signals of vector deflection that help maintain alignment between cooperative agents. ACT has been shown to be highly accurate in explaining verbal behaviours of mock leaders in a computer-simulated business [34], and group dynamics [18], among others [27].

<sup>2</sup> All EPA labels and values in the paper are taken from the Indiana 2002-2004 ACT lexicon [17]. Values range by historical convention from -4.3 to +4.3.

### 2.3 Bayesian Affect Control Theory

Recently, ACT was generalised and formulated as a POMDP for human-interactive artificially intelligent systems [22]. This new model, called *BayesAct*, generalises the original theory in three ways. First, sentiments and impressions are viewed as probability distributions over latent variables (e.g.,  $\mathbf{f}$  and  $\boldsymbol{\tau}$ ) rather than points in the EPA space, allowing for multimodal, uncertain and dynamic affective states to be modeled and learned. Second, affective interactions are augmented with *propositional* states and actions (e.g. the usual state and action space considered in AI applications). Third, an explicit reward function allows for goals that go beyond simple deflection minimization. We give a simplified description here; see [21, 22] for details.

A *BayesAct* POMDP models an interaction between two agents (human or machine) denoted *agent* and *client*. The state,  $\mathbf{s}$ , is the product of six 3-dimensional continuous random variables corresponding to fundamental and transient sentiments about the *agent*'s identity ( $\mathbf{F}_a, \mathbf{T}_a$ ), the current (*agent* or *client*) behaviour ( $\mathbf{F}_b, \mathbf{T}_b$ ) and the *client*'s identity ( $\mathbf{F}_c, \mathbf{T}_c$ ). We use  $\mathbf{F} = \{\mathbf{F}_a, \mathbf{F}_b, \mathbf{F}_c\}$  and  $\mathbf{T} = \{\mathbf{T}_a, \mathbf{T}_b, \mathbf{T}_c\}$ . The state also contains an application-specific set of random variables  $\mathbf{X}$  that are interpreted as *propositional* (i.e. not *affective*) elements of the domain (e.g. whose turn it is, game states - see Section 4), and we write  $\mathbf{s} = \{\mathbf{f}, \boldsymbol{\tau}, \mathbf{x}\}$ . Here the *turn* is deterministic (*agent* and *client* take turns), although this is not necessary in *BayesAct*. The *BayesAct* reward function is application-specific over  $\mathbf{x}$ . The state is not observable, but observations  $\Omega_x$  and  $\Omega_f$  are obtained for  $\mathbf{X}$  and for the affective behaviour  $\mathbf{F}_b$ , and modeled with probabilistic observation functions  $Pr(\omega_x|\mathbf{x})$  and  $Pr(\omega_f|\mathbf{f}_b)$ , respectively.

Actions in the *BayesAct* POMDP are factored in two parts:  $\mathbf{b}_a$  and  $a$ , denoting the *affective* and *propositional* components, respectively. For example, if a tutor gives a hard exercise to do, the manner in which it is presented, and the difficulty of the exercise, combine to form an affective impression  $\mathbf{b}_a$  that is communicated. The actual exercise (content, difficulty level, etc) is the *propositional* part,  $a$ .

The state dynamics factors into three terms as  $Pr(\mathbf{s}'|\mathbf{s}, \mathbf{b}_a, a) = Pr(\boldsymbol{\tau}'|\boldsymbol{\tau}, \mathbf{f}', \mathbf{x})Pr(\mathbf{f}'|\mathbf{f}, \boldsymbol{\tau}, \mathbf{x}, \mathbf{b}_a)Pr(\mathbf{x}'|\mathbf{x}, \mathbf{f}', \boldsymbol{\tau}', a)$ , and the fundamental behaviour,  $\mathbf{F}_b$ , denotes either observed *client* or taken *agent* affective action, depending on whose *turn* it is (see below). That is, when *agent* acts, there is a deterministic mapping from the affective component of his action ( $\mathbf{b}_a$ ) to the *agent*'s behaviour  $\mathbf{F}_b$ . When *client* acts, *agent* observes  $\Omega_f$  (the affective action of the other agent). The third term in the factorization of the state dynamics is the *Social Coordination Bias*, and is described in Section 2.4. Now we focus on the first two terms.

The transient impressions,  $\mathbf{T}$ , evolve according to the impression-formation operator in ACT ( $M\mathcal{G}$ ), so that  $Pr(\boldsymbol{\tau}'|\dots)$  is deterministic. Fundamental sentiments are expected to stay approximately constant over time, but are subject to random drift (with noise  $\Sigma_f$ ) and are expected

to also remain close to the transient impressions because of the *affect control principle*. Thus, the dynamics of  $\mathbf{F}$  is<sup>3</sup>:

$$Pr(\mathbf{f}'|\mathbf{f}, \boldsymbol{\tau}) \propto e^{-\psi(\mathbf{f}', \boldsymbol{\tau}) - \xi(\mathbf{f}', \mathbf{f})} \quad (1)$$

where  $\psi \equiv (\mathbf{f}' - M\mathcal{G}(\mathbf{f}', \boldsymbol{\tau}))^T \Sigma^{-1} (\mathbf{f}' - M\mathcal{G}(\mathbf{f}', \boldsymbol{\tau}))$  combines the *affect control principle* with the impression formation equations, assuming Gaussian noise with covariance  $\Sigma$ . The inertia of fundamental sentiments is  $\xi \equiv (\mathbf{f}' - \mathbf{f})^T \Sigma_f^{-1} (\mathbf{f}' - \mathbf{f})$ , where  $\Sigma_f$  is diagonal with elements  $\beta_a, \beta_b, \beta_c$ . The state dynamics are non-linear due to the features in  $\mathcal{G}$ . This means that the belief state will be non-Gaussian in general, and *BayesAct* uses a *bootstrap filter* [11] to compute belief updates.

The distribution in (1) gives the prescribed (if *agent* turn), or expected (if *client* turn), action as the component  $\mathbf{f}'_b$  of  $\mathbf{f}'$ . Thus, by integrating over  $\mathbf{f}'_a$  and  $\mathbf{f}'_c$  and the previous state, we obtain a probability distribution,  $\pi^\dagger$ , over  $\mathbf{f}'_b$  that acts as a *normative action bias*: it tells the agent what to expect from other agents, and what action is expected from it in belief state  $b(\mathbf{s})$ :

$$\pi^\dagger(\mathbf{f}'_b) = \int_{\mathbf{f}'_a, \mathbf{f}'_c} \int_{\mathbf{s}} Pr(\mathbf{f}'|\mathbf{f}, \boldsymbol{\tau}, \mathbf{x}) b(\mathbf{s}) \quad (2)$$

### 2.4 BayesAct Instances

As affective identities ( $\mathbf{f}_a, \mathbf{f}_c$ ) are latent (unobservable) variables, they are learned (as inference) in the POMDP. If behaving normatively (according to the *normative action bias*), an agent will perform affective actions  $\mathbf{b}_a = \arg \max_{\mathbf{f}'_b} \pi^\dagger(\mathbf{f}'_b)$  that allow other agents to infer what his (true) identity is. The *normative action bias* (NAB) defines an affective signaling mechanism as a shared set of prescriptions for translating information about identity into messages. In *BayesAct*, the NAB is given by Equation (2).

The NAB is only prescriptive: all agents are free to select individually what they really send, allowing for deception (e.g. “faking” an identity by sending incorrect information in the affective dimension of communication). Possible outcomes are manipulation (the other agent responds correctly, as its own identity, to the “fake” identity), and intercasting (the other agent assumes a complementary identity to the faked identity, and responds accordingly), both possibly leading to gains for the deceptive agent.

The dynamics of  $\mathbf{X}$  is given by  $Pr(\mathbf{x}'|\mathbf{f}', \boldsymbol{\tau}', \mathbf{x}, a)$ , that we refer to as the *social coordination bias* (SCB): it defines what agents are expected to do (how the state is expected to change, including other agents' propositional behaviours) in a situation  $\mathbf{x}$  when action  $a$  was taken that resulted in sentiments  $\mathbf{f}'$  and  $\boldsymbol{\tau}'$ . For example, we may expect faster student learning if deflection is low, as cognitive resources do not need to be spent dealing with mis-alignment.

The SCB is a set of shared rules about how agents, when acting normatively, will behave *propositionally* (action  $a$ ,

<sup>3</sup>We leave out the dependence on  $\mathbf{x}$  for clarity, and on  $\mathbf{b}_a$  since this is replicated in  $\mathbf{f}'_b$ .

as opposed to affectively with action  $\mathbf{b}_a$ ). Assuming identities are correctly inferred (as insured by the shared nature of the NAB), each agent can both recognize the type of the other agent and can thereby uncover an optimistic policy<sup>4</sup> that leads to the normative mean accumulated future reward (as defined by the social coordination bias). However, with sufficient resources, an agent can use this prescribed action as a heuristic only, searching for nearby actions that obtain higher individual reward. For example, a teacher who seems very powerful and ruthless at the start of a class, often may choose to do so (in a way that would be inappropriate in another setting, e.g., the home, but is appropriate within the classroom setting) in order to establish a longer-term relationship with her students. The teacher’s actions feel slightly awkward if looked at in the context of the underlying social relationship with each student (e.g. as would be enacted according to normative *BayesAct*), but are leading to longer-term gains (e.g. the student passes).

Thus, the NAB (along with a communication mechanism) allows the relaying of information about identity, while the SCB allows agents to make predictions about other agents’ future actions *given* the identities. This combination allows agents to assume cooperative roles in a joint task, and is used as an emotional “fast thinking” heuristic (Kahneman’s “System 1” [23]). If agents are fully cooperative and aligned, then no further planning is required to ensure goal achievement. Agents do what is expected (which may involve planning over  $\mathbf{X}$ , but not  $\mathbf{F}$  and  $\mathbf{T}$ ), and expect others to as well. However, when alignment breaks down, or in non-cooperative situations, then slower, more deliberative (“System 2”) thinking arises. The Monte-Carlo method in Section 3 naturally trades-off slow vs. fast thinking.

### 3 POMCP-C

POMCP [36] is a Monte-Carlo tree search algorithm for POMDPs that progressively builds a search tree consisting of nodes representing histories and branches representing actions or observations. It does this by generating samples from the belief state, and then propagating these samples forward using a blackbox simulator (the known POMDP dynamics). The nodes in the tree gather statistics on the number of visits, states visited, values obtained, and action choices during the simulation. Future simulations through the same node then use these statistics to choose an action according to the UCB1 formula, which adds an exploration bonus to the value estimate based on statistics of state visits (less well-visited states are made to look more salient or promising). Leaves of the tree are evaluated using a set of *rollouts*: forward simulations with random action selection. The key idea is that fast and rough rollouts blaze the trail for the building of the planning tree, which is more carefully explored using the UCB1 heuristic. POMCP uses a timeout (processor or clock time) providing an anytime solution.

<sup>4</sup>optimistic in the sense that it assumes all agents will also follow the same normative policy.

In our algorithm, POMCP-C, we make use of an *action bias*,  $\pi_{heur}$ : a probability distribution over the action space that guides action choices<sup>5</sup>. In *BayesAct*, we naturally have such a bias: the normative action bias (for  $\mathbf{b}_a$ ) and the social coordination bias (for  $a$ ). At each node encountered in a POMCP-C simulation (at history  $h$ ), an action-observation pair is randomly sampled as follows. First, a random sample is drawn from the action bias,  $\mathbf{a} \sim \pi_{heur}$ . The action  $\mathbf{a}$  is then compared to all existing branches at the current history, and a new branch is only created if it is significantly different, as measured by distance in the action space (Euclidean for  $\mathbf{b}_a$ , binary for  $a$ ) and a threshold parameter  $\delta_a$  (‘action resolution’), from any of these existing branches. If a new branch is created, the history  $ha$  is added to the planning tree, and is evaluated with a rollout as usual. If a new branch is not created, then a random sample  $o$  is drawn from the observation distribution  $Pr(o|h, a)$ <sup>6</sup>.

The continuous observation space raises two significant problems. First, the branching factor for the observations is infinite, and no two observations will be sampled twice. To counter this, we use a dynamic discretisation scheme for the observations, in which we maintain  $\mathbf{o}(h)$ , a set of sets of observations at each history (tree node). So  $\mathbf{o}(h) = \{\mathbf{o}_1, \mathbf{o}_2, \dots, \mathbf{o}_{N_o}\}$ , where  $N_o \in \mathbb{N}$ . A new observation  $o$  is either added to an existing set  $\mathbf{o}_j$  if it is close enough to the mean of that set (i.e. if  $|o - \bar{\mathbf{o}}_j| < \delta_o$  where  $\delta_o$  is a constant, the ‘observation resolution’), or, if not, it creates a new set  $\mathbf{o}_{N_o+1} = \{o\}$ . This simple scheme allows us to dynamically learn the observation discretisation.

The second problem raised by continuous observations stems from the fact that POMCP uses a black box simulator that should draw samples from the same distribution as the environment does. Thus, the simulated search tree replicates actual trajectories of belief, and can be re-used after each action and observation in the real world (after each pruning of the search tree). This works for discrete observations, but it may not work for continuous observations since the same observation will rarely be encountered twice. Here, we prune the tree according to the closest observation set  $\mathbf{o}_j$  to the observation obtained (see also [4]).

## 4 EXPERIMENTS AND RESULTS

We present highlights of results on two social dilemmas. Full results and other experiments are in [4].

### 4.1 Prisoner’s Dilemma (Repeated)

The prisoner’s dilemma is a classic two-person game in which each person can either *defect* by taking \$1 from a (common) pile, or *cooperate* by giving \$10 from the same pile to the other person. There is one Nash equilibrium in which both players defect, but when humans play the game

<sup>5</sup>The idea of using a heuristic to guide action selection in POMCP was called *preferred actions* [36].

<sup>6</sup>POMCP-C also uses a cut-off  $N_A^{max}$  on the branching factor.

they often are able to achieve the optimal solution where both cooperate. A rational agent would first compute the strategy for the game as the Nash equilibrium (of “defect”), and then look up the affective meaning of such an action using e.g. a set of appraisal rules, and finally apply a set of coping rules. For example, such an agent might figure out that the goals of the other agent would be thwarted, and so that he should feel ashamed or sorry for the other agent. However, appraisal/coping theories do not specify the probabilities of emotions, do not take into account the affective identities of the agents, and do not give consistent accounts of how coping rules should be formulated.

Instead, a *BayesAct* agent (called a *pd-agent* for brevity here), computes what *affective* action is prescribed in the situation (given his estimates of his and the other’s identities, and of the affective dynamics), and then seeks the best propositional action ( $a \in \{\textit{cooperate}, \textit{defect}\}$ ) to take that is consistent with this prescribed affect. As the game is repeated, the *pd-agent* updates his estimates of identity (for self and other), and adjusts his play accordingly. For example, a player who defects will be seen as quite negative, and appropriate affective responses will be to defect, or to cooperate and give a nasty look.

The normative action bias (NAB) for *pd-agents* is the usual deflection minimizing affective  $f_b$  given distributions over identities of *agent* and *client* (Equation 2). Thus, if *agent* thought of himself as a *friend* (EPA: {2.75, 1.88, 1.38}) and knew the other agent to be a *friend*, the deflection minimizing action would likely be something good (high E). Indeed, a simulation shows that one would expect a behaviour with EPA= {1.98, 1.09, 0.96}, with closest labels such as *treat* or *toast*. Intuitively, cooperate seems like a more aligned propositional action than defect. This intuition is confirmed by the distances from the predicted (affectively aligned) behaviour to *collaborate with* (EPA: {1.44, 1.11, 0.61}) and *abandon* (EPA: {-2.28, -0.48, -0.84}) of 0.4 and 23.9, respectively. Table 1 shows all combinations if each agent could also be a *scrooge* (EPA: {-2.15, -0.21, -0.54}). We see that a *friend* would still collaborate with a *scrooge* (in an attempt to *reform* the scrooge), a *scrooge* would abandon a *friend* (*look away from* in shame), and two scrooges would defect.

The *agent* will predict the *client*’s behavior using the same principle: compute the deflection minimizing affective action, then deduce the propositional action based on that. Thus, a *friend* would be able to predict that a *scrooge* would defect. If a *pd-agent* has sufficient resources, he could search for an affective action near to his optimal one, but that would still allow him to defect. To get a rough idea of this action, we find the point on the line between his optimal action {0.46, 1.14, -0.27} and *abandon* that is equidistant from *abandon* and *collaborate with*. This point, at which he would change from cooperation to defection, is {-0.8, 0.6, -0.4} (*glare at*), which only has a slightly higher deflection than *reform* (6.0 vs 4.6). Importantly, he is *not trading off costs in the game with costs of disobeying the*

| agent | client | optimal behaviour   | closest labels           | dist. from |      |
|-------|--------|---------------------|--------------------------|------------|------|
|       |        |                     |                          | coll.      | ab.  |
| F     | F      | 1.98, 1.09, 0.96    | treat<br>toast           | 0.4        | 23.9 |

| S     | S      | -0.91, -0.80, -0.01 | borrow money<br>chastise | 9.6        | 2.7  |

Table 1: Optimal (deflection minimising) behaviours for two *pd-agents* with fixed identities. F=friend, S=scrooge, coll.=collaborate with, ab.=abandon

*social prescriptions*: his resource bounds and action search strategy are preventing him from finding the more optimal (individual) strategy, implicitly favoring those actions that benefit the group and solve the social dilemma.

*PD-agents* are dealing with a slightly more difficult situation, as they do not know the identity of the other agent. However, the same principle applies, and the social coordination bias (SCB) is that agents will take and predict the propositional action that is most consistent with the affective action. Agents have culturally shared sentiments about the propositional actions (defection and cooperation), and the distance of the deflection minimizing action (*agent*,  $b_a$ ) or behaviour (*client*,  $f_b$ ) to these sentiments is a measure of how likely each propositional action is to be chosen (*agent* turn), or predicted (*client* turn). That is, on *agent* turn, the affective actions  $b_a$  will be sampled and combined with a propositional action  $a$  sample drawn proportionally to the distance from  $b_a$  to the shared sentiments for each  $a$ . On *client* turn, affective behaviours  $f_b$  will be predicted and combined with a value for a variable representing *client* play in  $\mathbf{X}$  drawn proportionally to the distance from  $f_b$ .

We model *agent* and *client* as having two (simultaneous) identities: *friend* or *scrooge* with probabilities 0.8 and 0.2, respectively. Each *pd-agent* starts with a mixture of two Gaussians centered at these identities with weights 0.8/0.2 and variances of 0.1. The SCB interprets cooperation as *collaborate with* (EPA: {1.44, 1.11, 0.61}) and defection as *abandon* (EPA: {-2.28, -0.48, -0.84}), and the probability of the propositional actions using a Gibbs measure over distance with a variance of 4.0. We use propositional state  $\mathbf{X} = \{\textit{Turn}, \textit{Ag\_play}, \textit{Cl\_play}\}$  denoting whose turn it is ( $\in \{\textit{agent}, \textit{client}\}$ ) and *agent* and *client* state of play ( $\in \{\textit{not\_played}, \textit{cooperate}, \textit{defect}\}$ ). The agents’ reward is only over the game (e.g. 10, 1, or 0), so there is no intrinsic reward for deflection minimization as in [22]. We use a two time-step game in which both *agent* and *client* choose their actions at the first time step, and then communicate this to each other on the second step. The agents also communicate affectively, so that each agent gets to see both what action the other agent took (cooperate or defect), and also *how* they took it (expressed in  $f_b$ )<sup>7</sup>. If one were to imple-

<sup>7</sup>Agents may also relay emotions (see Sec. 2.2), but here we only use emotional labels for explanatory purposes.

ment this game in real life, then  $\mathbf{f}_b$  would be relayed by e.g. a facial expression. We use a Gaussian observation function  $Pr(\omega_f|\mathbf{f}_b)$  with mean at  $\mathbf{f}_b$  and std. dev. of  $\sigma_b = 0.1$ . Our simulations consist of 10 trials of 20 games/trial, but agents use an infinite horizon with a discount  $\gamma$ .

We simulate one *pd-agent* (*pdA*) with a POMCP-C (processor time) timeout value of  $t_a$ , and the other (*pdC*) either: (1), a similar agent with the same timeout  $t_c = t_a$ , or with a timeout of  $t_c = 1s$ ; or (2), a fixed strategy agent that plays one of: (co) always cooperate; (de) always defect; (tt) tit-for-tat; (to): two-out; (t2): tit-for-two-tat; (2t): two-tit-for-tat. Except for (de), these fixed strategy agents always cooperate on the first turn, and then: (tt) mirrors the other agent; (to) cooperates twice, then always defects; (t2): defects if the other agent defects twice in a row; (2t): cooperates if the other agent cooperates twice in a row<sup>8</sup>. Fixed strategy agents always relay *collaborate with* and *abandon* as  $\mathbf{f}_b$  when playing cooperate and defect, respectively.

First, we consider agents that use the same timeout. In this case, if the discount factor is 0.99, both agents cooperate all the time, and end up feeling like *warm*, *earnest* or *introspective ladies*, *visitors* or *bridesmaids* (EPA $\sim\{2, 0.5, 1.0\}$ ). This occurs regardless of the amount of timeout given to both agents. Essentially, both agents are following the norm. If they don't have a long timeout, this is all they can evaluate. With longer timeouts, they figure out that there is no better option. However, if the discount is 0.9 (more discounting, so they will find short-term solutions), then again cooperation occurs if the timeout is short (less than 10s), but then one agent starts trying to defect after a small number of games, and this number gets smaller as the timeout gets longer (see Figure 1). With more discounting, more time buys more breadth of search (the *agent* gets to explore more short-term options), and finds more of them that look appealing (it can get away with a defection for a short while). With less discounting, more time buys more depth, and results in better long-term decisions.

Table 2 shows the first five games with a *client* playing two-out (to), who sends affective values of  $\{1.44, 1.11, 0.61\}$  and cooperates on the first two moves. This affective action makes the *pd-agent* feel much less good (E) and powerful (P) than he normally would (as a *failure*), as he'd expect a more positive and powerful response (such as *flatter* EPA= $\{2.1, 1.45, 0.82\}$ ) if he was a *friend*, so this supports his *scrooge* identity more strongly<sup>9</sup>. He infers *client* is friendly (a *newlywed* is like a *girlfriend* in EPA space). He therefore cooperates on the second round, and feels somewhat better. Then, the *client* defects on the third round, to which the *agent* responds by re-evaluating the *client* as less good (an *immoral purchaser*). He still tries to cooperate, but gives up after two more rounds, after which he thinks of the *client* as nothing but a *selfish hussy*, and himself as a *disapproving divorcée*. The *agent* consistently defects after this point. Interactions with (tt), (2t) and (t2) generally fol-

<sup>8</sup>(t2) is more "generous", and (2t) is more "wary" than (tt).

<sup>9</sup>Examples of more positive affective actions in [4].

| $\gamma$ | (tt)            | (t2)            | (2t)            |
|----------|-----------------|-----------------|-----------------|
| 0.9      | $1.64 \pm 2.24$ | $3.98 \pm 2.48$ | $1.72 \pm 2.35$ |
| 0.99     | $7.33 \pm 1.17$ | $7.28 \pm 1.68$ | $7.63 \pm 0.91$ |

Table 3: Results (avg. rewards) against the tit-for strategies

low a similar pattern, because any defection rapidly leads to both agents adopting long-term defection strategies. However, as shown in Table 3 (also see full results [4]), less discounting leads to better solutions against these strategies, as longer-term solutions are found.

When playing against (co), *pd-agents* generally start by cooperating, then defect, resulting in a feeling of being a *self-conscious divorcée* (EPA: $\{-0.23, -0.62, 0.32\}$ ) playing against a *conscientious stepsister* (EPA: $\{0.12, -0.04, 0.35\}$ ). When playing against (de), *pd-agents* generally start by cooperating, but then defect, feeling like a *dependent klutz* (EPA: $\{-0.76, -1.26, 0.37\}$ ) playing against an *envious ex-boyfriend* (EPA: $\{-1.30, -0.49, -0.13\}$ ).

## 4.2 Affective Cooperative Robots (CoRobots)

*CoRobots* is a multi-agent cooperative robot game based on the classic "Battle of the Sexes" problem<sup>10</sup>. We are specifically interested in asymmetrical situations wherein one robot has more resources and can do planning in order to *manipulate* the other robot, taking advantage of the social coordination bias. We start with a simplified version in which the two robots maintain affective fundamental sentiments, but do not represent the transient impressions. The normative action bias is a simple average instead of as the result of more complex impression formation equations.

Concretely, two robots, Rob1 and Rob2, move in a 1D continuous state space. We denote their positions with variables  $X_1$  and  $X_2$ . At each time step, Rob1, Rob2 take actions  $a_1, a_2 \in \mathbb{R}$  respectively. This updates their respective positions  $x_i, i \in \{1, 2\}$  according to  $x_i \leftarrow x_i + a_i + \nu_i$  and  $\nu_i \sim \mathcal{N}(0, \sigma)$ . There are two fixed locations  $L_1 \in \mathbb{R}^+$  and  $L_2 \in \mathbb{R}^-$ . For each robot, one of these locations is the major goal  $g$  (with associated high reward  $r$ ) and the other is the minor goal  $\bar{g}$  (with associated low reward  $\bar{r}$ ). A robot is rewarded according to its distance from  $g$  and  $\bar{g}$ , but only if the other robot is nearby. The reward for Rob $i$  is:

$$R_i(x_1, x_2) = \mathbb{I}(|x_1 - x_2| < \Delta_x) [r \cdot e^{-(x_i - g)^2 / \sigma_r^2} + \bar{r} \cdot e^{-(x_i - \bar{g})^2 / \sigma_r^2}], \quad (3)$$

where  $\mathbb{I}(y) = 1$  if  $y$  is true, and 0 otherwise, and where  $\sigma_r$  is the reward variance,  $\Delta_x$  is a threshold parameter governing how "close" the robots need to be, and  $r, \bar{r} \in \mathbb{R}$ , such that  $r \gg \bar{r} > 0$ . Both  $\sigma_r$  and  $\Delta_x$  are fixed and known by both robots. Each robot only knows the location of its own major goal. Furthermore, at any time step, each robot

<sup>10</sup>A husband wants to go to a football game, and his wife wants to go shopping, but neither wants to go alone. There are two pure Nash equilibria, but the optimal strategy requires coordination.

Figure 1: PD with client strategy: (same) and discount  $\gamma = 0.9$ . Red=client; Blue=agent; dashed=std.dev.; solid (thin, with markers): mean; solid (thick): median. As timeout increases, more defections give less reward for both agents.

| game # | post-play sentiments ( <i>agent</i> ) |                 |                   | deflection | identities    |           | emotions     |                | actions |        |
|--------|---------------------------------------|-----------------|-------------------|------------|---------------|-----------|--------------|----------------|---------|--------|

Table 2: Example games with *client* playing (to). Identities and emotions are *agent* interpretations.

can move in any direction, receives observations of the locations of both robots, and has a belief over  $X_1$  and  $X_2$ .

In order to coordinate their actions, the robots must relay their reward locations to each other, and must choose a *leader* according to some social coordination bias. The robots each have a 3D *identity* (as *BayesAct*), where the valence,  $\mathbf{f}_{ae}$ , describes their goal: if  $\mathbf{f}_{ae} > 0$ , then  $g = L_1$ . If  $\mathbf{f}_{ae} < 0$ , then  $g = L_2$ . The power and activity dimensions will be used for coordination (see below). Robots can move (propositional action  $a$ ) at any time step, but must coordinate their communications. That is, only one robot can communicate at a time (with affective action  $\mathbf{b}_a$  perceived by the other robot as  $\omega_f$ ), but this turn-taking behaviour is fixed. The normative action bias (NAB) in the first (simplified) CoRobots problem is the mean of the two identities:

$$\pi^\dagger \propto \mathcal{N}((\mathbf{f}_a + \mathbf{f}_c)/2, \Sigma_b). \quad (4)$$

In *BayesAct* Corobots, the NAB is given by Equation (2).

The social coordination bias (that the leader will lead) defines each robot’s action bias for  $a_i$ , and action prediction function (for *client*’s  $x$ ) through a 2D sigmoid *leader* function, known to both agents. This sigmoid function is  $\geq 0.5$  if the *agent* estimates he is more powerful or more active than the *client* ( $(\mathbf{f}_{ap} > \mathbf{f}_{cp}) \vee (\mathbf{f}_{aa} > \mathbf{f}_{ca})$ ) and is  $< 0.5$  otherwise. If the *agent* is the leader, his action bias will be a Gaussian with mean at  $+1.0$  in the direction of his major goal (as defined by  $\mathbf{f}_{ae}$ ), and in the direction of the *client*’s major goal (as defined by his estimate of  $\mathbf{f}_{ce}$ ) otherwise. *Agent*’s prediction of *client*’s motion in  $x$  is that the *client* will stay put if *client* is the leader, and will follow the *agent* otherwise, as given succinctly by:

$$Pr(x'_c | \mathbf{f}'_a, \mathbf{f}'_c) = \mathcal{N}(\mathbb{I}(\text{leader}(\mathbf{f}'_a, \mathbf{f}'_c) \geq 0.5) \lambda_a + x_c, \sigma_p) \quad (5)$$

where  $\lambda_a = 1$  if  $\mathbf{f}'_{ae} > 0$ , and  $-1$  otherwise and  $\sigma_p = 1.0$ .

Figure 2: *BayesAct* Corobots cannot coordinate properly when the communication channel is bad or non-existent.

We first investigate whether corobots can coordinate when they have identities drawn from the set of 500 human (male) identities in the ACT lexicon (see footnote 2). In the first experiment, the two identities are selected at random on each trial. Each corobot knows his self-ID ( $\mathcal{N}(\text{self-ID}, 0.1)$ ) but does not know the other’s ID ( $\mathcal{N}([0.0, 0.0, 0.0], 2.0)$ ). Furthermore, each corobot has a stable self-identity ( $\beta_a = 0.1$ ), but it believes that the other is less stable ( $\beta_c = 2.0$ ). Finally, both corobots have equal POMCP-C planning resources ( $\Sigma_b = 0.5, N_A^{max} = 3, \delta_a = 2.0, \delta_o = 6.0$  and *Timeout* = 2.0 seconds). The other CoRobots game parameters are  $r = 100, \bar{r} = 30, L_1 = 10, L_2 = -10, \sigma_r = 2.5, \Delta_x = 1.0$  and iterations = 30. We run 5 sets of 100 simulated trials of the CoRobots Game with varying *environmental noise*, i.e., we add a normally distributed value, with standard deviation corresponding to the noise level, to the computation and communication of  $\Omega_x$  and  $\Omega_f$  (observations of  $x$  and  $\mathbf{f}$ , resp.). Figure 2 (green line) shows the mean and standard error of mean number of successful coordinations by the corobots.

The percentage of successful coordination falls from 91% to 6% when the environmental noise is increased, and the average total reward per trial falls from 1403 to 19.4. We see that with no environmental noise, the corobots are able to easily learn the other’s identity, and can coordinate based on the social coordination bias. As the environmental noise increases, corobots are unable to easily relay identities, and require a much longer time to find cooperative solutions.

Figure 2 (orange line) shows results where the self-ID is also unknown initially ( $\mathcal{N}([0.0, 0.0, 0.0], 2.0)$ ), and is less stable ( $\beta_a = 2.0$ ). We see that the general trend is the same; however, the corobots have a higher percentage of successful coordinations, and consequently gain a higher average total reward, for the three lowest noise values. It is surprising to see that the corobots perform better with unknown self-IDs. This is because corobots quickly assume contrasting identities (i.e. one assumes a less powerful identity than the other) in order to coordinate. With known self-IDs, however, the corobots show less flexibility and spend the initial few iterations trying to convince and pull the other corobot towards themselves. Due to this rigidity, these corobots suffer a lot when they have similar power; this does not happen when the self-ID is unknown.

Next, we investigate whether one agent can *manipulate* the other. A manipulation is said to occur when the weaker and less active agent deceives the client into believing that the agent is more powerful or active, thereby persuading the client to converge to the agent’s major goal  $g$  (to within  $\pm|0.2g|$ ). In order to demonstrate manipulative behaviour, we introduce asymmetry between the two agents by changing the parameters  $\Sigma_b$ ,  $N_A^{max}$  and  $Timeout$  for one agent (unknown to the other). In addition, we allow this agent to start with a slightly better estimate of the other’s identity. This agent will then sample actions that are farther from the norm than expected by the other agent, and will allow such an agent to “fake” his identity so as to manipulate the other agent. The agent’s and client’s self-identities are noisy ( $\sigma = 0.1$ ) versions of  $[2.0, -1.0, -1.0]$  and  $[-2.0, 1.0, 1.0]$  respectively,  $r = 100$ ,  $\bar{r} = 30$ ,  $L_1 = 5$ ,  $L_2 = -5$ ,  $\Delta_x = 1$ ,  $\sigma_r = 2.5$ ,  $\delta_a = 2.0$ ,  $\delta_o = 6.0$ ,  $N_A^{max} = 3$ ,  $\Sigma_b = 0.5$  and  $Timeout = 2.0$  for both robots. Each game is set to run for 40 iterations, and starts with the agent and client located at 0.0. Since  $g_a = 5$ ,  $g_c = -5$ , both robots should converge to  $g_c = -5$  (*client* is leader) if following normative actions.

When  $N_A^{max} = 3$ ,  $\Sigma_b = 0.5$ , and  $Timeout = 2.0$  for the agent, the agent displays manipulative behaviour in only 80/1000 games, as expected (both follow normative behaviour). If we allow the *agent* to start with a better estimate of the *client*’s identity (*agent*’s initial belief about  $\mathbf{f}_c$  is a Gaussian with mean  $[-2.0, 1.0, 1.0]$  and variance 1.0), we see manipulative behaviour in almost twice as many games (150). However, it is not a significant proportion, because although it spends less time learning the other’s identity, it cannot find much more than the normative behaviour.

Next, we also give the *agent* more planning resources by setting  $N_A^{max} = 6$  and  $\Sigma_b = 2$  for the agent, and we run

Figure 3: CoRobots: With higher  $N_A^{max}$ ,  $\Sigma_b$  and  $Timeout$ , a weaker and less active agent becomes increasingly manipulative by ‘faking’ his identity, and accumulates higher rewards.

10 sets of 100 simulated trials for each of the following values of agent’s  $Timeout$  : 2, 30, 60, 120, 360, 600 seconds<sup>11</sup>. Figure 3 (solid red line) shows means and standard error of agent reward per trial (in each set of 100 trials). As the model incorporates noise in movements as well as observations, the robots spend about 20 initial iterations coordinating with each other to choose a leader, during which time they do not receive reward. Thus, a realistic upper bound on the *agent*’s reward is  $20 \times 100 = 2000$ . Figure 3 shows that at  $Timeout = 600$ , the reward is about 61% of this realistic maximum, which makes sense given the manipulation rate of about 48%. There is a diminishing rate of return as timeout increases in Figure 3 that is explained by the exponential growth of the MCTS search tree as  $Timeout$  increases linearly. The results are relatively insensitive to the choice of parameters such as  $\delta_a$  and  $\delta_o$ .

Finally, we play the CoRobots Game with *BayesAct* Robots. This means that the normative behaviour is the deflection minimising action given by Affect Control Theory, instead of Equation (4), and the transient impressions are used to compute the deflection. The game trials are set up exactly as before, and the results are shown in Figure 3 (blue line). As expected, we see the same trends as those obtained previously, but with correspondingly lower values as the transient impressions are used and introduce further complexity to the planning problem (18D state space rather than 9D). Our results demonstrate that the POMCP-C algorithm is able to find and exploit manipulative affective actions within the *BayesAct* POMDP, and gives some insight into manipulative affective actions in *BayesAct*.

## 5 RELATED WORK

Damasio has convincingly argued, both from a functional and neurological standpoint, for emotions playing a key role in decision making and for human social action [7]. His *Somatic Marker Hypothesis* is contrasted against the

<sup>11</sup>We use a Python implementation that is unoptimized. An optimised version will result in realistic timeouts.

Platonic “high-reason” view of intelligence, in which pure rationality is used to make decisions. Damasio argues that, because of the limited capacity of working memory and attention, the Platonic view will not work. Instead, learned neural markers focus attention on actions that are likely to succeed, and act as a neural bias allowing humans to work with fewer alternatives. These *somatic markers* are “cultural prescriptions” for behaviours that are “rational relative to the social conventions and ethics” ([7], p200).

LeDoux [24] argues the same thing from an evolutionary standpoint. He theorises that the subjective feeling of emotion must take place at both unconscious and conscious levels in the brain, and that consciousness is the ability to relate stimuli to a sense of identity, among other things.

With remarkably similar conclusions coming from a more functional (economic) viewpoint, Kahneman has demonstrated that human emotional reasoning often overshadows, but is important as a guide for, cognitive deliberation [23]. Kahneman presents a two-level model of intelligence, with a fast/normative/reactive/affective mechanism being the “first on the scene”, followed by a slow/cognitive/deliberative mechanism that operates if sufficient resources are available. Akerlof and Kranton attempt to formalise *fast thinking* by incorporating a general notion of identity into an economic model (utility function) [2]. Earlier work on *social identity theory* foreshadowed this economic model by noting that simply assigning group membership increases individual cooperation [38].

The idea that unites Kahneman, LeDoux, and Damasio (and others) is the tight connection between emotion and action. These authors, from very different fields, propose emotional reasoning as a “quick and dirty”, yet absolutely necessary, guide for cognitive deliberation. ACT gives a functional account of the quick pathway as sentiment encoding prescriptive behaviour, while *BayesAct* shows how this account can be extended with a slow pathway that enables exploration and planning away from the prescription.

Our work fits well into a wide body of work on *affective computing* (AC) [30, 32], with a growing focus on socio-cultural agents (e.g. [9]). In AC, emotions are usually framed following the rationalistic view proposed by Simon as “interrupts” to cognitive processing [37]. Emotions are typically inferred based on cognitive appraisals (e.g. a thwarted goal causes anger) that are used to guide action through a set of “coping” mechanisms. Gratch and Marsella [15] are possibly the first to propose a concrete computational mechanism for coping. They propose a five stage process wherein beliefs, desires, plans and intentions are first formulated, and upon which emotional appraisals are computed. Coping strategies then use a set of *ad hoc* rules by modifying elements of the model such as probabilities and utilities, or by modifying plans or intentions. Si *et al.* [35] compute emotional appraisals from utility measures (including beliefs about other agent’s utilities, as in an I-POMDP [13]), but they leave to future work “*how emotion affects the agents decision-making and belief up-*

*date processes*” ([35] section 8). Goal prioritization using emotional appraisals have been investigated [3, 25, 28], as have normative multi-agent systems (NorMAS) [5]. There has been recent work on facial expressions in PD games, showing that they can significantly affect the outcomes [8].

Most approaches to emotional action guidance only give broad action guides in extreme situations, leaving all else to the cognitive faculties. *BayesAct* specifies one simple coping mechanism: minimizing inconsistency in continuous-valued sentiment. This, when combined with mappings describing how sentiments are appraised from events and actions, can be used to prescribe actions that maximally reduce inconsistency. These prescriptions are then used as guides for higher-level cognitive (including rational) processing and deliberation. *BayesAct* therefore provides an important step in the direction of building models that integrate “cognitive” and “affective” reasoning.

*BayesAct* requires anytime techniques for solving large continuous POMDPs with non-Gaussian beliefs. There has been much recent effort in solving continuous POMDPs with Gaussian beliefs (e.g. [10]), but these are usually in robotics motion planning where such approximations are reasonable. Point-based methods (e.g. [31]) require the value function to be closed under the Bellman operator, which is not possible for *BayesAct*.

Monte-Carlo tree search (MCTS) methods have seen more scalability success [6], and are anytime. POMCP [36] uses MCTS to efficiently solve POMDPs with continuous state spaces. By design, POMCP is unable to handle models with continuous action spaces, such as *BayesAct*. POMCoP uses POMCP to guide a sidekick’s actions during a cooperative video game [26]. While this game has many similarities to CoRobots, it does not have continuous actions and restricts agent types to a small and countable set. MCTS methods are more appealing for *BayesAct* than other solvers because: (1) MCTS does not require a computation of the value function over the continuous state space and non-linear dynamics; (2) MCTS provides an anytime “quick and dirty” solution that corresponds naturally to our interpretation of the “fast thinking” heuristic.

## 6 CONCLUSION

We have studied decision-theoretic planning in a class of POMDP models of affective interactions, *BayesAct*, in which culturally shared sentiments are used to provide normative action guidance. *BayesAct* is an exciting new development in artificial intelligence that combines affective computing, sociological theory, and probabilistic modeling. We use a Monte-Carlo Tree Search (MCTS) method to show how a simple and parsimonious model of human affect in decision making can yield solutions to two classic social dilemmas. We investigate how asymmetry between agent’s resources can lead to manipulative or exploitative, yet socially aligned, strategies.

## Abstract

We address the problem of communicating domain knowledge from a user to the designer of a clustering algorithm. We propose a protocol in which the user provides a clustering of a relatively small random sample of a data set. The algorithm designer then uses that sample to come up with a data representation under which  $k$ -means clustering results in a clustering (of the full data set) that is aligned with the user’s clustering. We provide a formal statistical model for analyzing the sample complexity of learning a clustering representation with this paradigm. We then introduce a notion of capacity of a class of possible representations, in the spirit of the VC-dimension, showing that classes of representations that have finite such dimension can be successfully learned with sample size error bounds, and end our discussion with an analysis of that dimension for classes of representations induced by linear embeddings.

## 1 INTRODUCTION

Clustering can be thought as the task of automatically dividing a set of objects into “coherent” subsets. This definition is not concrete, but its vagueness allows it to serve as an umbrella term for a wide diversity of algorithmic paradigms. Clustering algorithms are being routinely applied in a huge variety of fields.

Given a dataset that needs to be clustered for some application, one can choose among a variety of different clustering algorithms, along with different pre-processing techniques, that are likely to result in dramatically different answers. It is therefore critical to incorporate prior knowledge about the data and the intended semantics of the clustering into the process of picking a clustering algorithm (or, clustering model selection). Regretfully, there seem to be no system-

atic tool for incorporation of domain expertise for clustering model selection, and such decisions are usually being made in embarrassingly *ad hoc* ways. This paper aims to address that critical deficiency in a formal statistical framework.

We approach the challenge by considering a scenario in which the domain expert (i.e., the intended user of the clustering) conveys her domain knowledge by providing a clustering of a small random subset of her data set. For example, consider a big customer service center that wishes to cluster incoming requests into groups to streamline their handling. Since the data base of requests is too large to be organized manually, the service center wishes to employ a clustering program. As the clustering designer, we would then ask the service center to pick a random sample of requests, manually cluster them, and show us the resulting grouping of that sample. The clustering tool then uses that sample clustering to pick a clustering method that, when applied to the full data set, will result in a clustering that follows the patterns demonstrated by that sample clustering. We address this paradigm from a statistical machine learning perspective. Aiming to achieve generalization guarantees for such an approach, it is essential to introduce some *inductive bias*. We do that by restricting the clustering algorithm to a predetermined hypothesis class (or a set of concrete clustering algorithms).

In a recent Dagstuhl workshop, Blum (2014) proposed to do that by fixing a clustering algorithm, say  $k$ -means, and searching for a metric over the data under which  $k$ -means optimization yields a clustering that agrees with the training sample clustering. One should note that, given any domain set  $X$ , for any  $k$ -partitioning  $P$  of  $X$ , there exists some distance function  $d_P$  over  $X$  such that  $P$  is the optimal  $k$ -means clustering solution to the input  $(X, d_P)$ <sup>1</sup>. Consequently, to protect against potential overfitting, the class of potential distance functions should be constrained. In this paper, we provide (apparently the first) concrete formal framework for such a paradigm, as well as a generalization analysis of this approach.

---

<sup>1</sup>This property is sometimes called  $k$ -Richness

In this work we focus on center based clustering - an important class of clustering algorithms. In these algorithms, the goal is to find a set of “centers” (or prototypes), and the clusters are the Voronoi cells induced by this set of centers. The objective of such a clustering is to minimize the expected value of some monotonically increasing function of the distances of points to their cluster centers. The  $k$ -means clustering objective is arguably the most popular clustering paradigm in this class. Currently, center-based clustering tools lack a vehicle for incorporating domain expertise. Domain knowledge is usually taken into account only through an ad hoc choice of input data representation. Regretfully, it might not be realistic to require the domain expert to translate sufficiently elaborate task-relevant knowledge into hand-crafted features.

As a model for learning representations, we assume that the user-desirable clustering can be approximated by first mapping the sample to some Euclidean (or Hilbert) space and then performing  $k$ -means clustering in the mapped space (or equivalently, replacing the input data metric by some kernel and performing center-based clustering with respect to that kernel). However, the clustering algorithm is supposed to learn a suitable mapping based on the given sample clustering.

The main question addressed in this work is that of the sample complexity: what is the size of a sample, to be clustered by the domain expert, that suffices for finding a close-to-optimal mapping (i.e., a mapping that generalizes well on the test data)? Intuitively, this sample complexity depends on the richness of the class of potential mappings that the algorithm is choosing from. In standard supervised learning, there are well established notions of capacity of hypothesis classes (e.g., VC-dimension) that characterize the sample complexity of learning. This paper aims to provide such relevant notions of capacity for clustering.

## 1.1 Previous Work

In practice, there are methods that use some forms of supervision for clustering. These methods are sometimes called “semi-supervised clustering” (Basu et al. (2002, 2004); Kulis et al. (2009)). The most common method to convey such supervision is through a set of pairwise *must/cannot-link* constraints on the instances (Wagstaff et al. (2001)). A common way of using such information is by changing the objective of clustering so that violations of these constraints are penalized (Demiriz et al. (1999); Law et al. (2005); Basu et al. (2008)). Another approach, which is closer to ours, keeps the clustering optimization objective fixed, and instead, searches for a metric that best fits given constraints. The metric is learned based on some objective function over metrics ((Xing et al., 2002; Alipanahi et al., 2008)), so that pairs of instances marked *must-link* will be close in the new metric space (and *cannot-link* pairs be con-

sidered as far apart). The two above approaches can also be integrated (Bilenko et al. (2004)). However, these objective functions are usually rather ad hoc. In particular, it is not clear in what sense they are compatible with the adopted clustering algorithm (such as  $k$ -means clustering).

A different approach to the problem of communicating user expertise for the purpose of choosing a clustering tool is discussed in Ackerman et al. (2010). They considered a set of *properties*, or *requirements*, for clustering algorithms, and investigated which of those properties hold for various algorithms. The user can then pick the right algorithm based on the requirements that she wants the algorithm to meet. However, to turn such an approach into a practically useful tool, one will need to come up with properties that are relevant to the end user of clustering – a goal that is still far from being reached.

Statistical convergence rates of sample clustering to the optimal clustering, with respect to some data generating probability distribution, play a central role in our analysis. From that perspective, most relevant to our paper are results that provide generalization bounds for  $k$ -means clustering. Ben-David (2007) proposed the first dimension-independent generalization bound for  $k$ -means clustering based on compression techniques. Biau et al. (2008) tightened this result by an analysis of Rademacher complexity. Maurer and Pontil (2010) investigated a more general framework, in which generalization bounds for  $k$ -means as well as other algorithms can be obtained. It should be noted that these results are about the standard clustering setup (without any supervised feedback), where the data representation is fixed and known to the clustering algorithm.

## 1.2 Contributions

Our first contribution is to provide a statistical framework to analyze the problem of learning representation for clustering. We assume that the expert has some implicit target clustering of the dataset in his mind. The learner however, is unaware of it, and instead has to select a mapping among a set of potential mappings, under which the result of  $k$ -means clustering will be similar to the target partition. An appropriate notion of loss function is introduced to quantify the success of the learner. Then, we define the analogous notion of PAC-learnability<sup>2</sup> for the problem of learning representation for clustering.

The second contribution of the paper is the introduction of a combinatorial parameter, a specific notion of the capacity of the class of mappings, that determines the sample complexity of the clustering learning tasks. This combinatorial notion is a multivariate version of *pseudo-dimension* of a class of real-valued mappings. We show that there is *uniform convergence* of empirical losses to the true loss, over

<sup>2</sup>PAC stands for the well known notion of “probably approximately correct”, popularized by Valiant (1984).

any class of embeddings,  $\mathcal{F}$ , at a rate that is determined by the proposed dimension of that  $\mathcal{F}$ . This implies that any empirical risk minimization algorithm (ERM) will successfully learn such a class from sample sizes upper bounded by those rates. Finally, we analyze a particular natural class – the class of linear mappings from  $\mathbb{R}^{d_2}$  to  $\mathbb{R}^{d_1}$  – and show that a roughly speaking, sample size of  $O(\frac{d_1 d_2}{\epsilon^2})$  is sufficient to guarantee an  $\epsilon$ -optimal representation.

The rest of this paper is organized as follows: Section 2 defines the problem setting. Then in Section 3, we investigate ERM-type algorithms and show that, “uniform convergence” is sufficient for them to work. Furthermore, this section presents the uniform convergence results and the proof of an upper bound for the sample complexity. Finally, we conclude in section 4 and provide some directions for future work.

## 2 PROBLEM SETTING

### 2.1 Preliminaries

Let  $X$  be a finite domain set. A  $k$ -clustering of  $X$  is a partition of  $X$  into  $k$  subsets. If  $C$  is a  $k$ -clustering, we denote the subsets of the partition by  $C_1, \dots, C_k$ , therefore we have  $C = \{C_1, \dots, C_k\}$ . Let  $\pi^k$  denote the set of all permutations over  $[k]$  where  $[k]$  denotes  $\{1, 2, \dots, k\}$ . The clustering difference between two clusterings,  $C^1$  and  $C^2$ , with respect to  $X$  is defined by

$$\Delta_X(C^1, C^2) = \min_{\sigma \in \pi^k} \frac{1}{|X|} \sum_{i=1}^k |C_i^1 \Delta C_{\sigma(i)}^2| \quad (1)$$

where  $|\cdot|$  and  $\Delta$  denote the cardinality and the symmetric difference of sets respectively. For a sample  $S \subset X$ , and  $C^1$  (a partition of  $X$ ), we define  $C^1|_S$  to be a partition of  $S$  induced by  $C^1$ , namely  $C^1|_S = \{C_1^1 \cap S, \dots, C_k^1 \cap S\}$ . Accordingly, the sample-based difference between two partitions is defined by

$$\Delta_S(C^1, C^2) = \Delta_S(C^1|_S, C^2|_S) \quad (2)$$

Let  $f$  be a mapping from  $X$  to  $\mathbb{R}^d$ , and  $\mu = (\mu_1, \dots, \mu_k)$  be a vector of  $k$  centers in  $\mathbb{R}^d$ . The clustering defined by  $(f, \mu)$  is the partition over  $X$  induced by the  $\mu$ -Voronoi partition in  $\mathbb{R}^d$ . Namely,

$$C_f(\mu) = (C_1, \dots, C_k), \text{ where for all } i,$$

$$C_i = \{x \in X : \|f(x) - \mu_i\|_2 \leq \|f(x) - \mu_j\|_2 \text{ for all } j \neq i\}$$

The  $k$ -means cost of clustering  $X$  with a set of centers  $\mu = \{\mu_1, \dots, \mu_k\}$  and with respect to a mapping  $f$  is defined by

$$COST_X(f, \mu) = \frac{1}{|X|} \sum_{x \in X} \min_{\mu_i \in \mu} \|f(x) - \mu_i\|_2^2 \quad (3)$$

The  $k$ -means clustering algorithm finds the set of centers  $\mu_X^f$  that minimize this cost<sup>3</sup>. In other words,

$$\mu_X^f = \arg \min_{\mu} COST_X(f, \mu) \quad (4)$$

Also, for a partition  $C$  and mapping  $f$ , we can define the cost of clustering as follows.

$$COST_X(f, C) = \frac{1}{|X|} \sum_{i \in [k]} \min_{\mu_j} \sum_{x \in C_i} \|f(x) - \mu_j\|_2^2 \quad (5)$$

For a mapping  $f$  as above, let  $C_X^f$  denote the  $k$ -means clustering of  $X$  induced by  $f$ , namely

$$C_X^f = C_f(\mu_X^f) \quad (6)$$

The difference between two mappings  $f_1$  and  $f_2$  with respect to  $X$  is defined by the difference between the result of  $k$ -means clustering using these mappings. Formally,

$$\Delta_X(f_1, f_2) = \Delta_X(C_X^{f_1}, C_X^{f_2}) \quad (7)$$

The following proposition shows the “ $k$ -richness” property of  $k$ -means objective.

**Proposition 1.** *Let  $X$  be a domain set. For every  $k$ -clustering of  $X$ ,  $C$ , and every  $d \in \mathbb{N}^+$ , there exist a mapping  $g : X \mapsto \mathbb{R}^d$  such that  $C_X^g = C$ .*

*Proof.* The mapping  $g$  can be picked such that it collapses each cluster  $C_i$  into a single point in  $\mathbb{R}^n$  (and so the image of  $X$  under mapping  $g$  will be just  $k$  single points in  $\mathbb{R}^n$ ). The result of  $k$ -means clustering under such mapping will be  $C$ .  $\square$

In this paper, we investigate the *transductive* setup, where there is a given data set, known to the learner, that needs to be clustered. Clustering often occurs as a task over some data generating distribution (e.g., Von Luxburg and Ben-David (2005)). The current work can be readily extended to that setting. However, in that case, we assume that the clustering algorithm gets, on top of the clustered sample, a large unclustered sample drawn from that data generating distribution.

<sup>3</sup>We assume that the solution to  $k$ -means clustering is unique. We will elaborate about this issue in the next sections.

## 2.2 Formal Problem Statement

Let  $C^*$  be the target  $k$ -clustering of  $X$ . A (supervised) *representation learner* for clustering, takes as input a sample  $S \subset X$  and its clustering,  $C^* \big|_S$ , and outputs a mapping  $f$  from a set of potential mappings  $\mathcal{F}$ . In the following, PAC stands for the notion of ‘‘probably approximately correct’’.

**Definition 1.** *PAC Supervised Representation Learner for K-Means (PAC-SRLK)*

Let  $\mathcal{F}$  be a set of mappings from  $X$  to  $\mathbb{R}^d$ . A *representation learning algorithm*  $A$  is a PAC-SRLK with sample complexity  $m_{\mathcal{F}} : (0, 1)^2 \mapsto \mathbb{N}$  with respect to  $\mathcal{F}$ , if for every  $(\epsilon, \delta) \in (0, 1)^2$ , every domain set  $X$  and every clustering of  $X$ ,  $C^*$ , the following holds:

if  $S$  is a randomly (uniformly) selected subset of  $X$  of size at least  $m_{\mathcal{F}}(\epsilon, \delta)$ , then with probability at least  $1 - \delta$

$$\Delta_X(C^*, C_X^{f_A}) \leq \inf_{f \in \mathcal{F}} \Delta_X(C^*, C_X^f) + \epsilon \quad (8)$$

where  $f_A = A(S, C^* \big|_S)$ , is the output of the algorithm.

This can be regarded as a formal PAC framework to analyze the problem of learning representation for k-means clustering. The learner is compared to the best mapping in the class  $\mathcal{F}$ .

A natural question is providing bounds on the sample complexity of PAC-SRLK with respect to  $\mathcal{F}$ . Intuitively, for richer classes of mappings, we need larger clustered samples. Therefore, we need to introduce an appropriate notion of ‘‘capacity’’ for  $\mathcal{F}$  and bound the sample complexity based on it. This is addressed in the next sections.

## 3 ANALYSIS AND RESULTS

### 3.1 Empirical Risk Minimization

In order to prove an upper bound for the sample complexity of representation learning for clustering, we need to consider an algorithm, and prove a sample complexity bound for it. Here, we show that any ERM-type algorithm can be used for this purpose. Therefore, we will be able to prove an upper bound for the sample complexity of PAC-SRLK.

Let  $\mathcal{F}$  be a class of mappings and  $X$  be the domain set. A TERM<sup>4</sup> learner for  $\mathcal{F}$  takes as input a sample  $S \subset X$  and its clustering  $Y$  and outputs:

$$A^{TERM}(S, Y) = \arg \min_{f \in \mathcal{F}} \Delta_S(C_X^f \big|_S, Y) \quad (9)$$

Note that we call it transductive, because it is implicitly assumed that it has access to unlabeled dataset (i.e.,  $X$ ). A

TERM algorithm goes over all mappings in  $\mathcal{F}$  and selects the mapping which is the most consistent mapping with the given clustering: the mapping under which if we perform k-means clustering of  $X$ , the sample-based  $\Delta$ -difference between the result and  $Y$  is minimized.

Note that we are not studying this algorithm as a computational tool; we only use it to show an upper bound for the sample complexity.

Intuitively, this algorithm will work well when the empirical  $\Delta$ -difference and the true  $\Delta$ -difference of the mappings in the class are close to each other. In this case, by minimizing the empirical difference, the algorithm will automatically minimize the true difference as well. In order to formalize this idea, we define the notion of ‘‘representativeness’’ of a sample.

**Definition 2.** ( *$\epsilon$ -Representative Sample*) Let  $\mathcal{F}$  be a class of mappings from  $X$  to  $\mathbb{R}^d$ . A sample  $S$  is  $\epsilon$ -representative with respect to  $\mathcal{F}$ ,  $X$  and the clustering  $C^*$ , if for every  $f \in \mathcal{F}$  the following holds

$$|\Delta_X(C^*, C_X^f) - \Delta_S(C^*, C_X^f)| \leq \epsilon \quad (10)$$

The following theorem shows that for the TERM algorithm to work, it is sufficient to supply it with a representative sample.

**Theorem 1.** (*Sufficiency of Uniform Convergence*) Let  $\mathcal{F}$  be a set of mappings from  $X$  to  $\mathbb{R}^d$ . If  $S$  is an  $\frac{\epsilon}{2}$ -representative sample with respect to  $X$ ,  $\mathcal{F}$  and  $C^*$  then

$$\Delta_X(C^*, C_X^{f^*}) \leq \Delta_X(C^*, C_X^{f^*}) + \epsilon \quad (11)$$

where  $f^* = \arg \min_{f \in \mathcal{F}} \Delta_X(C^*, C_X^f)$  and  $\hat{f} = A^{TERM}(S, C^* \big|_S)$ .

*Proof.* Using  $\frac{\epsilon}{2}$ -representativeness of  $S$  and the fact that  $\hat{f}$  is the empirical minimizer of the loss function, we have

$$\Delta_X(C^*, C_X^{\hat{f}}) \leq \Delta_S(C^*, C_X^{\hat{f}}) + \frac{\epsilon}{2} \quad (12)$$

$$\leq \Delta_S(C^*, C_X^{f^*}) + \frac{\epsilon}{2} \quad (13)$$

$$\leq \Delta_X(C^*, C_X^{f^*}) + \frac{\epsilon}{2} + \frac{\epsilon}{2} \quad (14)$$

$$\leq \Delta_X(C^*, C_X^{f^*}) + \epsilon \quad (15)$$

□

<sup>4</sup>TERM stands for Transductive Empirical Risk Minimizer

Therefore, we just need to provide an upper bound for the sample complexity of uniform convergence: “how many instances do we need to make sure that with high probability our sample is  $\epsilon$ -representative?”

### 3.2 Classes of Mappings with a Uniqueness Property

In general, the solution to k-means clustering may not be unique. Therefore, the learner may end up with finding a mapping that corresponds to multiple different clusterings. This is not desirable, because in this case, the output of the learner will not be interpretable. Therefore, it is reasonable to choose the class of potential mappings in a way that it includes only the mappings under which the solution is unique.

In order to make this idea concrete, we need to define an appropriate notion of uniqueness. We use a notion similar to the one introduced by Balcan et al. (2009) with a slight modification<sup>5</sup>.

**Definition 3.** ( $(\eta, \epsilon)$ -Uniqueness) We say that k-means clustering for domain  $X$  under mapping  $f : \mathcal{X} \mapsto \mathbb{R}^d$  has a  $(\eta, \epsilon)$ -unique solution, if every  $\eta$ -optimal solution of the k-means cost is  $\epsilon$ -close to the optimal solution. Formally, the solution is  $(\eta, \epsilon)$ -unique if for every partition  $P$  that satisfies

$$COST_X(f, P) < COST_X(f, C_X^f) + \eta \quad (16)$$

would also satisfy

$$\Delta_X(C_X^f, P) < \epsilon \quad (17)$$

In the degenerate case where the optimal solution to k-means is not unique itself (and so  $C_X^f$  is not well-defined), we say that the solution is not  $(\eta, \epsilon)$ -unique.

It can be noted that the definition of  $(\eta, \epsilon)$ -uniqueness not only requires the optimal solution to k-means clustering to be unique, but also all the “near-optimal” minimizers of the k-means clustering cost should be “similar”. This is a natural strengthening of the uniqueness condition, to guard against cases where there are  $\eta_0$ -optimizers of the cost function (for arbitrarily small  $\eta_0$ ) with totally different solutions.

Now that we have a definition for uniqueness, we can define the set of mappings for  $X$  under which the solution is unique. We say that a class of mappings  $F$  has  $(\eta, \epsilon)$ -uniqueness property with respect to  $X$ , if every mapping in  $F$  has  $(\eta, \epsilon)$ -uniqueness property over  $X$ .

Note that given an arbitrary class of mappings  $F$ , we can find a subset of it that satisfies  $(\eta, \epsilon)$ -uniqueness property

<sup>5</sup>Our notion is additive in both parameters rather than multiplicative

over  $X$ . Also, as argued above, this subset is the useful subset to work with. Therefore, in the rest of the paper, we investigate learning for classes with  $(\eta, \epsilon)$ -uniqueness property. In the next section, we prove uniform convergence results for such classes.

### 3.3 Uniform Convergence Results

In Section 3.1, we defined the notion of  $\epsilon$ -representative samples. Also, we proved that if a TERM algorithm is fed with such a representative sample, it will work satisfactorily. The most technical part of the proof is then about the question “how large should be the sample in order to make sure that with high probability it is actually a representative sample?”

In order to formalize this notion, let  $\mathcal{F}$  be a set of mappings from a domain  $X$  to  $(0, 1)^{n6}$ . Define the sample complexity of uniform convergence,  $m_{\mathcal{F}}^{UC}(\epsilon, \delta)$ , as the minimum number  $m$  such that for every fixed partition  $C^*$ , if  $S$  is a randomly (uniformly) selected subset of  $X$  with size  $m$ , then with probability at least  $1 - \delta$ , for all  $f \in \mathcal{F}$  we have

$$|\Delta_X(C^*, C_X^f) - \Delta_S(C^*, C_X^f)| \leq \epsilon \quad (18)$$

The technical part of this paper is devoted to provide an upper bound for this sample complexity.

#### 3.3.1 Preliminaries

**Definition 4.** ( $\epsilon$ -cover and covering number) Let  $\mathcal{F}$  be a set of mappings from  $X$  to  $(0, 1)^n$ . A subset  $\hat{F} \subset \mathcal{F}$  is called an  $\epsilon$ -cover for  $\mathcal{F}$  with respect to the metric  $d(\cdot, \cdot)$  if for every  $f \in \mathcal{F}$  there exists  $\hat{f} \in \hat{F}$  such that  $d(f, \hat{f}) \leq \epsilon$ . The covering number,  $\mathcal{N}(\mathcal{F}, d, \epsilon)$  is the size of the smallest  $\epsilon$ -cover of  $\mathcal{F}$  with respect to  $d$ .

In the above definition, we did not specify the metric  $d$ . In our analysis, we are interested in the  $L_1$  distance with respect to  $X$ , namely:

$$d_{L_1}^X(f_1, f_2) = \frac{1}{|X|} \sum_{x \in X} \|f_1(x) - f_2(x)\|_2 \quad (19)$$

Note that the mappings we consider are not real-valued functions, but their output is an  $n$ -dimensional vector. This is in contrast to the usual analysis used for learning real-valued functions. If  $f_1$  and  $f_2$  are real-valued, then  $L_1$  distance is defined by

$$d_{L_1}^X(f_1, f_2) = \frac{1}{|X|} \sum_{x \in X} |f_1(x) - f_2(x)| \quad (20)$$

<sup>6</sup>In the analysis, for simplicity, we will assume that the set of mappings is a function to the bounded space  $(0, 1)^n$  wherever needed

We will prove sample complexity bounds for our problem based on the  $L_1$ -covering number of the set of mappings. However, it will be beneficial to have a bound based on some notion of capacity, similar to VC-dimension, as well. This will help in better understanding and easier analysis of sample complexity of different classes. While VC-dimension is defined for binary valued functions, we need a similar notion for functions with outputs in  $\mathbb{R}^n$ . For real-valued functions, we have such notion, called pseudo-dimension (Pollard (1984)).

**Definition 5.** (*Pseudo-Dimension*) Let  $\mathcal{F}$  be a set of functions from  $X$  to  $\mathbb{R}$ . Let  $S = \{x_1, x_2, \dots, x_m\}$  be a subset of  $X$ . Then  $S$  is pseudo-shattered by  $\mathcal{F}$  if there are real numbers  $r_1, r_2, \dots, r_m$  such that for every  $b \in \{0, 1\}^m$ , there is a function  $f_b \in \mathcal{F}$  with  $\text{sgn}(f_b(x_i) - r_i) = b_i$  for  $i \in [m]$ . Pseudo dimension of  $\mathcal{F}$ , called  $\text{Pdim}(\mathcal{F})$ , is the size of the largest shattered set.

It can be shown (e.g., Theorem 18.4. in Anthony and Bartlett (2009)) that for a real-valued class  $F$ , if  $\text{Pdim}(F) \leq q$  then  $\log \mathcal{N}(F, d_{L_1}^X, \epsilon) = \mathcal{O}(q)$  where  $\mathcal{O}()$  hides logarithmic factors of  $\frac{1}{\epsilon}$ . In the next sections, we will generalize this notion to  $\mathbb{R}^n$ -valued functions.

### 3.3.2 Reduction to Binary Hypothesis Classes

Let  $f_1, f_2 \in \mathcal{F}$  be two mappings and  $\sigma$  be a permutation over  $[k]$ . Define the binary-valued function  $h_{\sigma}^{f_1, f_2}(\cdot)$  as follows

$$h_{\sigma}^{f_1, f_2}(x) = \begin{cases} 1 & x \in \cup_{i=1}^k (C_i^{f_1} \Delta C_{\sigma(i)}^{f_2}) \\ 0 & \text{otherwise} \end{cases} \quad (21)$$

Let  $H_{\sigma}^{\mathcal{F}}$  be the set of all such functions with respect to  $\mathcal{F}$  and  $\sigma$ :

$$H_{\sigma}^{\mathcal{F}} = \{h_{\sigma}^{f_1, f_2}(\cdot) : f_1, f_2 \in \mathcal{F}\} \quad (22)$$

Finally, let  $H^{\mathcal{F}}$  be the union of all  $H_{\sigma}^{\mathcal{F}}$  over all choices of  $\sigma$ . Formally, if  $\pi$  is the set of all permutations over  $[k]$ , then

$$H^{\mathcal{F}} = \cup_{\sigma \in \pi} H_{\sigma}^{\mathcal{F}} \quad (23)$$

For a set  $S$ , and a binary function  $h(\cdot)$ , let  $h(S) = \frac{1}{|S|} \sum_{x \in S} h(x)$ . We now show that a uniform convergence result with respect to  $H^{\mathcal{F}}$  is sufficient to have uniform convergence for the  $\Delta$ -difference function. Therefore, we will be able to investigate conditions for uniform convergence of  $H^{\mathcal{F}}$  rather than the  $\Delta$ -difference function.

**Theorem 2.** Let  $X$  be a domain set,  $\mathcal{F}$  be a set of mappings, and  $H^{\mathcal{F}}$  be defined as above. If  $S \subset X$  is such that

$$\forall h \in H^{\mathcal{F}}, |h(S) - h(X)| \leq \epsilon \quad (24)$$

then  $S$  will be  $\epsilon$ -representative with respect to  $\mathcal{F}$ , i.e., for all  $f_1, f_2 \in \mathcal{F}$  we will have

$$|\Delta_X(C_X^{f_1}, C_X^{f_2}) - \Delta_S(C_X^{f_1}, C_X^{f_2})| \leq \epsilon \quad (25)$$

*Proof.*

$$|\Delta_S(C_X^{f_1}, C_X^{f_2}) - \Delta_X(C_X^{f_1}, C_X^{f_2})| \quad (26)$$

$$= \left| \left( \min_{\sigma} \frac{1}{|S|} \sum_{x \in S} h_{\sigma}^{f_1, f_2} \right) - \left( \min_{\sigma} \frac{1}{|X|} \sum_{x \in X} h_{\sigma}^{f_1, f_2} \right) \right| \quad (27)$$

$$\leq \left| \max_{\sigma} \left( \frac{1}{|S|} \sum_{x \in S} h_{\sigma}^{f_1, f_2} - \frac{1}{|X|} \sum_{x \in X} h_{\sigma}^{f_1, f_2} \right) \right| \quad (28)$$

$$\leq \left| \max_{\sigma} (h_{\sigma}^{f_1, f_2}(S) - h_{\sigma}^{f_1, f_2}(X)) \right| \leq \epsilon \quad (29)$$

□

The fact that  $H^{\mathcal{F}}$  is a class of binary-valued functions enables us to provide sample complexity bounds based on VC-dimension of this class. However, providing bounds based on  $\text{VC-Dim}(H^{\mathcal{F}})$  is not sufficient, in the sense that it is not convenient to work with the class  $H^{\mathcal{F}}$ . Instead, it will be nice if we can prove bounds directly based on the capacity of the class of mappings,  $\mathcal{F}$ . In the next section, we address this issue.

### 3.3.3 $L_1$ -Covering Number and Uniform Convergence

The classes introduced in the previous section,  $H^{\mathcal{F}}$  and  $H_{\sigma}^{\mathcal{F}}$ , are binary hypothesis classes. Also, we have shown that proving a uniform convergence result for  $H^{\mathcal{F}}$  is sufficient for our purpose. In this section, we show that a bound on the  $L_1$  covering number of  $\mathcal{F}$  is sufficient to prove uniform convergence for  $H^{\mathcal{F}}$ .

In Section 3.2, we argued that we only care about the classes that have  $(\eta, \epsilon)$ -uniqueness property. In the rest of this section, assume that  $\mathcal{F}$  is a class of mappings from  $X$  to  $(0, 1)^n$  that satisfies  $(\eta, \epsilon)$ -uniqueness property.

**Lemma 1.** Let  $f_1, f_2 \in \mathcal{F}$ . If  $d_{L_1}(f_1, f_2) < \frac{\eta}{12}$  then  $\Delta_X(f_1, f_2) < 2\epsilon$

We leave the proof of this lemma for the appendix, and present the next lemma.

**Lemma 2.** Let  $H^{\mathcal{F}}$  be defined as in the previous section. Then,

$$\mathcal{N}(H^{\mathcal{F}}, d_{L_1}^X, 2\epsilon) \leq k! \mathcal{N}(\mathcal{F}, d_{L_1}^X, \frac{\eta}{12}) \quad (30)$$

*Proof.* Let  $\hat{\mathcal{F}}$  be the  $\frac{\eta}{12}$ -cover corresponding to the covering number  $\mathcal{N}(\mathcal{F}, d_{L_1}^X, \frac{\eta}{12})$ . Based on the previous lemma,  $H_\sigma^{\hat{\mathcal{F}}}$  is a  $2\epsilon$ -cover for  $H_\sigma^{\mathcal{F}}$ . But we have only  $k!$  permutations of  $[k]$ , therefore, the covering number for  $H^{\hat{\mathcal{F}}}$  is at most  $k!$  times larger than  $H_\sigma^{\hat{\mathcal{F}}}$ . This proves the result.  $\square$

Basically, this means that if we have a small  $L_1$  covering number for the mappings, we will have the uniform convergence result we were looking for. The following theorem proves this result.

**Theorem 3.** *Let  $\mathcal{F}$  be a set of mappings with  $(\eta, \epsilon)$ -uniqueness property. Then there for some constant  $\alpha$  we have*

$$m_{\mathcal{F}}^{UC}(\epsilon, \delta) \leq O\left(\frac{\log k! + \log \mathcal{N}(\mathcal{F}, d_{L_1}^X, \frac{\eta}{\alpha}) + \log(\frac{1}{\delta})}{\epsilon^2}\right) \quad (31)$$

*Proof.* Following the previous lemma, if we have a small  $L_1$ -covering number for  $\mathcal{F}$ , we will also have a small covering number for  $H^{\mathcal{F}}$  as well. But based on standard uniform convergence theory, if a hypothesis class has small covering number, then it has uniform convergence property. More precisely, (e.g., Theorem 17.1 in Anthony and Bartlett (2009)) we have:

$$m_{H^{\mathcal{F}}}^{UC}(\epsilon_0, \delta) \leq O\left(\frac{\log \mathcal{N}(H^{\mathcal{F}}, d_{L_1}^X, \frac{\epsilon_0}{16}) + \log(\frac{1}{\delta})}{\epsilon_0^2}\right) \quad (32)$$

Applying Lemma 2 to the above proves the result.  $\square$

### 3.4 Bounding $L_1$ -Covering Number

In the previous section, we proved if the  $L_1$  covering number of the class of mappings is bounded, then we will have uniform convergence. However, it is desirable to have a bound with respect to a combinatorial dimension of the class (rather than the covering number). Therefore, we will generalize the notion of pseudo-dimension for the class of mappings that take value in  $\mathbb{R}^n$ .

Let  $\mathcal{F}$  be a set of mappings from  $X$  to  $\mathbb{R}^n$ . For every mapping  $f \in \mathcal{F}$ , define real-valued functions  $f_1, \dots, f_n$  such that  $f(x) = (f_1(x), \dots, f_n(x))$ . Now let  $F_i = \{f_i : f \in \mathcal{F}\}$ . This means that  $F_1, F_2, \dots, F_n$  are classes of real-valued functions. Now we define pseudo-dimension of  $\mathcal{F}$  as follow.

$$Pdim(\mathcal{F}) = n \max_{i \in [n]} Pdim(F_i) \quad (33)$$

**Proposition 2.** *Let  $\mathcal{F}$  be a set of mappings from  $X$  to  $\mathbb{R}^n$ . If  $Pdim(\mathcal{F}) \leq q$  then  $\log \mathcal{N}(\mathcal{F}, d_{L_1}^X, \epsilon) = \mathcal{O}(q)$  where  $\mathcal{O}()$  hides logarithmic factors.*

*Proof.* The result follows from the corresponding result for bounding covering number of real-valued functions based on pseudo-dimension mentioned in the preliminaries section. The reason is that we can create a cover by composition of the  $\frac{\epsilon}{n}$ -covers of all  $F_i$ . However, this will at most introduce a factor of  $n$  in the logarithm of the covering number.  $\square$

Therefore, we can rewrite the result of the previous section in terms of pseudo-dimension.

**Theorem 4.** *Let  $\mathcal{F}$  be a class of mappings with  $(\eta, \epsilon)$ -uniqueness property. Then*

$$m_{\mathcal{F}}^{UC}(\epsilon, \delta) \leq O\left(\frac{k + Pdim(\mathcal{F}) + \log(\frac{1}{\delta})}{\epsilon^2}\right) \quad (34)$$

where  $\mathcal{O}()$  hides logarithmic factors of  $k$  and  $\frac{1}{\eta}$ .

### 3.5 Sample Complexity of PAC-SRLK

In Section 3.1, we showed that uniform convergence is sufficient for a TERM algorithm to work. Also, in the previous section, we proved a bound for the sample complexity of uniform convergence. The following theorem, which is the main technical result of this paper, combines these two and provides a sample complexity upper bound for PAC-SRLK framework.

**Theorem 5.** *Let  $\mathcal{F}$  be a class of  $(\eta, \epsilon)$ -unique mappings. Then the sample complexity of learning representation for  $k$ -means clustering with respect to  $\mathcal{F}$  is upper bounded by*

$$m_{\mathcal{F}}(\epsilon, \delta) \leq O\left(\frac{k + Pdim(\mathcal{F}) + \log(\frac{1}{\delta})}{\epsilon^2}\right) \quad (35)$$

where  $\mathcal{O}$  hides logarithmic factors of  $k$  and  $\frac{1}{\eta}$ .

The proof is done by combining Theorems 1 and 4.

The following result shows an upper bound for the sample complexity of learning linear mappings (or equivalently, Mahalanobis metrics).

**Corollary 1.** *Let  $\mathcal{F}$  be a set of  $(\eta, \epsilon)$ -unique linear mappings from  $\mathbb{R}^{d_1}$  to  $\mathbb{R}^{d_2}$ . Then we have*

$$m_{\mathcal{F}}(\epsilon, \delta) \leq O\left(\frac{k + d_1 d_2 + \log(\frac{1}{\delta})}{\epsilon^2}\right) \quad (36)$$

*Proof.* It is a standard result that the pseudo-dimension of a vector space of real-valued functions is just the dimensionality of the space (in our case  $d_1$ ) (e.g., Theorem 11.4 in Anthony and Bartlett (2009)). Also, based on our definition of  $Pdim$  for  $\mathbb{R}^{d_2}$ -valued functions, it should scale by a factor of  $d_2$ .  $\square$

## 4 CONCLUSIONS AND OPEN PROBLEMS

In this paper we provided a formal statistical framework for learning the representation (i.e., a mapping) for k-means clustering based on supervised feedback. The learner, unaware of the target clustering of the domain, is given a clustering of a sample set. The learner’s task is then finding a mapping function  $\hat{f}$  (among a class of mappings) under which the result of k-means clustering of the domain is as close as possible to the true clustering. This framework was called PAC-SRLK.

A notion of  $\epsilon$ -representativeness was introduced, and it was proved that any ERM-type algorithm that has access to such a sample will work satisfactorily. Finally, a technical uniform convergence result was proved to make sure that a large enough sample is (with high probability)  $\epsilon$ -representative. This was used to prove an upper bound for the sample complexity of PAC-SRLK based on covering numbers of the set of mappings. Furthermore, a notion of pseudo-dimension for the class of mappings was defined, and the sample complexity was upper bounded based on it.

Note that in the analysis, the notion of  $(\eta, \epsilon)$ -uniqueness (similar to that of Balcan et al. (2009)) was used and it was argued that it is reasonable to require the learner to output a mapping under which the solution is “unique” (because otherwise the output of k-means clustering would not be interpretable). Therefore, in the analysis, we assumed that the class of potential mappings has the  $(\eta, \epsilon)$ -uniqueness property.

It can be noted that we did not analyze the computational complexity of algorithms for PAC-SRLK framework. We leave this analysis to the future work. We just note that a similar notion of uniqueness proposed by Balcan et al. (2009) resulted in being able to efficiently solve the k-means clustering algorithm.

One other observation is that representation learning can be regarded as a special case of metric learning; because for every mapping, we can define a distance function that computes the distance in the mapped space. In this light, we can make the problem more general by making the learner find a distance function rather than a mapping. This is more challenging to analyze, because we do not even know a generalization bound for center-based clustering under general distance functions. An open question will be providing such general results.

### Acknowledgments

## 5 APPENDIX

Proof of Lemma 1. Let  $\mathcal{F} : X \mapsto (0, 1)^n$  be a set of mappings that have  $(\eta, \epsilon)$ -uniqueness property. Let

$f_1, f_2 \in \mathcal{F}$  and  $d_{L_1}(f_1, f_2) < \frac{\eta}{12}$ . We need to prove that  $\Delta_X(f_1, f_2) < 2\epsilon$ . In order to prove this, note that due to triangular inequality, we have

$$\begin{aligned} \Delta_X(f_1, f_2) &= \Delta_X(C^{f_1}(\mu^{f_1}), C^{f_2}(\mu^{f_2})) \\ &\leq \Delta_X(C^{f_1}(\mu^{f_1}), C^{f_1}(\mu^{f_2})) + \\ &\quad \Delta_X(C^{f_1}(\mu^{f_2}), C^{f_2}(\mu^{f_2})) \end{aligned} \quad (37)$$

Therefore, it will be sufficient to show that each of the  $\Delta$ -terms above is smaller than  $\epsilon$ . We start by proving a useful lemma.

**Lemma 3.** *Let  $f_1, f_2 \in \mathcal{F}$  and  $d_{L_1}(f_1, f_2) < \frac{\eta}{6}$ . Let  $\mu$  be an arbitrary set of  $k$  centers in  $(0, 1)^n$ . Then*

$$|COST_X(f_1, \mu) - COST_X(f_2, \mu)| < \frac{\eta}{2}$$

*Proof.*

$$\begin{aligned} &|COST_X(f_1, \mu) - COST_X(f_2, \mu)| \\ &= \left| \left( \frac{1}{|X|} \sum_{x \in X} \min_{\mu_j \in \mu} \|f_1(x) - \mu_j\|^2 \right) \right. \\ &\quad \left. - \left( \frac{1}{|X|} \sum_{x \in X} \min_{\mu_j \in \mu} \|f_2(x) - \mu_j\|^2 \right) \right| \end{aligned} \quad (38)$$

$$\leq \frac{1}{|X|} \sum_{x \in X} \max_{\mu_j \in \mu} \left| \|f_1(x) - \mu_j\|^2 - \|f_2(x) - \mu_j\|^2 \right| \quad (39)$$

$$= \frac{1}{|X|} \sum_{x \in X} \max_{\mu_j \in \mu} \left| \|f_1(x)\|^2 - \|f_2(x)\|^2 - 2 \langle \mu_j, f_1 - f_2 \rangle \right| \quad (40)$$

$$= \frac{1}{|X|} \sum_{x \in X} \max_{\mu_j \in \mu} \left| \langle f_1 - f_2, f_1 + f_2 - 2\mu_j \rangle \right| \quad (41)$$

$$\leq \frac{3}{|X|} \sum_{x \in X} \|f_1 - f_2\| \leq \frac{3\eta}{6} \leq \frac{\eta}{2} \quad (42)$$

□

Now we are ready to prove that the first  $\Delta$ -term is smaller than  $\epsilon$ , i.e.,  $\Delta_X(C^{f_1}(\mu^{f_1}), C^{f_1}(\mu^{f_2})) < \epsilon$ . But to do so, we only need to show that  $COST_X(f_1, \mu^{f_2}) - COST_X(f_1, \mu^{f_1}) < \eta$ ; because in that case, due to  $(\eta, \epsilon)$ -uniqueness property of  $f_1$ , the result will follow. Now, using Lemma 3, we have

$$COST_X(f_1, \mu^{f_2}) - COST_X(f_1, \mu^{f_1}) \quad (43)$$

$$\leq \left( COST_X(f_2, \mu^{f_2}) + \frac{\eta}{2} \right) - COST_X(f_1, \mu^{f_1}) \quad (44)$$

$$= \min_{\mu} (COST_X(f_2, \mu)) - \min_{\mu} (COST_X(f_1, \mu)) + \frac{\eta}{2} \quad (45)$$

$$\leq \max_{\mu} (COST_X(f_2, \mu) - COST_X(f_1, \mu)) + \frac{\eta}{2} \quad (46)$$

$$\leq \frac{\eta}{2} + \frac{\eta}{2} \leq \eta \quad (47)$$

where in the first and the last line we used Lemma 3.

Finally, we need to prove the second  $\Delta$ -inequality, i.e.,  $\Delta_X(C^{f_1}(\mu^{f_2}), C^{f_2}(\mu^{f_2})) \leq \epsilon$ . Assume contrary. But based on  $(\eta, \epsilon)$ -uniqueness property of  $f_2$ , we conclude that  $COST_X(f_2, C^{f_1}(\mu^{f_2})) - COST_X(f_2, C^{f_2}(\mu^{f_2})) \geq \eta$ . In the following, we prove that this cannot be true, and hence a contradiction.

Let  $m_x = \arg \min_{\mu_0 \in \mu^{f_2}} \|f_1(x) - \mu_0\|^2$ . Then, based on the boundedness of  $f_1(x), f_2(x)$  and we have:

$$COST_X(f_2, C^{f_1}(\mu^{f_2})) - COST_X(f_2, C^{f_2}(\mu^{f_2})) \quad (48)$$

$$= \left( \frac{1}{|X|} \sum_{x \in X} \|f_2(x) - m_x\|^2 \right) - COST_X(f_2, \mu_2) \quad (49)$$

$$= \left( \frac{1}{|X|} \sum_{x \in X} \|f_2(x) - f_1(x) + f_1(x) - m_x\|^2 \right) - COST_X(f_2, \mu_2) \quad (50)$$

$$= \frac{1}{|X|} \sum_{x \in X} \|f_2(x) - f_1(x)\|^2 + \frac{1}{|X|} \sum_{x \in X} \|f_1(x) - m_x\|^2 + \frac{1}{|X|} \sum_{x \in X} 2 \langle f_2(x) - f_1(x), f_1(x) - m_x \rangle - COST_X(f_2, \mu_2) \quad (51)$$

$$\leq \frac{2}{|X|} \sum_{x \in X} \|f_2(x) - f_1(x)\| + COST_X(f_1, \mu_1) + \frac{4}{|X|} \sum_{x \in X} \|f_2(x) - f_1(x)\| - COST_X(f_2, \mu_2) \quad (52)$$

$$\leq \frac{6}{|X|} \sum_{x \in X} \|f_2(x) - f_1(x)\| + (COST_X(f_1, \mu_1) - COST_X(f_2, \mu_2)) \quad (53)$$

$$\leq \frac{6\eta}{12} + \frac{\eta}{2} \leq \eta \quad (54)$$

## Abstract

In many classification settings, mistakes incur different application-dependent penalties based on the predicted and actual class labels. Cost-sensitive classifiers minimizing these penalties are needed. We propose a robust minimax approach for producing classifiers that directly minimize the cost of mistakes as a convex optimization problem. This is in contrast to previous methods that minimize the empirical risk using a convex surrogate for the cost of mistakes, since minimizing the empirical risk of the actual cost-sensitive loss is generally intractable. By treating properties of the training data as uncertain, our approach avoids these computational difficulties. We develop theory and algorithms for our approach and demonstrate its benefits on cost-sensitive classification tasks.

## 1 INTRODUCTION

In many applications of machine learning, the penalty or cost for classification errors depends on both the predicted label and the actual label. For example, an incorrect disease diagnosis may lead to treatments that cause complications of varying severity depending on the patient’s actual disease. These different incurred penalties for mistakes can be represented as a confusion cost matrix that is indexed by the predicted class (row) and actual class (column). As shown in the following confusion cost matrix for a classification task with four possible labels,

$$\mathbf{C} = \begin{bmatrix} 0 & 1 & 2 & 0 \\ 3 & 0 & 1 & 3 \\ 4 & 2 & 0 & 1 \\ 1 & 1 & 2 & 0 \end{bmatrix}, \quad (1)$$

the confusion costs need not be symmetric or possess any other specific relationships. Here, correct predictions incur

zero cost ( $C_{i,i} = 0$ ), but even this property is not required. Additionally, other classification errors may incur zero cost ( $C_{1,4} = 0$ ) if, e.g., the same treatment cures two different diseases. Note that the zero-one loss is a special case with off-diagonal values of one and on-diagonal costs of zero.

A natural goal for machine learning is to obtain a classifier that minimizes the expected cost incurred when classifying an example. Previous research primarily takes existing classification methods based on empirical risk minimization and tries to adapt them in various ways to be sensitive to these misclassification costs. Reweighting methods artificially augment the training data with copies of “high cost” examples to make the classifier more cost-sensitive to them [Chan and Stolfo, 1998, Elkan, 2001, Zadrozny et al., 2003, Zhou and Liu, 2010]. Other methods modify the criteria used to obtain a classifier that incorporates mistake-specific losses [Knoll et al., 1994, Turney, 1995, Elkan, 2001, Brefeld et al., 2003, Ling et al., 2004, Lomax and Vadera, 2013]. However, in both cases the non-convexity of the cost-sensitive loss function makes empirical risk minimization impractical [Hoffgen et al., 1995]. Surrogate loss functions that are convex (e.g., the hinge loss) are instead minimized, but this can introduce significant suboptimality.

Rather than integrating cost-sensitivity into existing machine learning techniques, we formulate a new machine learning approach from first principles to robustly minimize the expected cost. Our approach treats classifier construction as a game against an adversarial evaluator [Topsøe, 1979, Grünwald and Dawid, 2004]. This enables us to directly minimize the cost-sensitive loss on an approximation of the training data instead of using a convex approximation of the cost-sensitive loss, as is done with empirical risk minimization. Inference reduces to solving a zero-sum game in our approach. This is efficiently accomplished using linear programming. We obtain parameter estimates by constructing game payoff parameters using convex optimization methods. The key benefit of our approach is that the exact confusion cost matrix is employed rather than a convex surrogate. We provide important bounds

on the generalization error and demonstrate the conceptual and empirical benefits of our approach in practice.

## 2 PRELIMINARIES & RELATED WORK

### 2.1 EMPIRICAL RISK MINIMIZATION

A standard approach to parametric classification is to assume some functional form for the classifier (e.g., a linear discriminant function,  $f_\theta(\mathbf{x}) = \operatorname{argmax}_y \theta^\top \phi(\mathbf{x}, y)$ , where  $\phi(\mathbf{x}, y) \in \mathbb{R}^k$  is a feature function) and then select model parameters  $\theta$  that minimize the empirical risk,

$$\operatorname{argmin}_\theta \mathbb{E}_{\tilde{P}(\mathbf{x}, y)} [\operatorname{loss}(Y, f_\theta(\mathbf{X}))] + \lambda \|\theta\|, \quad (2)$$

with a regularization penalty  $\lambda \|\theta\|$  often added to avoid overfitting to available training data<sup>1</sup>. Unfortunately, many combinations of classification functions,  $f_\theta(\mathbf{x})$ , and loss functions,  $\operatorname{loss}(\cdot, \cdot)$ , do not lend themselves to efficient parameter optimization under the empirical risk minimization (ERM) formulation. For example, the zero-one loss measuring the misclassification rate will generally lead to a non-convex empirical risk minimization problem that is NP-hard to solve [Hoffgen et al., 1995].

To avoid these intractabilities, convex surrogate loss functions (Figure 1) that serve as upper bounds on the desired loss function are often used to create tractable optimization problems. The popular support vector machine (SVM) classifier [Cortes and Vapnik, 1995], for example, employs the hinge-loss—an upper bound on the zero-one loss—to avoid the often intractable empirical risk minimization problem. Adaboost [Freund and Schapire, 1997] incrementally minimizes the exponential loss. The difference between the actual loss and its convex surrogate can introduce a substantial mismatch between optimal parameter estimation under the surrogate loss function and optimal parameter estimates for the original performance objective.

Adaboost [Freund and Schapire, 1997] incrementally minimizes the exponential loss. The difference between the actual loss and its convex surrogate can introduce a substantial mismatch between optimal parameter estimation under the surrogate loss function and optimal parameter estimates for the original performance objective.

### 2.2 COST-SENSITIVE LEARNING

Cost-sensitive learning considers more general loss functions than the zero-one loss in which the loss depends on the actual and the predicted class. One approach is to estimate the conditional label distribution,  $\tilde{P}(y|\mathbf{x})$ , and employ the Bayesian optimal classifier:  $\hat{f}(\mathbf{x}) =$

<sup>1</sup>Lowercase non-bold,  $x$ , and bold,  $\mathbf{x}$ , denote scalar and vector values, and capitals,  $X$  or  $\mathbf{X}$ , denote random variables.

$\operatorname{argmin}_{y' \in \mathcal{Y}} \mathbb{E}_{\tilde{P}(y|\mathbf{x})} [C_{y', Y}]$ , using, e.g., the cost matrix of Eq. (1). However, accurately estimating the conditional label distribution will typically require much more data than methods that directly learn the best class prediction for a given loss function [Margeintu, 2002].

Early meta-learning methods for cost-sensitive learning attempt to modify how a cost-insensitive learner is used during training and/or prediction time so that the end result of its use is cost-sensitive. One approach for this is to either stratify or reweight available training data so that more costly mistakes will incur a larger overall cost and therefore the resulting classifier will be more sensitive to them [Chan and Stolfo, 1998, Elkan, 2001, Zadrozny et al., 2003, Zhou and Liu, 2010]. However, the validity of this approach is limited to a restricted class of *consistent* cost matrices when applied to multi-class prediction tasks [Domingos, 1999, Zhou and Liu, 2010]. A method that reduces multi-class predictions to binary predictions using iterative reweighting, data space expansion, and gradient boosting with stochastic ensembles [Abe et al., 2004] has been proposed to overcome these limitations. The *Metacost* algorithm [Domingos, 1999] similarly wraps around any underlying classifier. It uses bagging to produce label probability estimates, which it then uses to modify training data labels to produce more cost-sensitive predictions on the training set.

Direct cost-sensitive learning methods incorporate the confusion costs directly into the formulation of the classifier. Some classification methods are much more amenable to cost-sensitive modifications than others. In decision trees, for example, modified criteria for greedily selecting decision nodes and/or pruning the tree based on the confusion cost have been successfully employed [Knoll et al., 1994, Turney, 1995, Elkan, 2001, Ling et al., 2004, Davis et al., 2006, Lomax and Vadera, 2013], while relatively little attention has been given for developing cost-sensitive nearest neighbor classifiers [Qin et al., 2013].

Boosting iteratively creates an ensemble of weak classifiers that are then combined to create a much stronger classifier [Freund and Schapire, 1997] that often performs well in practice. Cost-sensitive boosting techniques employ cost-sensitive weak learners to produce a stronger learner that is cost-sensitive as well [Fan et al., 1999, Ting, 2000]. This is accomplished by minimizing the risk over the training dataset,  $\frac{1}{n} \sum_{i=1}^n \operatorname{loss}'(C, y_i, S(\mathbf{x}_i))$ , using a generalized surrogate loss function,  $\operatorname{loss}'(C, \tilde{y}, S_m(\mathbf{x}))$ , for the cost matrix  $C$ , class label  $\tilde{y}$ , and where  $S_y(\mathbf{x})$  represents the classifier confidence in assigning class  $y$  to data point  $\mathbf{x}$ . Recently developed loss functions are the Generalized Exponential Loss (GEL),  $\sum_{y'} C_{y, y'} e^{S_{y'}(\mathbf{x}) - S_y(\mathbf{x})}$  and the Generalized Logistic Loss (GLL),  $\log(1 + \sum_{y'} C_{y, y'} e^{S_{y'}(\mathbf{x}) - S_y(\mathbf{x})})$ . These loss functions are guess-averse and produce state-of-the-art perfor-

mance when used in boosting for cost-sensitive classification [Beijbom et al., 2014].

Support vector machines [Cortes and Vapnik, 1995] have been generalized in the binary classification setting by penalizing mistakes for one class more than for the other class [Brefeld et al., 2003]. Multiclass problems are reduced to binary classifiers using one-versus-all [Bottou et al., 1994] and one-versus-one [Knerr et al., 1990] prediction tasks. The *Cost-Sensitive One-Versus-All* (CSOVA) algorithm [Lin, 2008] trains a separate binary SVM classifier for each class. The *Cost-Sensitive One-Versus-One* (CSOVO) algorithm [Lin, 2010] instead constructs a total of  $k(k-1)/2$  classifiers—one for each pair of classes  $(i, j)$ . For both CSOVA and CSOVO, binary classifiers are aggregated to produce a multi-class prediction. Using structured SVM methods [Tsochantaridis et al., 2005] to directly incorporate cost-sensitivity into the multiclass generalization of the hinge loss [Lee et al., 2004],

$$\min_{\theta, \epsilon \geq 0} \theta \cdot \theta + \alpha \sum_i \epsilon_i \text{ such that:} \quad (3)$$

$$\theta \cdot \phi(\mathbf{x}_i, y_i) - \theta \cdot \phi(\mathbf{x}_i, y') \geq C_{y', y_i} - \epsilon_i, \forall i, y' \neq y_i,$$

creates a margin-based classifier that incorporates mistake costs additively. We note that central to each of these SVM-based methods is the hinge loss approximation of the cost-sensitive loss function. Our approach avoids such approximations of the loss function by instead approximating the available training data.

### 2.3 ADVERSARIAL METHODS

The adversarial perspective that we leverage in our approach has played a formative role in statistical estimation and decision making under uncertainty. These include Wald’s maximin model [Wald, 1949] of decision making as a sequential adversarial game, Savage’s minimax optimization of the regret of decisions [Savage, 1951], and statistical estimates under uncertainty that minimize worst-case risk [Wolfowitz, 1950]. We follow a relaxation of this idea, which estimates complete probability distributions as solutions to a minimax game [Topsøe, 1979, Grünwald and Dawid, 2004]. This formulation is most commonly known as a means for deriving the principle of maximum entropy using the logarithmic loss. From this, many exponential family distributions (e.g., Gaussian distribution, exponential) can be derived [Wainwright and Jordan, 2008].

Our approach differs substantially from adversarial machine learning formulations that are made robust to adversarial shifts in the dataset [Dalvi et al., 2004, Liu and Ziebart, 2014] or uncertainty in the loss function [Wang and Tang, 2012]. We assume training and testing data are IID and the cost-sensitive loss function is fully known. We restrict our uncertainty to the conditional label

distribution  $P(y|\mathbf{x})$  and adversarially estimate it. In contrast with minimax approaches to classification that assume parametric forms of the data [Lanckriet et al., 2003], our approach allows the estimation of any conditional label distribution. Instead, only training data properties are incorporated in the form of constraints on the adversary’s conditional label distribution [Grünwald and Dawid, 2004].

## 3 ADVERSARIAL COST-SENSITIVITY

### 3.1 FORMULATION

We begin to define our notation by considering an estimator for the conditional label distribution,  $\hat{P}(y|\mathbf{x})$ , the actual evaluation distribution  $P(y|\mathbf{x})$ , and an adversarial distribution  $\check{P}(y|\mathbf{x})$ . We compactly represent each as  $|\mathcal{Y}|$ -sized vectors  $\hat{\mathbf{p}}_{\mathbf{x}} = [\hat{P}(\hat{Y} = 1|\mathbf{x}) \hat{P}(\hat{Y} = 2|\mathbf{x}) \dots]^T$  for each input  $\mathbf{x} \in \mathcal{X}$ , and, similarly,  $\mathbf{p}_{\mathbf{x}}$  and  $\check{\mathbf{p}}_{\mathbf{x}}$ . The expected loss suffered from this estimator on input  $x$  for a confusion cost matrix  $\mathbf{C}$  is:  $\hat{\mathbf{p}}_{\mathbf{x}}^T \mathbf{C} \mathbf{p}_{\mathbf{x}} = \mathbb{E}_{\hat{P}(\hat{y}|\mathbf{x})P(y|\mathbf{x})}[C_{\hat{Y}, Y}]$ .

Only samples from the true conditional label distribution  $P(y|\mathbf{x})$  are available. We denote these by distribution  $\check{P}(y|\mathbf{x})$  (compactly represented as  $\check{\mathbf{p}}_{\mathbf{x}}$ ) and also input sample distribution  $\tilde{P}(\mathbf{x})$ . Minimizing the empirical risk under this distribution,  $\mathbb{E}_{\tilde{P}(\mathbf{x})}[\hat{\mathbf{p}}_{\theta, \mathbf{x}}^T \mathbf{C} \check{\mathbf{p}}_{\mathbf{x}}] = \frac{1}{n} \sum_{i=1}^n \sum_{\hat{y} \in \mathcal{Y}} \tilde{P}(\hat{y}|\mathbf{x}_i) C_{\hat{y}, y_i}$ , for some parametric form of the estimation distribution, e.g.,  $\hat{P}_{\theta}(y|\mathbf{x}) \propto e^{\theta \cdot \phi(\mathbf{x}, y)}$ , leads to a non-convex and generally intractable optimization problem, assuming  $\mathbf{P} \neq \mathbf{NP}$ , as discussed in §2.1.

To avoid these non-convex optimization concerns, we employ a robust minimax formulation [Topsøe, 1979, Grünwald and Dawid, 2004] to construct our cost-sensitive classifier (Definition 1). This formulation views the estimation task as a two-player game between estimator and adversary. The adversary is constrained to choose distributions that match a vector of moment statistics of the distribution,  $\mathbb{E}_{P(\mathbf{x})P(y|\mathbf{x})}[\phi(\mathbf{X}, Y)]$ . We denote the set of conditional distributions  $P(y|\mathbf{x})$  satisfying these statistics as  $\Xi$ .

**Definition 1.** *In the constrained cost-sensitive minimax game, the estimator player first selects a predictive distribution,  $\hat{\mathbf{p}}_{\mathbf{x}} \triangleq \hat{P}(\hat{y}|\mathbf{x}) \in \Delta$ , for each input  $\mathbf{x}$ , from the conditional probability simplex  $\Delta$ , and then the adversarial player selects an evaluation distribution,  $\check{\mathbf{p}}_{\mathbf{x}} \triangleq \check{P}(\check{y}|\mathbf{x}) \in \Delta$ , for each input  $x$  from the set  $\Xi$  of distributions consistent with known statistics:*

$$\min_{\{\hat{\mathbf{p}}_{\mathbf{x}}\} \in \Delta} \max_{\{\check{\mathbf{p}}_{\mathbf{x}}\} \in \Xi \cap \Delta} \mathbb{E}_{P(\mathbf{x})}[\hat{\mathbf{p}}_{\mathbf{x}}^T \mathbf{C} \check{\mathbf{p}}_{\mathbf{x}}] \quad (4)$$

where:  $\Xi : \mathbb{E}_{P(\mathbf{x})\check{P}(\check{y}|\mathbf{x})}[\phi(\mathbf{X}, \check{Y})] = \tilde{\phi}$ .

We denote the set of conditional probabilities for each input  $\mathbf{x}$  as  $\{\hat{\mathbf{p}}_{\mathbf{x}}\}$  and  $\{\check{\mathbf{p}}_{\mathbf{x}}\}$ . Here,  $\tilde{\phi}$  is a vector of provided feature moments measured from sample training data,  $\tilde{\phi} = \mathbb{E}_{\tilde{P}(\mathbf{x}, y)}[\phi(\mathbf{X}, Y)]$ , for example.

Conceptually, the feature statistics  $\phi(\mathbf{x}, y)$  defining the set  $\Xi$  should be chosen to restrict the adversary as much as possible from maximizing the loss. However, defining the set to be too restrictive leads to overfitting to the training data. Indeed, the complexity of the estimator  $\hat{P}(\hat{y}|\mathbf{x})$  implicitly grows with the dimensionality of the constraints in  $\Xi$ . Thoughtfully specifying the feature function  $\phi(\cdot, \cdot)$  and employing regularization can avoid this issue (§3.4).

### 3.2 INFERENCE AS ZERO-SUM GAME EQUILIBRIA

We establish efficient inference algorithms for our approach in this section. Theorem 1 transforms the joint adversary-constrained zero-sum games over many different inputs  $\mathbf{x}$  into a set of unconstrained zero-sum game that are independent for each input  $\mathbf{x}$  and connected by a parameterized cost matrix defining each player’s game outcomes.

**Theorem 1.** *Determining the value of the constrained cost-sensitive minimax game reduces to a minimization over the expectation of many unconstrained minimax game:*

$$\min_{\{\hat{\mathbf{p}}_{\mathbf{x}}\} \in \Delta} \max_{\{\check{\mathbf{p}}_{\mathbf{x}}\} \in \Xi \cap \Delta} \mathbb{E}_{P(\mathbf{x})}[\hat{\mathbf{p}}_{\mathbf{x}}^T \mathbf{C} \check{\mathbf{p}}_{\mathbf{x}}] \quad (5)$$

$$= \max_{\{\hat{\mathbf{p}}_{\mathbf{x}}\} \in \Xi \cap \Delta} \mathbb{E}_{P(\mathbf{x})} \left[ \min_{\check{\mathbf{p}}_{\mathbf{x}} \in \Delta} \hat{\mathbf{p}}_{\mathbf{x}}^T \mathbf{C} \check{\mathbf{p}}_{\mathbf{x}} \right] \quad (6)$$

$$= \min_{\theta} \mathbb{E}_{P(\mathbf{x})} \left[ \max_{\check{\mathbf{p}}_{\mathbf{x}} \in \Delta} \min_{\hat{\mathbf{p}}_{\mathbf{x}} \in \Delta} \hat{\mathbf{p}}_{\mathbf{x}}^T \mathbf{C}'_{\mathbf{x}, \theta} \check{\mathbf{p}}_{\mathbf{x}} \right], \quad (7)$$

where  $\theta$  parametrizes the new game characterized by matrix  $\mathbf{C}'_{\mathbf{x}, \theta} : (C'_{\mathbf{x}, \theta})_{\hat{y}, \check{y}} = C_{\hat{y}, \check{y}} + \theta^T (\phi(\mathbf{x}, \hat{y}) - \phi(\mathbf{x}, \check{y}))$ , and  $\phi(\cdot, \cdot)$  terms are from the definition of set  $\Xi$ .

*Proof of Theorem 1.*

$$\begin{aligned} & \min_{\{\hat{\mathbf{p}}_{\mathbf{x}}\} \in \Delta} \max_{\{\check{\mathbf{p}}_{\mathbf{x}}\} \in \Xi \cap \Delta} \mathbb{E}_{P(\mathbf{x})}[\hat{\mathbf{p}}_{\mathbf{x}}^T \mathbf{C} \check{\mathbf{p}}_{\mathbf{x}}] \\ \stackrel{(a)}{=} & \max_{\{\hat{\mathbf{p}}_{\mathbf{x}}\} \in \Xi \cap \Delta} \min_{\check{\mathbf{p}}_{\mathbf{x}} \in \Delta} \mathbb{E}_{P(\mathbf{x})}[\hat{\mathbf{p}}_{\mathbf{x}}^T \mathbf{C} \check{\mathbf{p}}_{\mathbf{x}}] \\ \stackrel{(b)}{=} & \max_{\{\hat{\mathbf{p}}_{\mathbf{x}}\} \in \Xi \cap \Delta} \mathbb{E}_{P(\mathbf{x})} \left[ \min_{\check{\mathbf{p}}_{\mathbf{x}} \in \Delta} \hat{\mathbf{p}}_{\mathbf{x}}^T \mathbf{C} \check{\mathbf{p}}_{\mathbf{x}} \right] \\ \stackrel{(c)}{=} & \max_{\{\hat{\mathbf{p}}_{\mathbf{x}}\} \in \Delta} \min_{\theta} \mathbb{E}_{P(\mathbf{x})} \left[ \min_{\check{\mathbf{p}}_{\mathbf{x}} \in \Delta} \hat{\mathbf{p}}_{\mathbf{x}}^T \mathbf{C} \check{\mathbf{p}}_{\mathbf{x}} \right. \\ & \quad \left. + \theta^T \mathbb{E}_{P(\mathbf{x})}[\Phi_{\mathbf{x}}(\check{\mathbf{p}}_{\mathbf{x}} - \hat{\mathbf{p}}_{\mathbf{x}})] \right] \\ \stackrel{(d)}{=} & \min_{\theta} \mathbb{E}_{P(\mathbf{x})} \left[ \max_{\check{\mathbf{p}}_{\mathbf{x}} \in \Delta} \min_{\hat{\mathbf{p}}_{\mathbf{x}} \in \Delta} \hat{\mathbf{p}}_{\mathbf{x}}^T \mathbf{C}'_{\mathbf{x}, \theta} \check{\mathbf{p}}_{\mathbf{x}} \right] \end{aligned}$$

where  $\Phi$  is the matrix defined by  $\Phi_{i,j} = \phi_i(\mathbf{x}, y_j)$  and  $\mathbf{C}'_{\mathbf{x}}$  is defined by elements:

$$(C'_{\mathbf{x}})_{\hat{y}, \check{y}} = C_{\hat{y}, \check{y}} + \theta^T (\phi(\mathbf{x}, \hat{y}) - \phi(\mathbf{x}, \check{y})). \quad (8)$$

Step (a) follows from minimax duality in zero-sum games [von Neumann and Morgenstern, 1947]. As an affine function of terms each with individual  $\check{\mathbf{p}}_{\mathbf{x}}$  term,

each minimization can be performed independently in step (b). Step (c) expresses the primal Lagrangian. For step (d),  $\mathbb{E}_{P(\mathbf{x})}[\min_{\check{\mathbf{p}}_{\mathbf{x}} \in \Delta} \hat{\mathbf{p}}_{\mathbf{x}}^T \mathbf{C} \check{\mathbf{p}}_{\mathbf{x}} + \theta^T \Phi_{\mathbf{x}}(\check{\mathbf{p}}_{\mathbf{x}} - \hat{\mathbf{p}}_{\mathbf{x}})]$ —a non-negative linear combination of minimums of affine functions—is a concave function of  $\check{\mathbf{p}}_{\mathbf{x}}$  terms. Given a feasible solution on the relative interior of  $\Xi$  [Boyd and Vandenberghe, 2004], strong Lagrangian duality holds. As in step (b), the maximizations can then be independently applied.  $\square$

Figure 2 shows the value of the game for a single  $\mathbf{x}$  from Eq. (6) as a function of the adversarial distribution  $\check{\mathbf{p}}_{\mathbf{x}}$  for zero-one loss and a more general cost matrix. The adversary is not free to independently maximize these functions for each  $\mathbf{x}$ , but must instead choose a structured prediction that resides within the constraint set  $\Xi$ .

Figure 2: The portion of the adversary’s objective function (6) for a single example,  $\min_{\check{\mathbf{p}}_{\mathbf{x}} \in \Delta} \hat{\mathbf{p}}_{\mathbf{x}}^T \mathbf{C} \check{\mathbf{p}}_{\mathbf{x}}$ , in the adversary-constrained game for zero-one loss (left) and a more general cost-sensitive loss with cost matrix  $[0 \ 2 \ 3; 2 \ 0 \ 1; 1 \ 3 \ 0]$  (right) in a three-class prediction task.

After applying Theorem 1 and given model parameters,  $\theta$ , (obtaining these parameters is discussed in §3.3) the unconstrained game,  $\max_{\check{\mathbf{p}}_{\mathbf{x}} \in \Delta} \min_{\hat{\mathbf{p}}_{\mathbf{x}} \in \Delta} \hat{\mathbf{p}}_{\mathbf{x}}^T \mathbf{C}'_{\mathbf{x}, \theta} \check{\mathbf{p}}_{\mathbf{x}}$ , can be solved independently for each  $\mathbf{x}$ . In this augmented game, our original cost matrix from Eq. (1) is transformed into the augmented cost matrix:

$$\mathbf{C}' = \begin{bmatrix} 0 + \psi_1 & 1 + \psi_2 & 2 + \psi_3 & 0 + \psi_4 \\ 3 + \psi_1 & 0 + \psi_2 & 1 + \psi_3 & 3 + \psi_4 \\ 4 + \psi_1 & 2 + \psi_2 & 0 + \psi_3 & 1 + \psi_4 \\ 1 + \psi_1 & 1 + \psi_2 & 2 + \psi_3 & 0 + \psi_4 \end{bmatrix}, \quad (9)$$

where Lagrangian potentials are compactly denoted as  $\psi_i = \theta^T (\phi(\mathbf{x}, i) - \phi(\mathbf{x}, \tilde{y}))$  with  $\tilde{y}$  representing the example’s actual label. For parameter estimation, the second feature function based on the actual label  $\tilde{y}$  serves an important role. However, since it is constant with respect to  $\tilde{y}$  and  $\hat{y}$ , and therefore does not influence the solution strategies for the game, it can be ignored when making predictions on data with unknown labels (or assigned an arbitrary value from  $\mathcal{Y}$  without affecting predictions).

Figure 3 shows the adversary’s objective function in the unconstrained, cost-augmented game. Conceptually, the adversary’s objective function from the constrained game

(Figure 2) is “placed” on top of a hyperplane shaped by the Lagrangian potential terms,  $\psi_i$ . The difference in these potential terms determines the adversary’s equilibrium strategy. For the binary classification task, there are three possible equilibrium strategies for the adversary. With three classes, there are seven possibilities: three pure strategies; three strategies that are mixtures of two classes; and one strategy that is a mixture of all three classes.

Figure 3: The adversary’s objective in the unconstrained game for a binary classification task with a mixed (uncertain) equilibrium solution (left) and a pure (certain) equilibrium solution (right). The third adversary strategy,  $P(\hat{y} = 2|x) = 0$ , is realized when  $\psi_1 \gg \psi_2$ .

Unlike the logarithmic loss under this minimax formulation, the cost-sensitive loss function does not provide a closed-form parametric solution<sup>2</sup>. Instead, the inner minimax game (inside the expectation of Eq. (7)) for each input  $\mathbf{x}$  can be solved as a linear program [von Neumann and Morgenstern, 1947]:

$$\begin{aligned} & \max_{v, \tilde{P}(\tilde{y}|\mathbf{x})} v & (10) \\ \text{subject to: } & v \leq \sum_{\tilde{y} \in \mathcal{Y}} \tilde{P}(\tilde{y}|\mathbf{x}) (C'_{\mathbf{x},\theta})_{\tilde{y},\tilde{y}} \quad \forall \tilde{y} \in \mathcal{Y} \\ & \sum_{\tilde{y} \in \mathcal{Y}} \tilde{P}(\tilde{y}|\mathbf{x}) = 1 \text{ and } \tilde{P}(\tilde{y}|\mathbf{x}) \geq 0, \quad \forall \tilde{y} \in \mathcal{Y}. \end{aligned}$$

The resulting distribution,  $\tilde{P}(\tilde{y}|\mathbf{x})$ , gives the adversary’s strategy  $\tilde{\mathbf{p}}_{\mathbf{x}}^*$ . The other strategy of the Nash equilibrium strategy pair,  $(\tilde{\mathbf{p}}_{\mathbf{x}}^*, \hat{\mathbf{p}}_{\mathbf{x}}^*)$  can be obtained by solving the same linear program with the cost matrix transposed and negated.

### 3.3 LEARNING VIA CONVEX OPTIMIZATION

Our key remaining task for employing the proposed approach is to obtain model parameters (Lagrangian multipliers)  $\theta$  that enforce the adversarial distribution to reside within the constraint set  $\Xi$ .

**Theorem 2.** *The subdifferential of the outer minimization problem (Eq. (7)) includes the expected feature difference as a subgradient:*

$$\begin{aligned} & \mathbb{E}_{P(\mathbf{x})\tilde{P}_{\hat{\theta}}^*(\tilde{y}|\mathbf{x})} [\phi(\mathbf{X}, \tilde{Y})] - \mathbb{E}_{P(\mathbf{x})P(y|\mathbf{x})} [\phi(\mathbf{X}, Y)] & (11) \\ & \in \partial_{\theta} \mathbb{E}_{P(\mathbf{x})} \left[ \min_{\tilde{\mathbf{p}}_{\mathbf{x}} \in \Delta} \max_{\hat{\mathbf{p}}_{\mathbf{x}} \in \Delta} \hat{\mathbf{p}}_{\mathbf{x}}^T C'_{\mathbf{x},\theta} \tilde{\mathbf{p}}_{\mathbf{x}} \right] \Big|_{\theta=\hat{\theta}} \end{aligned}$$

<sup>2</sup>Adversarial logarithmic loss minimization yields members of the exponential family [Wainwright and Jordan, 2008].

where  $\tilde{P}^*(\tilde{y}|\mathbf{x})$  is the solution to Eq. (10).

*Proof of Theorem 2.* Taking the subdifferential, we have:

$$\begin{aligned} & \partial_{\theta_k} \mathbb{E}_{P(\mathbf{x})} \left[ \min_{\tilde{\mathbf{p}}_{\mathbf{x}} \in \Delta} \max_{\hat{\mathbf{p}}_{\mathbf{x}} \in \Delta} \hat{\mathbf{p}}_{\mathbf{x}}^T C'_{\mathbf{x},\theta} \tilde{\mathbf{p}}_{\mathbf{x}} \right] \Big|_{\theta=\hat{\theta}} \\ & \stackrel{(a)}{=} \mathbb{E}_{P(\mathbf{x})} \left[ \partial_{\theta_k} \max_{\tilde{\mathbf{p}}_{\mathbf{x}} \in \Delta} \min_{\hat{\mathbf{p}}_{\mathbf{x}} \in \Delta} \hat{\mathbf{p}}_{\mathbf{x}}^T C'_{\mathbf{x},\theta} \tilde{\mathbf{p}}_{\mathbf{x}} \right] \Big|_{\theta=\hat{\theta}} \\ & \stackrel{(b)}{\ni} \mathbb{E}_{P(\mathbf{x})} \left[ \partial_{\theta_k} (\hat{\mathbf{p}}_{\mathbf{x}}^*)^T C'_{\mathbf{x},\theta} \tilde{\mathbf{p}}_{\mathbf{x}}^* \right] \Big|_{\theta=\hat{\theta}} \\ & \stackrel{(c)}{=} \mathbb{E}_{P(\mathbf{x})} \left[ (\hat{\mathbf{p}}_{\mathbf{x}}^*)^T (\partial_{\theta_k} C'_{\mathbf{x},\theta}) \tilde{\mathbf{p}}_{\mathbf{x}}^* \right] \Big|_{\theta=\hat{\theta}} \\ & \stackrel{(d)}{\ni} \mathbb{E}_{P(\mathbf{x})\tilde{P}_{\hat{\theta}}^*(\tilde{y}|\mathbf{x})} [\phi_k(\mathbf{X}, \tilde{Y})] - \mathbb{E}_{P(\mathbf{x})P(y|\mathbf{x})} [\phi_k(\mathbf{X}, Y)]. \end{aligned}$$

Step (a) follows from the rule for non-negative combinations of subdifferentials. Step (b) follows from the subdifferential of the function evaluated at the maximizing/minimizing values being a subset of the subdifferential of the maximum/minimum functions. Step (c), like step (a), follows from the rule for non-negative combinations of subdifferentials by noting that  $(\hat{\mathbf{p}}_{\mathbf{x}}^*)^T C'_{\mathbf{x},\theta} \tilde{\mathbf{p}}_{\mathbf{x}}^* = \hat{\mathbf{p}}_{\mathbf{x}}^* (\tilde{\mathbf{p}}_{\mathbf{x}}^*)^T \bullet C'_{\mathbf{x},\theta}$ , where  $\bullet$  represents the “matrix dot product” (i.e.,  $\mathbf{A} \bullet \mathbf{B} \triangleq \sum_{i,j} A_{i,j} B_{i,j}$ ). In step (d), the subdifferential terms for  $C'_{\mathbf{x}}$  include  $\phi_k(\mathbf{x}, \tilde{y}) - \phi_k(\mathbf{x}, y) \in (\partial_{\theta_k} C'_{\mathbf{x}})_{\tilde{y},y}$  and do not depend on  $\hat{\mathbf{p}}_{\mathbf{x}}$ .  $\square$

Leveraging the convexity of the formulation’s objective function (discussed in the Proof of Theorem 1), and using the common substitution of the sample training data distribution,  $\tilde{P}(\mathbf{x})$ , in place of the distribution  $P(\mathbf{x})$ , we employ standard subgradient-based optimization methods for convex optimization problems to obtain parameters for our cost-sensitive classifier (Algorithm 1).

Though we describe a stochastic subgradient in our algorithm, any convex optimization method for non-smooth objective functions can be employed.

### 3.4 PERFORMANCE GUARANTEES & ILLUSTRATIVE EXAMPLES

We establish performance guarantees and illustrate the behavior of our approach in this portion of the paper. We focus specifically on the similarities to and differences from support vector machines [Cortes and Vapnik, 1995] and their structured extensions [Tsochantaridis et al., 2004]. Given ideal data (linearly separable), Theorem 3 establishes an equivalence to hard-margin SVMs.

**Theorem 3.** *Given linearly separable training data, i.e.,*

$$\exists \theta : \forall i, y' \neq y_i, \theta \cdot \phi(\mathbf{x}_i, y_i) > \theta \cdot \phi(\mathbf{x}_i, y'), \quad (12)$$

and zero cost only for correct predictions  $C_{i,i} = 0$ , the adversarial cost-sensitive learner with sufficiently small  $L_2$  regularization is equivalent to a hard-margin cost-sensitive support vector machine.

*Proof.* Eq. (12) implies  $\exists \theta' : \forall i, y' \neq y_i, \theta' \cdot \phi(\mathbf{x}_i, y_i) > \theta' \cdot \phi(\mathbf{x}_i, y') + C_{y', y_i}$  (the hard-margin cost-sensitive SVM constraint set with  $\epsilon = \mathbf{0}$  in Eq. (3)) by multiplicatively scaling  $\theta$ . The Nash equilibrium is  $\hat{P}(\hat{y}_i | \mathbf{x}_i) = 1$  and  $\hat{P}(\hat{y}_i | \mathbf{x}_i) = 1$  with a cost-sensitive loss of zero *if and only if* this inequality is satisfied. Given this, the dual optimization in Eq. (7) realizes its minima (zero loss) only when these constraints are satisfied. The  $L_2$  regularization term is a monotonic transformation of the objective of the hard-margin SVM:  $\theta \cdot \theta$ . Thus, having the same constraints and objective functions with corresponding maxima, an equivalent solution is produced.  $\square$

As a result of this equivalence to hard-margin SVM, adversarial classification inherits the convergence properties of support vectors machines in the realizable case of Eq. (12).

The game strategies of each player are illustrated in Figure 4 for binary prediction using the zero-one loss in the separable setting. Between perfectly classified datapoints, our approach produces a region of uncertainty that is maximally uncertain for the adversary’s Nash equilibrium strategy ( $\hat{P}(\hat{Y} = \text{‘o’} | \mathbf{x}) = 0.5$ ), while the predictor’s Nash equilibrium strategy smoothly transitions from one class to the other in this region.

Given non-separable data, the adversarial approach suggests choosing a set  $\Xi$  of constraints based on training samples  $\hat{P}(\mathbf{x}, y)$  that will also contain the true label distribution,  $P(y | \mathbf{x})$ . When this is accomplished, Theorem 4 provides performance guarantees for generalization.

**Theorem 4.** *If  $P(y | \mathbf{x}) \in \Xi$ , confusion costs from the adversarial game upper bound the generalization error confusion costs:*

$$\mathbb{E}_{P(\mathbf{x})P(y|\mathbf{x})\hat{P}^*(\hat{y}|\mathbf{x})}[C_{\hat{Y}, Y}] \leq \mathbb{E}_{P(\mathbf{x})\hat{P}^*(\hat{y}|\mathbf{x})\hat{P}^*(\hat{y}|\mathbf{x})}[C_{\hat{Y}, \hat{Y}}].$$

Figure 4: Adversary (left) and predictor (right) distributions for separable data under zero-one loss

*Proof.* By definition, the adversarial conditional label distribution,  $\hat{P}^*(\hat{y} | \mathbf{x})$ , is a Nash equilibrium and it provides the worst possible loss for the estimator of all conditional label distributions from set  $\Xi$ . So long as the true label distribution used for evaluation,  $P(y | \mathbf{x})$ , is similar to training data properties (i.e, a member of  $\Xi$ ), then costs that are no worse than  $\hat{P}^*(\hat{y} | \mathbf{x})$  can result without  $P(y | \mathbf{x})$  being a better choice from  $\Xi$  than  $P(y | \mathbf{x})$  for maximizing the predictor’s loss, a contradiction.  $\square$

Slack can be added to the constraint set  $\Xi$  or regularization to the dual optimization problem of Eq. (6) to address finite sample approximation error when using sample data,  $\mathbb{E}_{\hat{P}(\mathbf{x}, y)}[\phi(\mathbf{X}, Y)]$ , as an estimate of the distribution’s statistics,  $\mathbb{E}_{P(\mathbf{x}, y)}[\phi(\mathbf{X}, Y)]$ .

Figure 5: Adversary (left) and predictor (right) distributions for nonseparable data under zero-one loss

Figure 5 shows the two equilibria strategies for data that is not linearly separable in the zero-one loss binary classification setting. The uncertainty region of our approach depends on summary statistics rather than the specific datapoint labels that define margin boundaries of SVMs (Figure 5). Increased non-separability of the data and greater regularization amounts expand this uncertainty region.

The equilibria under cost-sensitive losses, shown in Figure 6 shifts the region of uncertainty to better minimize the expected cost compared to Figure 5, which is based on the same data sample. Additionally, the adversary’s predictions shift ( $\hat{P}(Y = \text{‘o’} | \mathbf{x}) = .25$ ) within the region of uncertainty.

Figure 6: Adversary (left) and predictor (right) distributions for nonseparable data under  $[0 \ 1; 3 \ 0]$  cost matrix.

From the perspective of Theorem 3 and Theorem 4, adversarial cost-sensitive classification provides an alternative to hinge-loss “softening” of the hard-margin SVM. By posing cost-sensitive prediction as an adversarial game (Def. 1), our approach approximates aspects of the training data while being able to employ non-convex loss functions without the intractability encountered by empirical risk minimization. Prediction under this approach reduces to the well-studied problem of solving a zero-sum game, which is easily addressed using linear programming via Eq. (10). This is only a little more complicated than predictions for SVM based on the label that maximizes a linear potential function. Like SVMs, estimating model parameters can be posed as a convex optimization problem and solved using subgradient optimization methods (Alg. 1) under our approach.

## 4 EXPERIMENTS

Our adversarial approach provides the advantage of operating efficiently on non-convex cost-sensitive loss functions, but only through approximating the training data label information rather than minimizing loss on the actual labeled training data. We experimentally investigate the trade-off our approach provides in this section.

### 4.1 DATASETS

We employ publicly available datasets for multiclass classification to evaluate our approach. The number of classes and the number of examples (size) of each dataset are listed in Table 1. We rescale the attributes to  $[0,1]$  and enumerate the class labels.

### 4.2 METHODOLOGY

We conduct 10 cost-sensitive classification tasks for each dataset. We generate confusion cost matrices,  $\mathbf{C}$ , for each task by: (1) assigning all correct classifications a cost of zero ( $C_{i,i} = 0, \forall i$ ); and (2) sampling the remaining elements of the cost matrix from the uniform distribution ( $C_{i,j} \sim U[0, 1], \forall i \neq j$ ). For each classification task, we

Table 1: Evaluation datasets and dataset characteristics.

| Name            | Classes | Attributes | Training | Testing |
|-----------------|---------|------------|----------|---------|
| Iris            | 3       | 4          | 120      | 30      |

| Vertebral       | 3       | 6          | 248      | 62      |

split the data into training and testing sets as described in Table 1. We measure the expected cost of each method averaged over each of the 10 tasks.

### 4.3 COMPARISON METHODS

Our primary points of comparison for investigating this paper’s central hypothesis—that adversarial data approximation produces better cost-sensitive classifiers than convex loss approximation—are support vector methods. However, we also compare with recently reported state-of-the-art cost-sensitive boosting methods. We implement and compare our proposed approach against the following specific methods for cost-sensitive learning. The methodological details for each approach are:

- **Our approach:** We train our method via Algorithm 1 using a quadratic expansion of the original attributes and a “one-hot” encoding of the class label,  $\phi(\mathbf{x}, y) = [\text{vector}(\mathbf{x}\mathbf{x}^T)I(y = 1); \text{vector}(\mathbf{x}\mathbf{x}^T)I(y = 2); \dots]$ . To produce deterministic predictions, we “round” the estimator’s Nash equilibrium strategy,  $\hat{P}^*(\hat{y}|\mathbf{x})$  to the most probable label. This avoids the ambiguity of other methods for making deterministic predictions from mixed strategies (e.g., two or more actions may be the best response to the adversary’s Nash equilibrium strategy).
- **Guess Averse Cost-Sensitive Boosting:** We employ the guess averse cost-sensitive boosting method and implementation [Beijbom et al., 2014] with GLL loss described in §2.1. (We also investigated GEL, but found it to be consistently and significantly outperformed by GLL.) We use a linear regression model as the weak learner.
- **Cost-Sensitive One-Versus-One (CSOVO):** We employ the LIBSVM [Chang and Lin, 2011] implementation of the CSOVO SVM approach [Lin, 2010] described in §2.1. Our experiments use quadratic kernels

Table 2: CSOVO and CSOVA kernel parameters chosen using five-fold cross validation on the training set from  $\gamma_1 \in \{0.125, 1, 2, 5, 10, 1/\text{number of features}\}$  and  $\gamma_0 \in \{1, 2, 5, 10, 50, 100, 200, 300, \dots, 900\}$ .

| Name            | CSOVO      |            | CSOVA      |            |
|-----------------|------------|------------|------------|------------|
|                 | $\gamma_1$ | $\gamma_0$ | $\gamma_1$ | $\gamma_0$ |
| Iris            | 5          | 2          | 1          | 700        |
| Optical Digits  | 1          | 2          | 5          | 2          |
| Satellite Image | 10         | 50         | 1          | 1          |
| Shuttle         | 0.125      | 900        | 0.125      | 900        |
| Vehicle         | 10         | 5          | 10         | 10         |
| Wine            | 1          | 500        | 1          | 5          |
| Breast Tissue   | 0.125      | 900        | 10         | 400        |
| Ecoli           | 5          | 500        | 0.125      | 800        |
| Glass           | 5          | 400        | 10         | 700        |
| Image Segment   | 0.125      | 300        | 0.125      | 600        |
| Libras          | 1          | 5          | 1          | 2          |
| Pen Digits      | 0.125      | 700        | 5          | 5          |
| Vertebral       | 0.125      | 600        | 0.125      | 500        |

[Chang and Lin, 2011],  $K(u, v) = (\gamma_1 u^T v + \gamma_0)^2$  to match the expressiveness of our approach. We run five-fold cross validation on the training set of every dataset to choose quadratic kernel parameters (shown in Table 2), and then we use these best parameters to train from the training set and construct the final classifier model<sup>3</sup> Finally, we evaluate the CSOVO performance by measuring the prediction cost on the test data.

- **Cost-Sensitive One-Versus-All (CSOVA):** We similarly employ the LIBSVM implementation of the CSOVA SVM approach described in §2.1. Our methodology matches that of CSOVO for cross-validation (parameters shown in Table 2), training, and testing.
- **Structured SVM (SVM-Struct):** We employ the Large Scale Structured SVM (SVM LS) software package [Branson et al., 2013] to obtain a multiclass cost-sensitive predictor based on the additive cost-sensitive hinge loss of Eq. (3). SVM LS applies online subgradient methods [Ratliff et al., 2007] and sequential order optimization [Shalev-Shwartz et al., 2011] to improve efficiency. We evaluate the Online Dual Ascent (ODA) algorithm [Branson et al., 2013] as well as the Stochastic Gradient Descent (SGD) method for the purpose of our cost-sensitive experiments. We employ a trade-off parameter  $\alpha$  of 100.

<sup>3</sup>We use the default tolerance of termination criterion, 0.001, for most of the datasets except *image segmentation* and *shuttle*, which required a less sensitive criterion to converge.

## 4.4 RESULTS

Figure 7 shows the average loss incurred by each approach on the 13 different datasets. Our method generally performs well on all of the datasets except *wine* and *libras* datasets and has a similar performance with boosting. SVM methods except SVM-CSOVA are strong on some of the datasets (*optdigits*, *pendigits*, *wine* and *libras*). For many datasets, the performance of the reduction-based SVM approaches is significantly worse than our approach and boosting and the multi-class structured SVM approach. The multi-class structured SVM approach specifically is significantly worse than our method on many of the datasets (*satimage*, *shuttle*, *vehicle*, *breast tissue*, *pendigits*, and *vertebral*), while only significantly better on the *optdigits* dataset.

Figure 7: The average loss of predictions for the datasets of Table 1.

The differences between the results of our method and those of boosting are not as extreme. Indeed, for many of the datasets (*iris*, *wine*, *shuttle*, *optdigits*, *vertebral*, *ecoli*, *breast tissue*, and *libras*), the differences in average performance are not significant. For one dataset (*imgseg*), boosting is significantly better, while our method is significantly better for the remaining four (*satimage*, *shuttle*, *vehicle*, and *pendigits*).

We compare the average loss of the prediction methods aggregated over all of the datasets in Figure 8, showing that on average our method provides lower cost predictions. It is important to note that as an ensemble method, boosting is able to implicitly consider a much richer feature space than our approach. For classification, SVMs are often only comparable when incorporating kernels that can also implicitly consider richer feature spaces. Thus, exceeding the performance of the state-of-the-art boosting method using only quadratic features is a significant demonstration of our method. The comparisons with the structured SVM method, which considers an identical feature space, illustrates the general benefit our approach provides by adversarially approximating the training data rather than convexly approximating the loss function.

Figure 8: Average loss of predictions across all datasets of Table 1.

## 5 CONCLUSIONS

In this paper, we have developed an approach for minimizing the exact cost-sensitive loss using an adversarial formulation. In stark contrast with existing methods, which typically minimize a convex approximation of the cost-sensitive loss evaluated on available training data, our approach directly minimizes the actual cost-sensitive loss evaluated on an approximation of the training data. This perspective of placing uncertainty around the training data and resolving it by considering an adversarial evaluator leads to a zero-sum game formulation for inference and convex optimization for estimating model parameters.

We demonstrated the benefits of the approach on a total of 130 prediction tasks. Our approach performs competitively with a state-of-the-art boosting method across many of these tasks and better on average. This is despite the fact that boosting, as an ensemble method, is able to implicitly consider a richer feature space for the classifiers that it ultimately produces. The performance of our approach is much more significantly better than structured multi-class SVM methods and reduction-based SVM methods, which are more directly comparable as they employ the same quadratic feature space.

Our future work will investigate avenues for improving and expanding this adversarial approach to cost-sensitive learning. Foremost, we plan investigate the feasibility of incorporating kernel methods with our approach so that much larger or infinite feature spaces can be tractably incorporated into our cost-sensitive classifier. Additionally, we plan to investigate settings with cost functions that depend on the input attributes in addition to the predicted and actual labels.

## Abstract

Network analysis needs tools to compare networks and assess the significance of differences between networks. We propose a principled statistical approach to network comparison that approximates networks as probability distributions on negatively curved manifolds. We outline the theory, as well as implement the approach on simulated networks, where its accuracy can be confirmed.

## 1 INTRODUCTION

Many scientific questions about networks amount to problems of *network comparison*: one wants to know whether networks observed at different times, or in different locations, or under different environmental or experimental conditions, actually differ in their structure. Such problems arise in neuroscience (e.g., comparing subjects with disease conditions to healthy controls, or the same subject before and after learning), in biology (e.g., comparing gene- or protein- interaction networks across species, developmental stages or cell types), and in social science (e.g., comparing different social relations within the same group, or comparing social groups which differ in some outcome). That the graphs being compared are not identical or even isomorphic is usually true, but scientifically unhelpful. What we need is a way to say if the difference between the graphs exceeds what we should expect from mere population variability or stochastic fluctuations. Network comparison, then, is a kind of two-sample testing, where we want to know whether the two samples could have come from the same source distribution. It is made challenging by the fact that the samples being compared are very structured, high-dimensional objects (networks), and more challenging because we often have only *one* graph in each sample.

We introduce a method for network comparison. The crucial idea is to approximate networks by continuous geo-

metric objects, namely probability densities, and then do two-sample bootstrap tests on those densities. Specifically, we draw on recent work showing how many real-world networks are naturally embedded in hyperbolic (negatively curved) manifolds. Graphs then correspond to clouds of points in hyperbolic space, and can be viewed as being generated by sampling from an underlying density on that space. We estimate a separate density for each of the two networks being compared, calculate the distance between those densities, and compare it to the distance expected under sampling from a pooled density estimate.

Our method, while conceptually fairly straightforward, is admittedly more complicated than the current practice in the scientific literature, which is to compare networks by taking differences in *ad hoc* descriptive statistics (e.g., average shortest path lengths, or degree distributions). It is very hard to assess the statistical significance of these differences, and counter-examples are known where the usual summary statistics fail to distinguish graphs which are qualitatively radically different (e.g., grid-like graphs from highly clustered tree-like ones). Similarly, whole-graph metrics and similarity measures are of little statistical use, without probability models to gauge their fluctuations. Below, we show through simulations that our method let us do network comparisons where (i) we can assess significance, (ii) power is high for qualitative differences, and (iii) when we detect differences, we also get some idea *how* the networks differ.

## 2 MOTIVATION AND BACKGROUND

A fundamental issue with network comparison, mentioned in the introduction, is that we often have *only* two networks to compare, and nonetheless need to make some assessment of statistical significance. This can obviously only be done by regarding the networks as being drawn from (one or more) probability models, and restricting the form of the model so that an observation of a single graph is informative about the underlying distribution. That is, we must restrict ourselves to network models which obey some sort

of law of large numbers or ergodic theorem within a single graph, or else we always have  $n = 1$ . As in any other testing problem, the better the alignment between the model's restrictions and actual properties of the graphs, the more efficiently the test will use the available information.

**Salient properties of actual networks** Over the last two decades, it has become clear that many networks encountered in the real world, whether natural or human-made, possess a number of mathematically striking properties (Newman, 2010). They have highly right-skewed degree distributions, they show the “small-world effect” of short average path lengths (growing only logarithmically with the number of nodes) but non-trivial transitivity of links, and high clusterability, often with a hierarchical arrangement of clusters. This is all a far cry from what is expected of conventional random graphs. While a large literature of parametric stochastic models has developed to try to account for these phenomena (Newman, 2010), there are few situations where a data analyst can *confidently* assert that one of these models is even approximately well-specified.

**Current approaches to network comparison** The typical approach in the literature is *ad hoc* comparison of common descriptive statistics on graphs (path lengths, clustering coefficients, etc.). These statistics are often misapplied, as in the numerous incorrect claims to have found “power law” or “scale-free” networks (Clauset et al., 2009), but that is not the fundamental issue. Even the recent authoritative review of, and advocacy for, the “connectomics” approach to neuroscience by Sporns (2010) takes this approach. Disturbingly, Henderson and Robinson (2011) show that, with commonly used choices of statistics and criteria, this approach cannot distinguish between complex, hierarchically-structured networks, and simple two-dimensional grids (such as a grid over the surface of the cortex).

More formally, Pao et al. (2011) study the power of tests based on such summaries to detect departures from the null hypothesis of completely independent and homogeneous edges (Erdos-Renyi graphs) in the direction of independent but heterogeneous edges. Their results were inconclusive, and neither their null nor the alternative models are plausible for real-world networks. Apart from this, essentially nothing is known about either the significance of such comparisons or their power, how to combine comparisons of different descriptive statistics, which statistics to use, or if significant differences are found, how to infer changes in structure from them. The issue of statistical significance also afflicts graph metrics and similarity measures, even those with plausible rationales in graph theory (e.g., that of Koutra et al. 2013).

Hunter et al. (2008) show one way to check goodness-of-fit for a model of a single network, using simulations to

check whether the observed values of various graph statistics are plausible under the model's sampling distribution. But they are unable to combine checks with different statistics, cannot find the power of such tests, and do not touch on differences across networks.

More relevantly to comparisons, Middendorf et al. (2005) use machine-learning techniques to classify networks as coming from one or another of various generative models, taking features of the network (such as the counts of small sub-graphs, or “motifs”) as the inputs to the classifier. They demonstrate good operating characteristics in simulations, but rely on having a good set of generative models to start with.

The approach to network comparison most similar to ours is Tang et al. (2014), which, like our proposed methods, models the nodes as drawn from densities on a latent space and attaches edges based on the geometric relationship between node coordinates. The primary difference between both approaches is the choice of latent space. Tang et al. (2014) use a Euclidean inner product space, allowing for an algebraic method of network inference. Our choice is motivated by the desire to pick a latent space that matches geometric properties of the real-world networks we aim to study.

A final related approach to network comparison is Rosvall and Bergstrom (2010), which like our proposed methods, uses bootstrap resampling from models fit to the original networks to assess significance of changes. The goal there however is not to detect global changes in the network structure, but local changes in which nodes are most closely tied to one another.

**Hyperbolic geometry of networks** While waiting for scientifically-grounded parametric models, we seek a class of non-parametric models which can accommodate the stylized facts of complex networks. Here we draw on the more recent observation that for many real-world networks, if we view them as metric spaces with distance given by shortest path lengths, the resulting geometry is *hyperbolic* (Albert et al., 2014, Kennedy et al., 2013, Krioukov et al., 2010), rather than Euclidean. Said another way, many real-world networks can be naturally embedded into negatively-curved continuous spaces. Indeed, Krioukov et al. (2010) show that if one draws points representing nodes according to a “quasi-uniform” distribution on the hyperbolic plane (see (2) below), and then connects nodes with a probability that decays according to the hyperbolic distance between the representative points, one naturally obtains graphs showing right-skewed degree distributions, short average path lengths, and high, hierarchical clusterability.

**Continuous latent space models** The model of (Krioukov et al., 2010) is an example of a *continuous latent*

space model, characterized by a metric space  $(M, \rho)$ , a link probability function  $W$ , and a probability density  $f$  on  $M$ , the *node density*. Points representing nodes are drawn iid from  $f$ , and edges form independently between nodes at  $x$  and  $y$  with probability  $W(x, y) = W(\rho(x, y))$  decreasing in the distance. As a hierarchical model,

$$\begin{aligned} Z_i &\sim_{iid} f \\ A_{ij}|Z_1, \dots, Z_n &\sim_{ind} W(\rho(Z_i, Z_j)) \end{aligned} \quad (1)$$

where  $A_{ij}$  is the indicator variable for an edge between nodes  $i$  and  $j$ . Holding  $M, \rho, W$  fixed, but allowing  $f$  to vary, we obtain different distributions over graphs. Two densities  $f, g$  on  $M$  determine the same distribution over graphs if  $f$  is the image of  $g$  under some isometry of  $(M, \rho)$ . Note that node *densities* can be compared regardless of the number of nodes in the observed graphs.

The best-known continuous latent space model for social networks is that of Hoff et al. (2002), where the metric space is taken to be Euclidean and the density  $f$  is assumed to be Gaussian. Our general methodology for network comparison could certainly be used with such models. However, the striking properties of large real-world graphs, such as their highly-skewed degree distributions, lead us to favor the sort of hyperbolic model used by Krioukov et al. (2010), but without their restrictive assumptions on  $f$ . Rather, we will show how to non-parametrically estimate the node density from a single observed graph, and then reduce network comparison to a comparison of these probability densities.

Continuous latent space models are themselves special cases of models called *graphons*, lifting the restriction that  $M$  be a metric space, and requiring of the edge probability function  $W(x, y)$  only that it be measurable and symmetric in its arguments<sup>1</sup>. Any distribution over infinite graphs which is invariant under permuting the order of the nodes turns out to be a mixture of such graphons (Kallenberg, 2005, ch. 7). Moreover, as one considers larger and larger graphs, the properties of the observed graph uniquely identify the generating graphon (Diaconis and Janson, 2008); what almost comes to the same thing, the limit of a sequence of growing graphs is a graphon (Borgs et al., 2006, Lovász, 2012, Borgs et al., 2014). One might, then, try to use our approach to compare graphons with estimated  $f$  and  $W$ . While graphon estimation is known to be possible in principle (Bickel et al., 2011, Choi and Wolfe, 2014), there are no published, computationally feasible methods to do it. Moreover, we expect to gain power by tailoring our models to enforce salient network properties, as described above. Accordingly, we turn to some of the important as-

<sup>1</sup>Graphons are often *defined* to have  $M = [0, 1]$  and  $f$  Lebesgue measure. One can show that any graphon over another measure space or with another node density is equivalent to one of this form, i.e., generates the same distribution over infinite graphs (Kallenberg, 2005, ch. 7).

FIGURE 1: **Models of  $\mathbb{H}_2$**  A connected component of the hyperboloid  $x_3^2 = 1 + x_1^2 + x_2^2$  (left), with the metric given by the shortest possible Minkowski length of a path between points along the surface, is isometric to the Poincaré half-plane (right) under a suitable non-Euclidean metric. The half-plane is tiled into regions of equal area with respect to the metric. (Images from Rocchini (2007), under a Creative Commons license.)

pects of hyperbolic geometry.

## 2.1 HYPERBOLIC SPACES

Hyperbolic spaces are metric spaces which are negatively curved — the angles in a triangle of geodesics sum to less than 180 degrees. The oldest example of such a space is the surface of (one sheet of) the hyperboloid, the surface of points  $(x_1, x_2, x_3) \in \mathbb{R}^3$  such that

$$x_1^2 + x_2^2 - x_3^2 = -1,$$

with the distance between points taken to be the smallest possible Minkowski length of a path between them along the surface. Another, and perhaps even more basic, example of a hyperbolic space is a tree, again with the shortest-path metric. Our starting data will be observed networks, which are typically at least locally tree-like, and so also possess a hyperbolic geometry (Jonckheere et al., 2008).

As explained above, we aim to represent this discrete hyperbolic geometry with a density over a continuous hyperbolic space. For concreteness, we will focus on the hyperbolic plane  $\mathbb{H}_2$ , whose most basic geometric model is just the surface of the hyperboloid. It will be more convenient to work with another model of  $\mathbb{H}_2$ : the *Poincaré half-plane* of  $\mathbb{C}$ ,

$$\mathbb{H}_2 = \{x + iy \mid x \in \mathbb{R}, y \in (0, \infty)\}$$

equipped with the metric  $d\rho^2 = (dx^2 + dy^2)/y^2$ .

As mentioned above, (Krioukov et al., 2010) showed that if the density of nodes on the Poincaré half-plane is one of the *quasi-uniform* densities,

$$q_{\delta, R}(re^{i\theta}) = \frac{\delta \sinh \delta r}{2\pi(\sinh r) \cosh(\delta R - 1)}, \quad \delta > 0 \quad (2)$$

one obtains graphs which reproduce the stylized facts of right-skewed degree distributions, clusterability, etc., for

FIGURE 2: **Densities on  $\mathbb{H}_2$**  1000 points drawn iidly from quasi-uniform densities, Eq. 2 (top;  $\delta = 1, 10, 30$  from left to right,  $R = 1$  throughout), and from hyperbolic Gaussian densities, Eq. 8 (bottom,  $\sigma = 0.05, 0.1, 0.3$  from left to right).

FIGURE 3: **Hyperbolic latent-space graphs** Graphs formed by drawing 30 node locations as in Fig. 2, and applying the link probability function  $W(x, y) = \Theta(\rho(x, y) - 1.5)$ . Note how the graphs in the bottom row become more clustered as the  $\delta$  parameter increases from left to right.

a wide range of link probability functions  $W$ , including Heaviside step functions  $\Theta(\rho - c)$ . Note that the mode of  $q$  is always at  $0 + i$ , with the parameter  $\delta > 0$  controlling the dispersion around the mode, and  $R > 0$  being an over-all scale factor. As  $\delta$  grows, the resulting graphs become more clustered.

We will introduce another family of densities on  $\mathbb{H}_2$ , the hyperbolic *Gaussians*, in the next section.

Fig. 2 shows samples from quasi-uniform distributions on  $\mathbb{H}_2$ , and Fig. 3 the resulting graphs. While we will use such networks as test cases, we emphasize that we will go beyond (2) to a fully nonparametric estimation of the node density.

### 3 METHOD

Our goal is to compare networks by comparing node densities. Our procedure for estimating node densities has in

FIGURE 4: *Schematic of network inference*

turn two steps (Figure 4): we embed the nodes of an observed network into  $\mathbb{H}_2$  (§3.1), and then estimate a density from the embedded points (§3.2). We may then compare the observed difference between estimated node densities from two graphs to what would be expected if we observed two graphs drawn from a common node density (§3.3).

#### 3.1 GRAPH EMBEDDING

An *embedding* of a graph  $G$  is a mapping of its nodes  $V_G$  to points into a continuous metric space  $(M, \rho)$  which preserves the structure of the graph, or tries to. Specifically, the distances between the representative points should match the shortest-path distances between the nodes, as nearly as possible. This is a multidimensional scaling problem, where typically one seeks the embedding  $\phi : V_G \mapsto M$  minimizing

$$\sum_{(v,w) \in V_G^2} (\rho_G(v, w) - \rho(\phi(v), \phi(w)))^2, \quad (3)$$

where  $\rho_G$  is the shortest-path-length metric on  $V_G$ . Classically, when  $M = \mathbb{R}^n$  and  $\rho$  is the Euclidean metric, the arg-min of (3) can be found by spectral decomposition of the matrix of  $\rho_G(v, w)$  values (Hand et al., 2001, ch. 3).

Spectral decomposition does not however give the arg-min of (3) when  $M = \mathbb{H}_2$  with the appropriate non-Euclidean metric. While the solution could be approximated by gradient descent (Cvetkovski and Crovella, 2011), we follow Begelfor and Werman (2005) in changing the problem slightly. They propose minimizing

$$\sum_{(v,w) \in V_G^2} (\cosh \rho_G(v, w) - \cosh \rho(\phi(v), \phi(w)))^2 \quad (4)$$

which can be done exactly via a spectral decomposition. Specifically, let  $R_{ij} = \cosh \rho_G(i, j)$ , whose leading eigenvector is  $u_1$  and whose trailing eigenvectors are  $u_2$  and  $u_3$ . Then the  $i^{\text{th}}$  row of the matrix  $(u_1 u_2 u_3)$  gives the  $\mathbb{H}_2$  coordinates for node  $i$ . If  $R$  has one positive eigenvalue, exactly

2 negative eigenvalues, and all remaining eigenvalues vanish, this defines an exact isometric embedding (Begelfor and Werman, 2005).

We have not found a way of estimating the node density which avoids the initial step of embedding. Our method is, however, fairly indifferent as to *how* the nodes are embedded, so long as this is done well, and in a way which does not pre-judge the form of the node density.

FIGURE 5: **Re-embedded Generated Graphs** Results of embedding simulated graphs, formed as in Fig. 3, back into  $\mathbb{H}_2$ . Comparison with Fig. 2 illustrates the fidelity of the embedding process.

### 3.2 DENSITY ESTIMATION

Having embedded the graph into  $\mathbb{H}_2$ , we estimate the node density. Our procedure for doing so is more easily grasped by first reviewing the connections between kernel density estimation, convolution, and Fourier transforms in Euclidean space.

**Kernel density estimation in Euclidean space as convolution** In Euclidean space, kernel density estimation smooths out the empirical distribution by adding a little bit of noise around each observation. Given observations  $z_1, z_2, \dots, z_n \in \mathbb{R}^p$ , and a normalized kernel function  $K_h$ , the ordinary kernel density estimator  $\hat{f}^{n,h}$  at a point  $z \in \mathbb{R}^p$  is

$$\begin{aligned} \hat{f}^{n,h}(z) &= \frac{1}{n} \sum_{i=1}^n K_h(z - z_i) \\ &= \int_{\mathbb{R}^p} K_h(z - z') \left( \frac{1}{n} \sum_{i=1}^n \delta(z' - z_i) \right) dz' \\ &= \int_{\mathbb{R}^p} K_h(z - z') \hat{P}_n(dz') \\ &= (K_h * \hat{P}_n)(z) \end{aligned}$$

where the third line defines the empirical measure  $\hat{P}_n$ , and  $*$  denotes convolution. In words, the kernel density estimate is the convolution of the empirical measure with the

kernel. Here the role of the kernel  $K_h$  is not so much to be a distribution over the Euclidean space, as a distribution over *translations* of the space:  $K_h(z - z_i)$  is really the density at the translation mapping the data point  $z_i$  into the operating point  $z$ . As it happens, the group of translations of  $\mathbb{R}^p$  is also  $\mathbb{R}^p$ , but when we adapt to non-Euclidean spaces, this simplifying coincidence goes away.

Since, in Euclidean space, the Fourier transform  $\mathcal{F}$  converts convolutions into products (Stein and Weiss, 1971),

$$\mathcal{F} \left[ \hat{f}^{n,h} \right] (s) = \mathcal{F} [K_h] (s) \mathcal{F} \left[ \hat{P}_n \right] (s)$$

This relation often greatly simplifies computing  $\hat{f}^{n,h}$ . It also lets us define the bandwidth  $h$ , through the relation  $\mathcal{F} [K_h] (s) = \mathcal{F} [K] (hs)$ .

It is well known that kernel density estimators on  $\mathbb{R}^p$ , with  $h \rightarrow 0$  at the appropriate rate in  $n$ , are minimax-optimal in their  $L_2$  risk (van der Vaart, 1998). With suitable modifications, this still holds for compact manifolds (Pelletier, 2005), but the hyperbolic plane  $\mathbb{H}_2$  is not compact.

#### 3.2.1 $\mathbb{H}_2$ -Kernel Density Estimator

Our method for density estimation on  $\mathbb{H}_2$  is a generalization of Euclidean kernel density estimation. In  $\mathbb{R}^p$ , the kernel is a density on translations of  $\mathbb{R}^p$ . For  $\mathbb{H}_2$ , the appropriate set of isometric transformations are not translations, but rather the class of “Möbius transformations” represented by the Lie group  $\mathbb{S}\mathbb{L}_2$  (Terras, 1985, Huckemann et al., 2010). An  $\mathbb{H}_2$  kernel, then, is a probability density on  $\mathbb{S}\mathbb{L}_2$ . We may write  $K_h(z, z_i)$  to abbreviate the density the kernel  $K_h$  assigns to the Möbius transform taking  $z_i$  to  $z$ . The generalized kernel density estimator on  $\mathbb{H}_2$  takes the form

$$\hat{f}^{n,h}(z) = \frac{1}{n} \sum_{i=1}^n K_h(z, z_i) \quad (5)$$

$$= (K_h * \hat{P}_n)(z) \quad (6)$$

In Euclidean space, the Fourier transform analyzes functions (or generalized functions, like  $\hat{P}_n$ ) into linear combinations of the eigenfunctions of the Laplacian operator. The corresponding operation for  $\mathbb{H}_2$  is the *Helgason*, or *Helgason-Fourier*, transform  $\mathcal{H}$  (Terras, 1985). The Fourier basis functions are indexed by  $\mathbb{R}^p$ , which is the group of translations; for analogous reasons, the Helgason basis functions are indexed by  $\mathbb{C} \times \mathbb{S}\mathbb{O}_2$ . Many of the formal properties of the Fourier transform carry over to the Helgason transform. (See App. A.) In particular, convolution still turns into multiplication:

$$\mathcal{H} \left[ \hat{f}^{n,h} \right] = \mathcal{H} [K_h] \mathcal{H} \left[ \hat{P}_n \right], \quad (7)$$

where  $\mathcal{H}[K_h]$  denotes the Helgason-Fourier transform of the well-defined density on  $\mathbb{H}_2$  induced by the density  $K_h$

on  $\mathbb{S}\mathbb{L}_2$ , and we define the bandwidth  $h$  through

$$\mathcal{H}[K_h](s, M) = \mathcal{H}[K](hs, M).$$

As in Euclidean density estimation,  $h$  may be set through cross-validation.

In a separate manuscript (Asta, 2014), we show that the  $L_2$  risk of (5) goes to zero at the minimax-optimal rate, under mild assumptions on the smoothness of the true density, and of the kernel  $K$ . (This is a special case of broader results about generalized kernel density estimation on symmetric spaces.) The assumptions on the kernel are satisfied by what Huckemann et al. (2010) calls “hyperbolic Gaussians”, densities on  $\mathbb{H}_2$  with parameter  $\rho$  defined through their Helgason transforms,

$$\mathcal{H}[K](s, M) \propto e^{\rho s(s-1)}. \quad (8)$$

Just as the ordinary Gaussian density is the unique solution to the heat equation with a point source in Euclidean space, the hyperbolic Gaussian is the unique ( $\mathbb{S}\mathbb{O}_2$ -invariant) solution to the heat equation on  $\mathbb{H}_2$  (Terras, 1985).

### 3.3 NETWORK COMPARISON

Combining embedding with kernel density estimation in  $\mathbb{H}_2$  gives us a method of estimating node densities, and so of estimating a hyperbolic latent space model for a given network. We now turn to *comparing* networks, by comparing these estimated node densities.

Our method follows the general strategy advocated in Genovese et al. (2013). Given two graphs  $G_1$  and  $G_2$ , we may estimate two separate network models

$$\hat{\mathcal{P}}_1 = \hat{\mathcal{P}}(G_1), \quad \hat{\mathcal{P}}_2 = \hat{\mathcal{P}}(G_2).$$

We may also pool the data from the two graphs to estimate a common model

$$\hat{\mathcal{P}}_{12} = \hat{\mathcal{P}}(G_1, G_2).$$

We calculate a distance  $d^* = d(\hat{\mathcal{P}}_1, \hat{\mathcal{P}}_2)$  using any suitable divergence. We then compare  $d^*$  to the distribution of distances which may be expected under the pooled model  $\hat{\mathcal{P}}_{12}$ . To do so, we independently generate  $G'_1, G'_2 \sim \hat{\mathcal{P}}_{12}$ , and calculate

$$d(\hat{\mathcal{P}}(G'_1), \hat{\mathcal{P}}(G'_2)).$$

That is, we bootstrap two independent graphs out of the pooled model, fit a model to each bootstrapped graph, and calculate the distance between them. Repeated over many bootstrap replicates, we obtain the sampling distribution of  $d$  under the null hypothesis that  $G_1$  and  $G_2$  are drawn from the same source, and any differences between them are due to population variability or stochastic fluctuations.<sup>2</sup>

<sup>2</sup>This method extends easily to comparing sets of graphs,  $G_{11}, G_{12}, \dots, G_{1n}$  vs.  $G_{21}, G_{22}, \dots, G_{2m}$ , but the notation grows cumbersome.

In our case, we have already explained how to find  $\hat{\mathcal{P}}_1$  and  $\hat{\mathcal{P}}_2$ . Since we hold the latent space  $M$  fixed at  $\mathbb{H}_2$ , and the link probability function  $W$  fixed, we can label our models by their node densities,  $\hat{f}_1^{n,h}$  and  $\hat{f}_2^{n,h}$ . To obtain the pooled model  $\hat{\mathcal{P}}_{12}$ , we first embed  $G_1$  and  $G_2$  separately using generalized multidimensional scaling, and then do kernel density estimation on the union of their embedded points.

The generalized multidimensional scaling technique we use depends only on the eigendecomposition of matrices determined by shortest path lengths. Therefore the  $L_2$  difference

$$\|\hat{f}_1^{n,h} - \hat{f}_2^{n,h}\|_2 \quad (9)$$

between two estimated node densities  $\hat{f}_1^{n,h}, \hat{f}_2^{n,h}$  is 0 if and only if the original sets of vertices from the different samples are isometric and hence (9) approximates a well-defined metric  $d$  on our continuous latent space models. Moreover, since the Plancherel identity carries over to the Helgason-Fourier transform (Terras, 1985),

$$d_2(f_1, f_2) = \|\mathcal{H}[f_1] - \mathcal{H}[f_2]\|_2, \quad (10)$$

and, for our estimated node densities,  $\mathcal{H}[f]$  is given by (7). Appendix B gives full details on our procedure for computing the test statistic (10).

### 3.4 THEORETICAL CONSIDERATIONS

Let us sum up our method, before turning to theoretical considerations. (0) We observe two graphs,  $G_1$  and  $G_2$ . (1) Through multi-dimensional scaling, we embed them separately in  $\mathbb{H}_2$  (§3.1), getting two point clouds, say  $\mathbf{Z}_1$  and  $\mathbf{Z}_2$ . (2) From each cloud, we estimate a probability density on  $\mathbb{H}_2$ , using hyperbolic Gaussian kernels, getting  $\hat{f}^{n_1, h_1}$  and  $\hat{f}^{n_2, h_2}$  (§3.2). We calculate  $\|\hat{f}^{n_1, h_1} - \hat{f}^{n_2, h_2}\|_2$  using (10). We also form a third density estimate,  $\hat{f}^{n_1+n_2, h_{12}}$ , from  $\mathbf{Z}_1 \cup \mathbf{Z}_2$ . (3) We generate two independent graphs  $G_1^*, G_2^*$  from  $\hat{f}^{n_1+n_2, h_{12}}$  according to (1), and subject these graphs to re-embedding and density estimation, obtaining  $\hat{f}^{n_1, h_1^*}$  and  $\hat{f}^{n_2, h_2^*}$  and so  $\|\hat{f}^{n_1, h_1^*} - \hat{f}^{n_2, h_2^*}\|_2$ . Finally, (4) repeating step (3) many times gives us the sampling distribution of the test statistic under the null hypothesis that  $G_1$  and  $G_2$  came from the same source, and the  $p$ -value is the quantile of  $\|\hat{f}^{n_1, h_1} - \hat{f}^{n_2, h_2}\|_2$  in this distribution.

The final step of computing the  $p$ -value is a fairly unproblematic bootstrap test. The previous step of generating new graphs from the pooled model is also an unproblematic example of a model-based bootstrap. The kernel density estimates themselves are consistent, and indeed converge at the minimax rate (Asta, 2014), *given* the point clouds on the hyperbolic plane. This makes it seem that the key step is the initial embedding. Certainly, it would be convenient if the graphs  $G_1$  and  $G_2$  were generated by a hyperbolic

FIGURE 6: **Comparing Quasi-Uniforms** Power of our test, at size  $\alpha = 0.1$ , for detecting the difference between a 100-node graph generated from the quasi-uniform density  $q_{1,1}$  and a 100-node graph generated from  $q_{\delta,1}$ , as a function of the dispersion parameter  $\delta$ .

latent space model, and the embedding was a consistent estimator of the latent node locations. However, such strong conditions are not *necessary*. Suppose that if  $G_1 \sim \mathcal{P}_1$  and  $G_2 \sim \mathcal{P}_2 \neq \mathcal{P}_1$ , then  $\hat{f}_1^{n,h} \rightarrow f_1$  and  $\hat{f}_2^{n,h} \rightarrow f_2$ , with  $\|f_1 - f_2\|_2 > 0$ . Then at any nominal size (significance level)  $\alpha > 0$ , the power of the test will go to 1. For the nominal size of the test to match the actual size (probability of incorrectly rejecting the null hypothesis), however, will presumably require a closer alignment between the hyperbolic latent space model and the actual generating distribution.

## 4 SIMULATIONS

**Comparison of Graphs with Quasi-Uniform Node Densities** In our first set of simulation studies, we generated graphs which exactly conformed to the hyperbolic latent space model, and in fact ones where the node density was quasi-uniform (as in Fig. 3). One graph had 100 nodes, with latent locations drawn from a  $q_{1,1}$  distribution; the other, also of 100 nodes, followed a  $q_{\delta,1}$  distribution, with varying  $\delta$ . We used 50 bootstrap replicates (pairs of resampled networks) in each test, kept the nominal size  $\alpha = 0.1$ , and calculated power by averaging over 25 independent graph pairs (the number of power tests). Despite the graphs having only 100 nodes, Fig. 6 shows that our test has quite respectable power.

**Comparison of Watts-Strogatz Graphs** We have explained above, §2, why we expect hyperbolic latent space models to be reasonable ways of summarizing the structure of complex networks. However, they will also be more or less mis-specified for many networks of interest. We thus applied our methods to a class of graph distributions which do *not* follow a hyperbolic latent space model, namely Watts-Strogatz networks (Watts and Strogatz, 1998). Our

simulations used 100 node networks, with the base topology being a 1D ring with a branching factor of 40, and variable re-wiring probabilities. These graphs show the small-world property and high transitivity, but light-tailed degree distributions. Even in these cases, where the hyperbolic model is not the true generator, our comparison method had almost perfect power (Fig. 7).

FIGURE 7: **Comparing Watts-Strogatz models** Above, Watts-Strogatz graphs formed by re-wiring 1D ring lattices (85 nodes, branching factor 40) with probability  $p$  per edge; from left to right  $p = 0.1, 0.2, 0.3$ . Below, embeddings of the graphs into  $\mathbb{H}_2$ . At nominal  $\alpha = 0.1$ , the power to detect these differences in  $p$  was 1.0 to within Monte Carlo error.

## 5 CONCLUSIONS

We have shown how nonparametric hyperbolic latent space models let us compare the global structures of networks. Our approach has its limits, and it may work poorly when the networks being compared are very far from hyperbolic. However, our experiments with Watts-Strogatz graphs show that it can detect differences among graph distributions from outside our model class. When we do detect a change in structure, we have a model for each network, namely their node densities, and the difference in node densities is an interpretable summary of how the networks differ. Many important directions for future work are now open. One important direction is a better handling of sparse networks, network growth, and the comparison of networks of different sizes — perhaps through some size-dependent modification of the link-probability function  $W$ , as in Krioukov et al. (2010), or the sort of scaling of graphons introduced in Borgs et al. (2014). But this should only extend our method’s scope.

## Abstract

We consider the problem of learning and planning in Markov decision processes with temporally extended actions represented in the options framework. We propose to use predictions about the duration of extended actions to represent the state and show that this leads to a compact predictive state representation model independent of the set of primitive actions. Then we develop a consistent and efficient spectral learning algorithm for such models. Using just the timing information to represent states allows for faster improvement in the planning performance. We illustrate our approach with experiments in both synthetic and robot navigation domains.

## 1 INTRODUCTION

Modelling the dynamics of an agent embedded in a large, complex environment is key to building good planning algorithms for such agents. In most practical applications, models are carefully designed by hand, and the agent’s “state” is given by measurements which are understandable by the designer of the system (such as spatial location and velocity, in the case of a robot). However, learning dynamical models for such states from data, as well as planning with them can be quite tricky. An alternative idea is to use models that are “subjective”, centered on the agent’s own perception and action capabilities. For example, affordances [Gibson, 1977] describe “state” through the courses of action that are enabled. Similarly, in robotics, subjective representations have been used to model dynamics, e.g. [Bowling *et al.*, 2005; Stober *et al.*, 2011]. Such models are appealing from a psychological point of view, but run into computational problems in very large observation spaces.

In this paper, we focus on a special class of subjective models, *timing models*, which arise from restricting the observations available to the agent to just information about the

duration of certain courses of action. Timing of events is understood to be crucial to animal learning [Machado *et al.*, 2009]. The goal of this paper, however, is not learning of the timing of external events, but rather to learn the duration of courses of action that an agent might take. The ensemble of such durations will constitute the agent’s *state*, which will be maintained as new data is received. We use the framework of options [Sutton *et al.*, 1999] to model extended courses of actions, and we present an approach for learning a predictive model of option durations.

Our models over durations can be viewed as affordances if we consider an option to be available when its predicted duration is within some reasonable bounds. Note that these models are much simpler than full option models, which provide joint information on the timing as well as the state or observation in which the option will terminate, e.g. [Wolfe and Singh, 2006]. We emphasize that timing information is very cheap to measure and process, even with simple hardware. Hence, a major area of application for this type of approach is on devices in which processing can be costly, such as simple, Roomba-like robots (as in our experiments) or cellphones (on which using a lot of sensors or computation drains the battery).

Our approach can also be interpreted as a computationally and statistically efficient way of exploiting prior information about useful courses of action provided in the form of options. The size of our models is independent of the number of possible primitive actions in the underlying system, which is very useful in large or continuous action spaces. Moreover, because we are able to learn feature representations for states using timing information only, our method can be applied to observable settings with high-dimensional, complex observations, as well as to partially observable settings, where building a full model for planning would be too data and computation-hungry. Examples include investment problems (where the best strategy may include information about past performance, past trades, news etc, which is too hard to process) or robotics (where sensors may produce a lot of data, but this may not be easy to process in real-time).

Of course, the utility of timing models depends on the nature of the task to be solved by the agent, as well as on the “quality” of the options available to the agent. The simplest example in which option duration models are beneficial is that of minimum time to goal problems, in which an agent receives a fixed penalty per time step until its task is completed. In this case, knowing the duration of an option immediately provides the reward model, so the option duration model has direct value for a planner. More generally, option duration models are beneficial as a form of localization. If you imagine a robot that has models for options that move radially out from the current position, this would allow localizing with respect to all neighboring walls. Finally, consider a problem in which a financial agent is holding stocks, and options which hold a particular stock while it is above a certain value, and sell under that value. In this case, timing models tell us exactly when stocks would be crossing certain barriers. It is clear in this case that, even though we are estimating only durations, the model encodes important state information (because of the way in which the options are defined).

In this paper, we analyze the capacity of option duration models to represent states in a Markov Decision Process (MDP). We propose a spectral algorithm for learning option duration models which builds on existing work for learning transformed predictive state representations [Rosencrantz *et al.*, 2004]. Finally we evaluate the quality of learning and planning with this type of models in experiments with discrete and continuous MDPs.

## 2 PRELIMINARIES AND NOTATION

We use bold letters to denote vectors  $\mathbf{v} \in \mathbb{R}^d$  and matrices  $\mathbf{M} \in \mathbb{R}^{d_1 \times d_2}$ . For matrix  $\mathbf{M}$ ,  $\mathbf{M}^+$  denotes its Moore–Penrose pseudo-inverse. Sometimes we name the columns and rows of a matrix using ordered index sets  $\mathcal{I}$  and  $\mathcal{J}$ , so  $\mathbf{M} \in \mathbb{R}^{\mathcal{I} \times \mathcal{J}}$  denotes a matrix of size  $|\mathcal{I}| \times |\mathcal{J}|$  with rows and columns indexed by  $\mathcal{I}$  and  $\mathcal{J}$  respectively.

Let  $\Sigma$  be a finite set of symbols. We use  $\Sigma^*$  to denote the set of all finite strings over  $\Sigma$  and  $\lambda$  for the empty string. Given two strings  $u, v \in \Sigma^*$ ,  $w = uv$  is their concatenation, in which case  $u$  is called a prefix of  $w$ , and  $v$  is a suffix of  $w$ . Given two sets of strings  $\mathcal{P}, \mathcal{S} \subseteq \Sigma^*$ ,  $\mathcal{PS}$  is the set obtained by taking every string of the form  $uv$  with  $u \in \mathcal{P}$  and  $v \in \mathcal{S}$ .

Given a predicate  $\mu(x)$  we denote by  $\mathbb{I}[\mu(x)]$  the indicator function which is one when  $\mu(x)$  is true and zero otherwise.

### 2.1 Markov Decision Processes and Temporally Extended Actions

A *Markov decision process* (MDP) is a tuple  $M = \langle S, A, P, R \rangle$  where  $S$  is the state set,  $A$  is the action set,  $P : S \times A \rightarrow (S \rightarrow [0, 1])$  defines a probability distribu-

tion over next states, and  $R : S \times A \rightarrow \mathbb{R}$  is the expected reward function (see [Puterman, 1994] for a review). We refer to probability distributions on  $S$  by  $\alpha$ , but sometimes use  $\boldsymbol{\alpha}$  to stress that we view them as vectors in  $\mathbb{R}^S$ . Suppose  $\alpha$  is a distribution over  $S$  and  $\pi : S \times A \rightarrow [0, 1]$  is a stochastic action policy which, given state  $s$ , chooses action  $a$  with probability  $\pi(s, a)$ . The environment then returns a state sampled from  $P$ ; and the resulting state distribution  $\alpha'$  is given by:

$$\alpha'(s') = \sum_{s \in S} \alpha(s) \sum_{a \in A} \pi(s, a) P(s, a)(s') .$$

Temporal abstraction in MDPs has been used as a tool to speed up learning and planning algorithms. We adopt the framework of options [Sutton *et al.*, 1999], with the goal of learning state representations based on option timing models. An *option* is a tuple  $\omega = \langle I_\omega, \pi_\omega, \beta_\omega \rangle$  where  $I_\omega \subseteq S$  is the set of initial states,  $\pi_\omega : S \times A \rightarrow [0, 1]$  is the option’s stochastic action policy, and  $\beta_\omega : S \rightarrow [0, 1]$  is the option termination probability for each state. We will drop the option’s subscript and write  $\omega = \langle I, \pi, \beta \rangle$  when there is no risk of confusion.

We say that an agent *interacts with an MDP via a set of options*  $\Omega$  if at all times the actions performed by the agent follow the policy specified by some option  $\omega \in \Omega$ , which is executed until termination.

Each option has an associated reward model  $R(s, \omega)$  and an associated transition model  $P(s, \omega)(s')$ , which can be computed using the MDP model and the definition of the options (see [Sutton *et al.*, 1999] for details). Given a set of options  $\Omega$ , the optimal option-value function satisfies the following Bellman equation:

$$Q_\Omega^*(s, \omega) = R(s, \omega) + \sum_{s' \in S} P(s, \omega)(s') \max_{\omega' \in \Omega} Q_\Omega^*(s', \omega')$$

Planning with options aims to find the optimal policy over options  $\pi_\Omega^*$ , which is achieved most often by estimating  $Q_\Omega^*$ . This does not require a model to be known; instead, it can be done using samples, in similar fashion as Q-learning. If the state space is large or continuous, function approximation can be used to represent states. The option duration model that we develop in this paper will be used as a form of state representation in order to learn an approximation to  $Q_\Omega^*$ .

### 2.2 Predictive State Representations

A *predictive state representation* is a model of a dynamical system in which the current state is represented as a set of predictions about the future behavior of the system [Littman *et al.*, 2002; Singh *et al.*, 2004]. We use a particular instantiation of this general idea, the so-called *transformed linear predictive state representation* [Rosencrantz *et al.*, 2004], abbreviated as PSR.

Let  $\Sigma$  be a finite set of symbols. A PSR over  $\Sigma$  is a tuple  $\mathcal{A} = \langle \alpha_\lambda, \alpha_\infty, \{\mathbf{A}_\sigma\}_{\sigma \in \Sigma} \rangle$  where  $\alpha_\lambda, \alpha_\infty \in \mathbb{R}^n$  are the initial and final weights respectively, and  $\mathbf{A}_\sigma \in \mathbb{R}^{n \times n}$  are the transition weights. The dimension  $n$  of these vectors and matrices is the *number of states* of the PSR. Though PSR is the usual name for this type of model in the reinforcement learning literature, they are also called *weighted finite automaton* (WFA) [Droste and Vogler, 2009] or *observable operator models* (OOM) [Jaeger, 2000]. This distinction reflects the fact that this same parametrization can be used to define models with different semantics, depending on the meaning associated with the values computed by the model.

A PSR  $\mathcal{A}$  computes a function  $f_{\mathcal{A}} : \Sigma^* \rightarrow \mathbb{R}$  that assigns a number to each string  $x = x_1 x_2 \cdots x_t \in \Sigma^*$  as follows:

$$f_{\mathcal{A}}(x) = \alpha_\lambda^\top \mathbf{A}_{x_1} \mathbf{A}_{x_2} \cdots \mathbf{A}_{x_t} \alpha_\infty = \alpha_\lambda^\top \mathbf{A}_x \alpha_\infty .$$

In a PSR, a string  $x \in \Sigma^*$  represents a sequence of events produced by a dynamical system, and  $f_{\mathcal{A}}(x)$  is the probability that the system produces  $x$ . In many cases of interest,  $\Sigma = A \times O$ , where  $A$  is a set of actions and  $O$  a set of observations, so any  $x \in \Sigma^*$  represents a sequence of action-observation pairs. The vector  $\alpha_\lambda$  represents the initial state of the system.

If a history  $u \in \Sigma^*$  has already been observed, the conditional probability of observing a sequence of events  $v \in \Sigma^*$  after  $u$  is:

$$f_{\mathcal{A},u}(v) = \frac{f_{\mathcal{A}}(uv)}{f_{\mathcal{A}}(u)} = \frac{\alpha_\lambda^\top \mathbf{A}_u \mathbf{A}_v \alpha_\infty}{\alpha_\lambda^\top \mathbf{A}_u \alpha_\infty} = \frac{\alpha_u^\top \mathbf{A}_v \alpha_\infty}{\alpha_u^\top \alpha_\infty} .$$

Hence, given some history  $u$ , the initial state  $\alpha_\lambda$  can be updated to a new state  $\alpha_u / (\alpha_u^\top \alpha_\infty)$ , which allows computing probabilities of future observations conditioned on the current history. Because the partition of a sequence of observations  $x$  into a history  $u$  and a future  $v$  (also called *test*) yields  $x = uv$ , we sometimes call histories *prefixes* and futures *suffixes*.

### 2.3 Hankel and System Dynamics Matrices

The behavior of a stochastic dynamical system producing observations in a finite set  $\Sigma$  can be entirely characterized by the function  $f : \Sigma^* \rightarrow \mathbb{R}$  giving the probability  $f(x)$  of observing each possible sequence of observations  $x$ . A convenient algebraic way to summarize all the information conveyed by  $f$  is with its *Hankel matrix*, a bi-infinite matrix  $\mathbf{H}_f \in \mathbb{R}^{\Sigma^* \times \Sigma^*}$  with rows and columns indexed by strings in  $\Sigma^*$ . Strings indexing rows and columns are interpreted as prefixes and suffixes respectively. The entries in  $\mathbf{H}_f$  are given by  $\mathbf{H}_f(u, v) = f(u, v)$  for every  $u, v \in \Sigma^*$ .

Although  $\mathbf{H}_f$  is an infinite matrix, in some cases it can have finite rank. In particular, a well-known result states that  $\mathbf{H}_f$  has rank at most  $n$  if and only if there exists a PSR  $\mathcal{A}$

with  $n$  states satisfying  $f_{\mathcal{A}} = f$  [Carlyle and Paz, 1971; Fliess, 1974]. This result is the basis of recently developed spectral learning algorithms for PSRs [Boots *et al.*, 2011], which we review in Sec. 4.

Instead of looking at the full Hankel matrix, algorithms usually work with finite sub-blocks of this matrix. A convenient way to specify such blocks is to give the “names” to the rows and columns. Specifically, given a finite set of prefixes  $\mathcal{P} \subset \Sigma^*$  and a finite set of suffixes  $\mathcal{S} \subset \Sigma^*$ , the pair  $\mathcal{B} = (\mathcal{P}, \mathcal{S})$  is a *basis* defining the sub-block  $\mathbf{H}_{\mathcal{B}} \in \mathbb{R}^{\mathcal{P} \times \mathcal{S}}$  of  $\mathbf{H}_f$ , whose entries are given by  $\mathbf{H}_{\mathcal{B}}(u, v) = \mathbf{H}_f(u, v)$ . Note that every sub-block built in this way satisfies  $\text{rank}(\mathbf{H}_{\mathcal{B}}) \leq \text{rank}(\mathbf{H}_f)$ ; when equality is attained, the basis  $\mathcal{B}$  is *complete*.

Sometimes it is also convenient to look at one-step shifts of the finite Hankel matrices. Let  $\mathbf{H} \in \mathbb{R}^{\mathcal{P} \times \mathcal{S}}$  be a finite sub-block of  $\mathbf{H}_f$  specified by a basis  $\mathcal{B} = (\mathcal{P}, \mathcal{S})$ . Then, for every symbol  $\sigma \in \Sigma$ , we define the sub-block  $\mathbf{H}_\sigma \in \mathbb{R}^{\mathcal{P} \times \mathcal{S}}$  whose entries are given by  $\mathbf{H}_\sigma(u, v) = \mathbf{H}_f(u, \sigma v)$ . For a fixed basis, we also consider the vectors  $\mathbf{h}_{\mathcal{S}} \in \mathbb{R}^{\mathcal{S}}$  with entries given by  $\mathbf{h}_{\mathcal{S}}(v) = \mathbf{H}_f(\lambda, v)$  for every  $v \in \mathcal{S}$ , and  $\mathbf{h}_{\mathcal{P}} \in \mathbb{R}^{\mathcal{P}}$  with  $\mathbf{h}_{\mathcal{P}}(u) = \mathbf{H}_f(u, \lambda)$ .

The Hankel matrix  $\mathbf{H}_f$  is tightly related to the *system dynamics matrix* (SDM) of the stochastic process described by  $f$  [Singh *et al.*, 2004], but while the entries of the Hankel matrix represent *joint* probabilities over prefixes and suffixes, the corresponding entry in the SDM is the *conditional* probability of observing a suffix given the prefix. In particular, the SDM of  $f$  is the matrix  $\tilde{\mathbf{H}}_f \in \mathbb{R}^{\Sigma^* \times \Sigma^*}$  given by  $\mathbf{H}_f$  with the rows scaled by the probability of prefixes. The SDM of  $f$  shares a lot of properties with its Hankel counterpart. In particular, spectral learning algorithms for  $f$  can be derived in terms of sub-blocks of both  $\mathbf{H}_f$  and  $\tilde{\mathbf{H}}_f$ . We will work with the Hankel matrices of  $f$ , but all our algorithms can easily be adapted to work with the SDM instead.

## 3 OPTION DURATION MODELS

We are interested in the dynamics of an agent interacting with an MDP  $M$  via a set of options  $\Omega$ . Recall that in this setting the agent is not allowed to perform primitive actions, and options must be executed until termination. We are interested in situations in which the *duration* of an option is an informative statistic about the state of the MDP. That is, we would like to identify a state in  $M$  with the distribution over the durations of a sequence of options executed starting from that state. This section introduces a special PSR for this purpose that we call the *option duration model* (ODM). This is basically a dynamical model of an MDP viewed through the lens of a fixed set of options, in which the state is represented by a vector of parameters sufficient for predicting the duration of future options. In the following sections we present a spectral algorithm for

learning ODM from just information about the duration of options in an MDP, and explore the possibilities the state representation given by this ODM in order to plan with options in the original MDP.

The goal of this section is to understand what form the probability distributions over option durations take, and how to write these compactly in order to allow efficient learning from just duration information. To begin, assume we can reset the MDP  $M$  to a fixed state  $s_0$  and explore the environment from there by performing a sequence of  $t$  options  $\omega_1, \dots, \omega_t$ , e.g. chosen uniformly at random. From the point of view of the MDP dynamics, this process will generate a sequence of of state-action trajectories like the following:

$$\begin{aligned} \omega_1 &: (s_0, \pi_{\omega_1}(s_0), s_1, \pi_{\omega_1}(s_1), \dots, s_{T_1-1}, \pi_{\omega_1}(s_{T_1-1}), s_{T_1}) \\ \omega_2 &: (s_{T_1}, \pi_{\omega_2}(s_{T_1}), s_{T_1+1}, \pi_{\omega_2}(s_{T_1+1}), \dots, \pi_{\omega_2}(s_{T_2-1}), s_{T_2}) \\ &\dots \\ \omega_t &: (s_{T_{t-1}}, \pi_{\omega_t}(s_{T_{t-1}}), \dots, \pi_{\omega_t}(s_{T_t-1}), s_{T_t}) \end{aligned}$$

where  $\pi_{\omega}(s)$  denotes an action chosen according to the distribution given by  $\omega$ 's stochastic policy. Note that in this trace, the sequence of visited states, the actions executed, and the option stopping times form a stochastic dynamical process whose distribution can be computed in terms of the parameters of the MDP  $M$ , the parameters defining the options in  $\Omega$ , and the sequence of options  $\omega_1, \dots, \omega_t$ .

If one is only interested in the duration of the options executed in the above trace, then the interaction can be summarized in terms of termination and continuation events for the options being executed. That is, at each time step, we can ignore the current observed state and the action being chosen, and just focus on whether the current option terminates in the current state. We will use the symbol  $\sharp$  (*sharp*) to denote continuation, and  $\perp$  (*bottom*) to denote termination. Thus, at a given time step, we use  $(\omega, \sharp)$  to denote option  $\omega$  is being executed and does not terminate, and  $(\omega, \perp)$  if it terminates. Using this notation, the ‘‘duration information’’ in the previous trajectory can be expressed as:

$$(\omega_1, \sharp)^{d_1-1}(\omega_1, \perp)(\omega_2, \sharp)^{d_2-1}(\omega_2, \perp) \dots (\omega_t, \sharp)^{d_t-1}(\omega_t, \perp) \text{ ,}$$

where the durations are given by  $d_i = T_i - T_{i-1}$ ,  $T_0 = 0$ . In more compact form, we can write the duration information in a trace as a sequence of option-duration pairs:  $(\omega_1, d_1)(\omega_2, d_2) \dots (\omega_t, d_t)$ , with  $\omega_i \in \Omega$  and  $d_i \in \mathbb{N} = \{1, 2, \dots\}$ . Both notations will be convenient in our derivations.

Broadly speaking, an option duration model for an MDP  $M$  and a set of options  $\Omega$  is a mapping that associates with every state  $s$  in  $M$  a conditional probability distribution

$$\mathbb{P}_s[\vec{d} \mid \bar{\omega}] = \mathbb{P}_s[d_1, \dots, d_t \mid \omega_1, \dots, \omega_t]$$

that represents the stochastic process of stopping events induced by executing the options  $\bar{\omega} = \omega_1, \dots, \omega_t$  in  $M$  starting from  $s$ . More formally, let  $\mathcal{D}_t$  denote the set of

all<sup>1</sup> probability distributions over  $\mathbb{N}^t$ , and for every state  $s$  and  $\bar{\omega} \in \Omega^t$  let  $D_{\bar{\omega}}^s \in \mathcal{D}_t$  denote the distribution  $\mathbb{P}_s[\cdot \mid \bar{\omega}]$ . Now, by letting  $\bar{\omega}$  run over all possible sequence of options in  $\Omega^+$  we can associate with every  $s$  a mapping  $D_{\bullet}^s : \Omega^+ \rightarrow \cup_{t>0} \mathcal{D}_t$ . We say that the set of options  $\Omega$  is *rich* for MDP  $M$  if the maps  $D_{\bullet}^s$  are different for all  $s$ , that is, if the functional  $\Delta(s) = D_{\bullet}^s$  is injective, so for every  $s, s' \in S$  there exists some sequence of options  $\bar{\omega} \in \Omega^+$  such that  $D_{\bar{\omega}}^s \neq D_{\bar{\omega}}^{s'}$ . Clearly, in this case,  $\Delta(s)$  uniquely identifies the state  $s$ , indicating that the duration over options provides a unique representation for each state.

If  $\Delta$  is not injective, such models can still be sufficient for planning in special circumstances. For example, consider minimum-time-to-goal problems, in which fixed negative rewards are attributed per time step, and suppose the agent intends to plan using only options. In this case, states for which  $\Delta(s) = \Delta(s')$  will also have the same optimal value function  $V_{\Omega}^*$  (a result that follows directly from the way in which option models are defined [Sutton *et al.*, 1999]).

In next section we give a concrete realization of this abstract ODM by showing how to encode the collection of distributions  $\Delta(s)$  using a PSR.

### 3.1 Representing Option Duration Models with PSR

We now show that the probability distributions of the timing of options can be compactly represented in the form of a PSR. Given  $s \in S$  and an option  $\omega \in \Omega$ , we denote by  $\delta(s, \omega)$  the random variable counting the number of steps until termination when following  $\omega$  from  $s$ . Note that  $s$  might be an initial state for  $\omega$ , but also a state traversed during the execution of  $\omega$ , in which case  $\delta(s, \omega)$  is the remaining number of steps until termination. Let  $s_0 \in S$ ,  $\omega = \langle I, \pi, \beta \rangle$ , and  $d > 0$  be an integer. We start by considering the probability  $\mathbb{P}[\delta(s_0, \omega) = d]$ , which is given by:

$$\sum_{\bar{s} \in S^d} \sum_{\bar{a} \in A^d} \mathbb{P}[s_0, a_0, s_1, a_1, \dots, a_{d-1}, s_d, \perp] \text{ ,}$$

where  $\bar{s} = s_1 \dots s_d$  is the sequence of states traversed by  $\omega$ ,  $\bar{a} = a_0 \dots a_{d-1}$  is a sequence of actions chosen by  $\pi_{\omega}$ , and  $\perp$  denotes the option termination. Note the appearance of  $\perp$  at the end explicitly requires the option to last for exactly  $d$  steps; state trajectories which stop earlier are not

<sup>1</sup>We could be more precise and restrict ourselves to *discrete phase-type distributions* because these are enough to model the duration until absorption events in Markov chains; but this does not simplify our arguments at this point. The class of distributions we consider will become clear in Section 3.1

considered. By the Markov property,

$$\begin{aligned} & \mathbb{P}[s_0, a_0, \dots, s_{d-1}, a_{d-1}, s_d, \perp] \\ &= \left( \prod_{i=0}^{d-1} \mathbb{P}[a_i, s_{i+1} | s_i] \cdot \mathbb{P}[\# | s_{i+1}] \right) \cdot \frac{\mathbb{P}[\perp | s_d]}{\mathbb{P}[\# | s_d]} \\ &= \left( \prod_{i=0}^{d-1} \pi(s_i, a_i) \mathbb{P}(s_i, a_i, s_{i+1}) (1 - \beta(s_{i+1})) \right) \cdot \frac{\beta(s_d)}{1 - \beta(s_d)}. \end{aligned}$$

With some algebra, it can be shown that summing this expression over  $\bar{s}$  and  $\bar{a}$  yields:

$$\mathbb{P}[\delta(s_0, \omega) = d] = \mathbf{e}_{s_0}^\top \mathbf{A}_{\omega, \#}^{d-1} \mathbf{A}_{\omega, \perp} \mathbf{1}, \quad (1)$$

where  $\mathbf{e}_{s_0} \in \mathbb{R}^S$  is an indicator vector with  $\mathbf{e}_{s_0}(s) = \mathbb{I}[s = s_0]$ ,  $\mathbf{A}_{\omega, \#} \in \mathbb{R}^{S \times S}$  is a matrix with  $\mathbf{A}_{\omega, \#}(s, s') = \sum_{a \in A} \pi(s, a) P(s, a, s') (1 - \beta(s'))$ ,  $\mathbf{A}_{\omega, \perp} \in \mathbb{R}^{S \times S}$  is a matrix with  $\mathbf{A}_{\omega, \perp}(s, s') = \sum_{a \in A} \pi(s, a) P(s, a, s') \beta(s')$ , and  $\mathbf{1} \in \mathbb{R}^S$  is a vector of ones.

Using the ODM notation introduced in the previous section, Equation (1) can be written as

$$\mathbb{P}_{s_0}[d | \omega] = \mathbf{e}_{s_0}^\top \mathbf{A}_{\omega, \#}^{d-1} \mathbf{A}_{\omega, \perp} \mathbf{1}.$$

Now we would like to extend this expression to sequences containing more than one option. Using a similar derivation, for any  $t > 0$ ,  $\bar{d} \in \mathbb{N}^t$ , and  $\bar{\omega} \in \Omega^t$ , we can compute  $\mathbb{P}_{s_0}[\bar{d} | \bar{\omega}]$  as follows:

$$\mathbf{e}_{s_0}^\top \mathbf{A}_{\omega_1, \#}^{d_1-1} \mathbf{A}_{\omega_1, \perp} \mathbf{A}_{\omega_2, \#}^{d_2-1} \mathbf{A}_{\omega_2, \perp} \dots \mathbf{A}_{\omega_t, \#}^{d_t-1} \mathbf{A}_{\omega_t, \perp} \mathbf{1}.$$

Note that the same reasoning applies if we consider distributions over states. That is, instead of a fixed initial state  $s_0$ , we consider a state sampled according to some distribution  $\alpha_0$  over  $S$ . In that case, we define the random variable  $\delta(\alpha_0, \omega)$  representing the duration of option  $\omega$  when started from  $s_0 \sim \alpha_0$ . By the same argument as above,

$$\mathbb{P}_{\alpha_0}[d | \omega] = \mathbb{P}[\delta(\alpha_0, \omega) = d] = \boldsymbol{\alpha}_0^\top \mathbf{A}_{\omega, \#}^{d-1} \mathbf{A}_{\omega, \perp} \mathbf{1},$$

where  $\boldsymbol{\alpha}_0 \in \mathbb{R}^S$  is the vector representation of  $\alpha_0$ . Again, this can be extended in the same way to sequences with more than one option. Therefore, we have proved the following result.

**Theorem 1.** *Let  $M$  be an MDP with  $n$  states,  $\Omega$  a set of options, and  $\Sigma = \Omega \times \{\#, \perp\}$ . For every distribution  $\alpha_0$  over the states of  $M$ , there exists a PSR  $\mathcal{A} = \langle \boldsymbol{\alpha}_0, \mathbf{1}, \{\mathbf{A}_\sigma\} \rangle$  with at most  $n$  states that computes the distributions over durations of options executed from a state sampled according to  $\alpha_0$ .*

Note that the MDP transition kernel and the options' stochastic policies are coupled inside the transition matrices of PSR  $\mathcal{A}$  representing the ODM. This coupling is the reason why we can model the timing of options in an MDP via a process with observation on the set  $\Omega \times \{\#, \perp\}$  whose

size is *independent* of the set of primitive actions  $A$ , and whose transitions operators have size at most  $|S|$ . Note that this can be particularly interesting in settings where the number of possible actions is very large but a small number of options is enough to specify the ‘‘useful’’ modes of operation of an agent.

### 3.2 ODM for Explorable Trajectories

Note that the ODM representation  $\mathcal{A}$  given by Theorem 1 can be used to query the probability of observing any trajectory in  $(\Omega \times \{\#, \perp\})^*$  starting from a state sampled from  $\alpha$ . In principle, this includes trajectories which are not valid for an agent interacting with an MDP via options – e.g. we can query the probability of trajectories of the form  $(\omega_1, \#)^{d_1} (\omega_2, \#)^{d_2} \dots$ , where  $\omega_1$  was interrupted before termination. Note that this type of trajectories will never be observed by an agent that explores an environment by interacting with it only via options executed in call-and-return fashion. In particular, an agent does not need to learn about these trajectories if the goal is to plan via options only, and cannot hope to learn about these trajectories if it only explores the environment via options. We now show that a PSR representation for an ODM can be restricted to produce non-zero probabilities for legal trajectories only, without increasing the size of the model too much.

Recall that  $\Sigma = \Omega \times \{\#, \perp\}$ . When options are always executed to termination, valid trajectories belong to a subset of  $\Sigma^*$ :

$$V = \left( \bigcup_{\omega \in \Omega} \{(\omega, \#)^*(\omega, \perp)\} \right)^*.$$

That is, each sequence of option-continuation events must end with an option-termination event before a new option can be started.

Now we want to modify the model in Theorem 1 so that it only assigns non-zero probabilities to trajectories in  $V$ . Let  $f$  be the function computed by  $\mathcal{A}$ . Then we want another PSR computing the function given by  $\tilde{f}(x) = f(x)$  for  $x \in V$  and 0 otherwise. We now show that  $\tilde{f}$  can also be computed by a PSR with size close to that of  $\mathcal{A}$ .

**Theorem 2.** *If  $\mathcal{A}$  has  $n$  states, then there exists a PSR  $\tilde{\mathcal{A}}$  with at most  $(|\Omega| + 1)n$  states computing  $\tilde{f}$ .*

*Proof.* By the Carlyle–Paz–Fliess theorem, it suffices to show that  $\text{rank}(\tilde{\mathbf{H}}) \leq (|\Omega| + 1)n$ , where  $\tilde{\mathbf{H}} \in \mathbb{R}^{\Sigma^* \times \Sigma^*}$  is the bi-infinite Hankel matrix associated with  $\tilde{f}$ . Let  $\chi_V : \Sigma^* \rightarrow \mathbb{R}$  be the characteristic function of the regular language  $V$ , which is given by  $\chi_V(x) = 1$  if  $x \in V$  and  $\chi_V(x) = 0$  otherwise. Note that it is easy to construct a DFA with  $|\Omega| + 1$  states recognizing  $V$ . Such a DFA can also be written as a PSR with  $|\Omega| + 1$  states computing the function  $\chi_V$ . Thus, the rank of the Hankel matrix  $\mathbf{H}_V$  associated with  $\chi_V$  is at most  $|\Omega| + 1$ . Now note that we

can write  $\tilde{\mathbf{H}} = \mathbf{H} \circ \mathbf{H}_V$ , where  $\mathbf{H}$  is the Hankel matrix of  $f$  and  $\circ$  denotes entry-wise multiplication (also known as Hadamard matrix product). Finally, we use an elementary bound on the rank of Hadamard products to conclude that

$$\text{rank}(\tilde{\mathbf{H}}) \leq \text{rank}(\mathbf{H}) \cdot \text{rank}(\mathbf{H}_V) = (|\Omega| + 1)n . \quad \square$$

Note that the bound on the number of states of  $\tilde{\mathcal{A}}$  is in general not tight. For example, in our experiments with a grid-like environment, we observed that starting with an MDP with  $n$  states the true rank of  $\tilde{\mathbf{H}}$  is on the order of  $O(\sqrt{n})$ . So the PSR representation of ODM can lead to more compact models than the underlying MDP, and can potentially lead to faster learning and planning algorithms. This issue should be investigated further in future work.

## 4 SPECTRAL LEARNING OF ODM

The PSR representation of ODM given by the theorems in previous section can be computed explicitly if the underlying MDP is known exactly. In this section we explore the possibility of learning such a representation from data about option durations, without exploiting any knowledge about the underlying MDP. The rationale behind this approach is that it can lead to more compact representations that do not depend on the set of primitive actions, and learn only the parts of the MDP’s state space which are reachable via options.

Because an option duration model over valid trajectories can be represented with a PSR of moderate size, we can use the spectral learning algorithm in [Boots *et al.*, 2011] to estimate an ODM from a set of trajectories in  $\Sigma^*$  produced by the agent exploring the MDP using a fixed policy over options. For each trajectory, the initial state is sampled according to a fixed distribution  $\alpha$ . We assume that the options executed by the agent are selected according to some fixed open-loop policy. This is important if we want to use the sampled trajectories to learn a model of the environment which is independent of the exploration policy.

The algorithm takes as input  $\Sigma$  and a basis  $\mathcal{B}$  in  $\Sigma^*$ , uses them to estimate the corresponding Hankel matrices, and then recovers a PSR by performing singular value decomposition and linear algebra operations on these matrices. Although the method works almost out-of-the-box, in practice the results tend to be sensitive to the choice of basis. Thus, after briefly recapitulating how the spectral learning algorithm proceeds, we will devote the rest of the section to describe a procedure for building a basis which is tailored for the case of learning option duration models.

Suppose the basis  $\mathcal{B}$  is fixed and the desired number of states  $n$  is given. Suppose that a set of sampled trajectories was used to estimate the Hankel matrices  $\mathbf{H}, \mathbf{H}_\sigma \in \mathbb{R}^{\mathcal{P} \times \mathcal{S}}$  and vectors  $\mathbf{h}_\mathcal{P} \in \mathbb{R}^{\mathcal{P}}, \mathbf{h}_\mathcal{S} \in \mathbb{R}^{\mathcal{S}}$  defined in Sec. 2.3. The algorithm starts by taking the truncated SVD  $\mathbf{U}_n \mathbf{D}_n \mathbf{V}_n^\top$

of  $\mathbf{H}$ , where  $\mathbf{D}_n \in \mathbb{R}^{n \times n}$  contains the first  $n$  singular values of  $\mathbf{H}$ , and  $\mathbf{U}_n \in \mathbb{R}^{\mathcal{P} \times n}$  and  $\mathbf{V}_n \in \mathbb{R}^{\mathcal{S} \times n}$  contain the first left and right singular vectors respectively. Finally, we compute the transition operators of a PSR as  $\mathbf{A}_\sigma = \mathbf{D}_n^{-1} \mathbf{U}_n^\top \mathbf{H}_\sigma \mathbf{V}_n$ , and the initial and final weights as  $\alpha_\lambda^\top = \mathbf{h}_\mathcal{S}^\top \mathbf{V}_n$  and  $\alpha_\infty = \mathbf{D}_n^{-1} \mathbf{U}_n^\top \mathbf{h}_\mathcal{P}$ . This yields a PSR with  $n$  states. It was proved in [Boots *et al.*, 2011] this algorithm is statistically consistent: if the population Hankel matrices are known and the basis  $\mathcal{B}$  is complete, then the learned PSR is equivalent to the one that generated the data.

### 4.1 Basis Selection

Finding a complete basis for a given function  $f : \Sigma^* \rightarrow \mathbb{R}$  is in general a hard combinatorial problem: although if  $\mathbf{H}_f$  has rank  $n$ , there exists a complete basis with  $n$  prefixes and suffixes, the search space where these lie is doubly-exponential in  $n$ . To overcome this problem, randomized and greedy basis selection heuristics have been proposed in the past [Wiewiora, 2005; Balle *et al.*, 2012]. Greedy selection is in general computationally expensive because it requires re-learning the model every time a new element is added to the basis. Randomized search does not work in our case because it cannot take into account the fact that we have syntactic constraints on the valid trajectories. Therefore, we designed a procedure that takes the structure of our problem into account.

Our procedure is parametrized by various quantities depending on the environment and the observed trajectories: the maximum possible duration  $T_\omega$  of each option  $\omega \in \Omega$  in our training dataset, and  $T = \max_\omega T_\omega$ ; an upper bound  $K_r \geq 1$  on the number of option executions needed to reach every possible state in  $M$  when initial states are sampled from  $\alpha$ ; and, an upper bound  $K_d \geq 1$  on the number of option executions needed to distinguish/disambiguate every pair of states in  $M$  in terms of option duration information.

We assume these quantities are given, either because they can be derived from prior knowledge of the application domain, or because they are cross-validated. The definitions imply that  $T$  and  $K_r$  are a function of the geometry of the environment and how this relates to the available options. On the other hand,  $K_d$  measures the statistical similarity between states in  $M$  when seen through the lens of  $\Omega$ . The intuition is simple: we want to ensure that we have enough prefixes in the Hankel matrix to get to all reachable states in  $M$ , and enough suffixes to make sure each of these states can be distinguished from each other. The following construction formalizes this intuition.

We obtain the set  $\mathcal{P}$  of prefixes in the basis as the union of

two disjoint sets. The first set is:

$$\mathcal{P}_\perp = \{x_1 x_2 \cdots x_t \mid 1 \leq t \leq K_r, x_i = (\omega_i, \#)^{d_i}(\omega_i, \perp), \omega_i \in \Omega, 0 \leq d_i \leq T_{\omega_i}\} .$$

These are trajectories with at most  $K_r$  option executions, containing all possible sequences of options, and all possible option durations allowed by the model. A simple calculation shows that  $|\mathcal{P}_\perp| = O(K_r T^{K_r} |\Omega|^{K_r})$ . Note that each trajectory in  $\mathcal{P}_\perp$  terminates with a symbol  $(\omega, \perp)$ . If we remove this last symbol for each trajectory, we obtain a disjoint set of prefixes  $\mathcal{P}_\# = \{x \mid x(\omega, \perp) \in \mathcal{P}_\perp\}$ . Then we take  $\mathcal{P} = \mathcal{P}_\perp \cup \mathcal{P}_\#$ . Note that again we have  $|\mathcal{P}| = O(K_r T^{K_r} |\Omega|^{K_r})$ .

Similarly, the set of suffixes will be obtained as the union of two sets. These are defined as follows:

$$\begin{aligned} \mathcal{S}_\# &= \{x_1 x_2 \cdots x_t \mid 1 \leq t \leq K_s, x_i = (\omega_i, \#)^{d_i}(\omega_i, \perp), \\ &\quad \omega_i \in \Omega, 0 \leq d_i \leq T_{\omega_i}\} , \\ \mathcal{S}_\perp &= \{(\omega, \perp)x \mid x \in \mathcal{S}_\#, \omega \in \Omega\} . \end{aligned}$$

The suffixes in  $\mathcal{S}_\#$  are obtained like the prefixes in  $\mathcal{P}_\perp$ , with the only difference that the number of option executions is now upper bounded by  $K_s$  instead of  $K_r$ . Suffixes in  $\mathcal{S}_\perp$  are obtained by prefixing each string in  $\mathcal{S}_\#$  with each possible option termination symbol  $(\omega, \perp)$ . The whole set of suffixes is  $\mathcal{S} = \mathcal{S}_\perp \cup \mathcal{S}_\#$ , and we have  $|\mathcal{S}| = O(K_s T^{K_s} |\Omega|^{K_s+1})$ .

Note that not every string in  $\mathcal{PS}$  defines a valid trajectory. This is required for the Hankel matrices  $\mathbf{H}_\sigma$  to be different from zero; otherwise the operators  $\mathbf{A}_\sigma$  cannot be correctly recovered. To see why this is the case, consider the basis  $\mathcal{B}' = (\mathcal{P}_\perp, \mathcal{S}_\#)$ . By construction we have  $\mathcal{P}_\perp \mathcal{S}_\# \subset V$ . However, if we consider a system where some  $\omega$  never lasts for just one step, then every trajectory in  $\mathcal{P}_\perp \{(\omega, \perp)\} \mathcal{S}_\#$  has probability zero. In particular, in such a system the matrix  $\mathbf{H}_\sigma$  over the basis  $\mathcal{B}'$  is exactly zero. To work around this problem, it is necessary to introduce non-valid trajectories in the basis, to ensure that  $\mathbf{H}$  will contain some sub-blocks filled with zeros, but the  $\mathbf{H}_\sigma$  will contain some non-zero sub-blocks.

## 4.2 Scalability

Though at first glance the exponential dependence on  $K_r$  and  $K_s$  in the size of the basis may seem prohibitive, in practice the situation is much better. On one hand, these are worst-case bounds that assume all possible sequences of options and durations need to be considered. However, in practice some of those might never be observed — e.g. because the duration of certain options has little variance, or because some options are not available in many configurations. On the other hand, as already mentioned, we have prior knowledge indicating that a significant fraction of the entries appearing in the resulting Hankel matrices will

be zero because they correspond to non-valid trajectories. This will lead to highly sparse matrices which can benefit from sparse representations, sparse singular value decompositions, and sparse numerical linear algebra in general. In those cases, the complexity of the operations involved will not depend on the size of these matrices, but instead on the number of non-zero entries. This quantity will in practice be much smaller than the size of the Hankel matrices given by our choice of basis, and we have observed such benefits in our experiments.

## 5 PLANNING WITH ODM

In this section we want to briefly investigate the potential utility of ODM representations for planning with options. Specifically, we want to show how to use ODMs as a form of state representation for value function learning. In a nutshell, our main result states that nothing is lost by planning with options using a PSR representation of an ODM instead of the original MDP representation.

The first important observation is that the construction in Theorem 1 (and in consequence, the construction in Theorem 2) leads to a PSR with identical transition operators  $\{\mathbf{A}_\sigma\}$  regardless of which initial distribution over the states of  $M$  is chosen. That is, the only thing that needs to be modified when we change the initial distribution over the states is the initial state in the PSR. Thus, given an MDP  $M$  and a set of options  $\Omega$ , we can fix the transition structure of a PSR representation for the corresponding ODM — either over all trajectories or only valid trajectories (the distinction is not important for the purpose of this section). These will be given by  $\{\mathbf{A}_\sigma\}$  for  $\sigma \in \Sigma = \Omega \times \{\#, \perp\}$ , and the corresponding final weights  $\alpha_\infty$ . We denote by  $n'$  the dimension of this PSR. Then we can map each possible distribution  $\alpha$  over the states of  $M$  to a PSR state  $\theta_\alpha \in \mathbb{R}^{n'}$ . Note that although this mapping is straightforward for the construction in Theorem 1, this is not the case for the construction in Theorem 2, and even less for the PSR recovered by the learning algorithm in Section 4 because such a PSR is only equivalent to the original up to conjugation of the transition weights by an invertible matrix [Boots *et al.*, 2011]. In addition to distributions over initial states, we can also consider PSR states obtained by the state-update procedure. That is, if we are given a valid trajectory  $u \in V$  representing a history of options and associated continuation and termination events, then we can obtain the updated state

$$\theta_{\alpha, u}^\top = \frac{\theta_\alpha^\top \mathbf{A}_u}{\theta_\alpha^\top \mathbf{A}_u \alpha_\infty} .$$

This represents another probability distribution over the states of  $M$ . Note that by construction we have  $\theta_{\alpha, \lambda} = \theta_\alpha$ . With this notation we can show that the state-option value function of any policy over options is linear in the PSR state.

**Theorem 3.** Let  $\pi_\Omega : S \times \Omega \rightarrow [0, 1]$  be a stochastic stationary policy over options on the MDP  $M$ . For every  $\omega \in \Omega$  there exists a vector  $\rho_\omega \in \mathbb{R}^{n'}$  so that for every distribution  $\alpha$  over states in  $M$  and every history  $u \in V$ , we have  $\mathbb{E}_s[Q^{\pi_\Omega}(s, \omega)] = \theta_{\alpha, u}^\top \rho_\omega$ , where the expectation is over states  $s$  sampled from the distribution induced by observing  $u$  after starting in a state drawn from  $\alpha$ .

The above theorem includes as a special case the situation in which the agent is at a fixed state in  $M$ ; i.e. no uncertainty. The proof follows along the lines of a similar result known for PSRs with reward structure induced by a corresponding POMD [James *et al.*, 2004]. The key difference is that we need to take into account the semi-Markov nature of option termination events, which make the computations involved in the discount factors and extended transition kernels more involved. Though the details are not complicated, the algebra is too lengthy to be included in this version and will be presented in full in an extended version.

Although planning with PSRs has been studied using methods akin to POMDP planning [James *et al.*, 2004; Izadi and Precup, 2008; Boots *et al.*, 2011], we chose a more efficient alternative, the Fitted-Q Iteration (FQI) algorithm of Ernst *et al.* [2005]. Similar uses of FQI with PSR states have been proposed in Ong *et al.* [2012]; Hamilton *et al.* [2013]. FQI learns a policy through an iterative re-fitting process over batches of sampled transitions of the form:  $\langle s, a, r, s' \rangle$ . At every iteration, an ensemble of extremely randomized trees (ExtraTrees) [Geurts *et al.*, 2006] is fit to  $Q(s, a)_t = r + \gamma \max_{a'} Q_{t-1}(s', a')$  over all quadruples  $s, a, r, s'$ . In order to ensure convergence, the tree structure must be kept fixed across iterations. Hence, we fit the regressor in the first iteration and only refreshed the values and not the structure on subsequent iterations. We plan directly over the ODM state vector updated at each step with the corresponding operator (continuation or termination). So, in the first step, we compute  $\theta_0 = \alpha_\lambda^\top \mathbf{A}_{\sigma_0}$ , then update  $\theta_t = \theta_{t-1}^\top \mathbf{A}_{\sigma_t}$ . The ODM state vector is then normalized in order to prevent difficulties with the regressor. This approach is leveraging a well-known planning approach, so it is straightforward. It is possible that the structure of ODM can be exploited further to design more efficient planning algorithms. We leave this topic for future work.

## 6 EXPERIMENTS

We first assess the performance of the spectral learning algorithm with our data-driven basis construction method for  $K_r = 2$  and  $K_s = 1$ . We use a 4-connected grid with four actions representing the cardinal directions (NEWS). Unless the current state is a “wall” each action moves the agent one step in the specified direction with probability 0.9, and maintains the current state with probability 0.1. We also define one option for each cardinal direction. These options

take as many steps as possible in the specified direction until they hit a wall, at which point the option terminates. A uniformly random exploration policy is used for sampling 10000 episodes in which five options are executed to termination. We also collected a test set consisting of 10000 trajectories of 8 options sequences. We evaluate the prediction accuracy by computing the relative error over the estimated remaining number of steps in the currently executing option. For each test trajectory, we picked a time index uniformly at random and conditioned the learned ODM on the history up to this point. These random split points were then kept fixed throughout all evaluations. Figure 1b shows that the prediction accuracy increases with the dimension of the ODM. More samples also allow for better predictions. Since the prediction task is inherently stochastic, even the true ODM cannot achieve 0 relative error.

### 6.1 Planning in a grid world

We formulate the grid-world problem by giving a reward of +100 for entering the bottom-right state and -10 per collision, with discount factor 0.9. A dataset of 1000 trajectories of 8 options each was collected with a uniformly random policy over options. For each curve in figure 1, we use our dataset to simultaneously learn an ODM and plan over it. We evaluate the performance of the greedy policy by taking 100 Monte-Carlo estimates in the simulated environment. Given the true underlying MDP and a set of options, we compute the resulting Semi-Markov Decision Process (SMDP) (see p. 26 of Sutton *et al.* [1999]) and solve it using value iteration, to obtain the baseline (optimal achievable return) for our evaluation. We extended the ExtraTrees implementation of Pedregosa *et al.* [2011] with the freezing mechanism required for FQI. We used all available features for splitting internal nodes and fitted an ensemble of 10 trees with maximum depth of 5. Figure 1c shows that an optimal policy can be obtained using 1000 trajectories and one planning step.

### 6.2 Planning with a simulated robot

Using the same methodology, we experimented with the proposed ODM learning and planning approach in a simulated robot environment with continuous state space, non-linear dynamics, and actions that correspond to real actuators of the robot. We leverage the simulation capabilities of the 2D physics engine Box2D<sup>2</sup> to obtain realistic accelerations, collisions and friction effects.

We set the density of a circular differential wheeled robot to 3.0 and its radius to 0.17 cm. A primitive action in this domain consists in the application of force vector of (0.1, 0.1) on both wheels every 1/10 of a simulated second. At the beginning of every episode, the robot is initialized at position (0.5, 0.5) of a 2x2 meters environment.

<sup>2</sup><http://box2d.org>

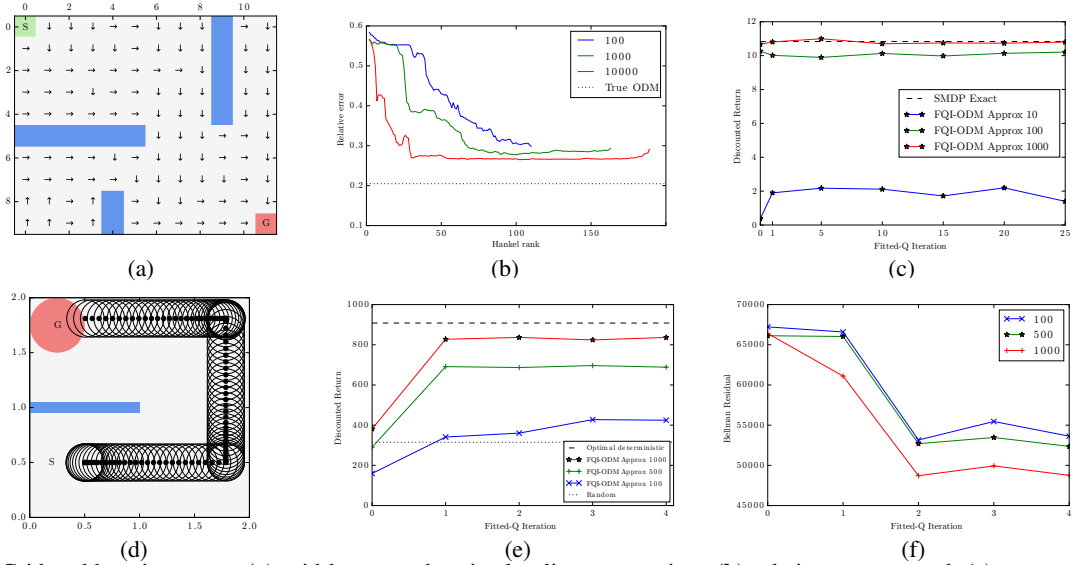

Figure 1: Gridworld environment: (a) grid layout and optimal policy over options (b) relative error vs rank (c) average discounted cumulative return. Simulated robot environment: (d) trajectory of an optimal policy (e) average discounted cumulative reward (f) mean square Bellman residual

A 10cm thick wall separates the robot from the goal location at  $(0.25, 0.75)$ . The episode finishes when the robot is within 25cm of the target.

As in the grid-world problem, we define a set of options over four radial directions. The termination condition triggers when the front-facing distance sensor detects an obstacle 6cm ahead. Because of the nonlinear dynamics, the hand-defined options controller does not always stop exactly within this distance. Given enough acceleration, the robot might sometimes touch the walls. This additional source of noise due to an imperfect controller is interesting from an experimental point of view. A stochastic component also makes the forward action ineffective 5% of the time. The rewards are 1000 for reaching the goal region and -10 by collision. Taking a primitive action incurs no cost but there is a discount factor  $\gamma = 0.999$ .

We collected 2000 trajectories of at most 10 options with a uniformly random policy over options. Due to the size of the environment, we found that trajectories of at most 5 options were insufficient to consistently learn good policies. We used  $K_r = 2, K_s = 1$  for the basis, considered all features for node splitting and used 10 trees of maximum depth 8. The results presented in Figure 1e were obtained by resampling 10 times the original dataset without replacement, to characterize the stability of the learning algorithm. The greedy policy derived from FQI was then evaluated with 10 Monte-Carlo rollouts. Since the underlying MDP is unknown, we could not compute the exact optimal policy, so we upper-bounded the achievable return through the policy in Figure 1d under 100% success rate for the forward command. We used the average return of a uniform random policy as baseline. As expected,

the mean square Bellman residual [Ernst *et al.*, 2005] decreases for larger sample sizes and over longer planning horizon (Fig. 1f). While 100 episodes yield ODM policies slightly better than random, 1000 episodes are sufficient to recover a close-to-optimal solution (Fig. 1e).

## 7 DISCUSSION

The approach we presented learns a predictive model for option durations, and we illustrates its use in robot navigation tasks. As discussed, timing models are simple, yet in many problems they are sufficient for good quality planning. To see why having simpler models might be useful, consider the prevalence of bandit problems in ad placement; the task could be done better with full MDPs, data efficiency is more important for the application. Similarly, we believe that being able to exploit simple yet efficient timing models is interesting and important. The use of this type of model in planning algorithms should be investigated further. Models of states in terms of what happens after executing certain actions are known to be useful, e.g. Dayan [1993]. But our models are simplified, hence different both from action-respecting embeddings Bowling *et al.* [2005, 2007] and predictive state representations with options Wolfe and Singh [2006], which aim to learn full observation models conditioned on extended actions, in order to characterize the current state. Timing models get around the problem of both large action spaces (by using a finite set of options) and the problem of large observation spaces (by focusing only on continuation and termination). A theoretical analysis of the error of planning with timing models instead of true transition models is left for future work. We also aim to study the sample efficiency of this approach.

## Abstract

Network statistics such as node degree distributions, average path lengths, diameters, or clustering coefficients are widely used to characterize networks. One statistic that received considerable attention is the distance distribution — the number of pairs of nodes for each shortest-path distance — in undirected networks. It captures important properties of the network, reflecting on the dynamics of network spreading processes, and incorporates parameters such as node centrality and (effective) diameter. So far, however, no parameterization of the distance distribution is known that applies to a large class of networks. Here we develop such a closed-form distribution by applying maximum entropy arguments to derive a general, physically plausible model of path length histograms. Based on the model, we then establish the generalized Gamma as a three-parameter distribution for shortest-path distance in strongly-connected, undirected networks. Extensive experiments corroborate our theoretical results, which thus provide new approaches to network analysis.

## 1 INTRODUCTION

As networks are combinatorial structures, network analysis typically relies on statistics such as node degree distributions, average path lengths, clustering coefficients, or measures of assortativity [11]. One statistic that received considerable attention is the distance distribution — the number of pairs of nodes for each shortest-path distance — in undirected networks. First of all, features such as average path lengths or network diameters can be determined therefrom. Second of all, path length statistics are closely related to velocities or durations of network spreading processes. Analytically tractable models of shortest path distributions would thus allow for inferring network properties as well

Figure 1: A highly infectious *SIR* cascade on a network realizes a node discovery process. (a) at onset time  $t = 0$ , most nodes are *susceptible* and only a single node is *infected*. (b)–(d) infected nodes immediately *recover* but always infect their susceptible neighbors. This way, the number of newly infected nodes  $n_t$  at time  $t$  corresponds to the number  $n_d$  of nodes that are at distance  $d = t$  from the source node of the epidemic.

as for reasoning about diffusion dynamics. Yet, analytic models and in particular parameterizing the distance distribution prove difficult to achieve and related reports are curiously scarce [7, 9, 14, 34, 35]. Here, we contribute to these efforts and derive a novel, principled general model of shortest path length distributions in strongly connected networks. Considering a duality between network spreading processes and shortest path lengths, we then show that maximum entropy arguments as to diffusion dynamics lead to the generalized Gamma distribution as a three-parameter distribution in closed form.

The work presented here was motivated by questions as to the dynamics of network spreading processes. Models of such processes play an important role in various disciplines. They model the dynamics of epidemic diseases [20, 27, 22], explain the diffusion of innovations or viral messages [1, 24], and, in the wake of social media, a

Figure 2: Shortest path histogram resulting from the network spreading process in Fig. 1 and a corresponding maximum likelihood fit of the generalized Gamma distribution.

quickly growing body of research develops graph diffusion models to study patterns of information dissemination in Web-based social networks [2, 10, 16, 25, 36]. Each of these examples concerns an instance of a rather general phenomenon: An agent (a virus, a rumor, an urge to buy a product, etc.) spreads in form of a contact process and thus cascades through a network of interlinked entities (people, computers, blogs, etc.). At the onset of the agent’s activity, many networked entities are *susceptible* to its effects but only few are actually *infected* (see Fig. 1(a)). As time progresses, susceptible entities related to infected ones may become infected whereas infected entities may remain infected, *recover*, become susceptible again, or even be removed from the population (see Fig. 1(b)–(d)). Crucial properties of such a process are its infection rate, its recovery rate, or the number of infected entities per unit of time. If an (information) epidemic is observed to rage through a community, these features help assessing its progression or final outbreak size and thus inform contagion or dissemination strategies. For instance, while public health authorities need to devise immunization protocols to curtail epidemic diseases, viral marketers typically aim at maximizing the effects of their campaigns. In any case, knowledge as to the structure of a community through which an epidemic spreads would be beneficial. Alas, in practice, community structures are hardly ever known but available information only consists of outbreak data as shown in Fig. 2.

Relating such outbreak data to network structures is the key idea underlying our contribution and is orthogonal to related approaches such as [2, 21, 26, 15, 36], which assume outbreak data *and* information about network members to be available and apply machine learning to identify hubs, link structures, or infection routes. Instead, we follow the paradigm in [4, 7, 16, 28, 29, 35] which asks for physical explanations of the noticeably skewed appearance of outbreak histograms and attempts to relate corresponding physical models to network properties.

More precisely, we make two technical contributions. First, we relate outbreak data to network structures via a novel maximum entropy model. Then, based on the model, we establish the generalized Gamma distribution as a physically-

plausible, continuous parameterization of the distance distribution of networks of arbitrary topology. Considering the fact that temporal distributions of infection counts in highly infectious spreading processes and distributions of shortest path lengths are dual phenomena allows us to invoke maximum entropy arguments from which we derive physical characterizations of path lengths- and outbreak statistics. In other words, our model results from first principles rather than from data mining. It also generalizes previous theoretical results [7, 35] and provides an explanation for a recent empirical observation as to path length distributions in social networks [8].

We proceed as follows. We start off by briefly reviewing existing analytical models of shortest path- and outbreak distributions in Section 2. Afterwards, we show that the generalized Gamma distribution naturally generalizes these, and discuss its properties and characteristics in Section 3. In particular, we demonstrate how the generalized Gamma emerges as a maximum entropy model of path length- and outbreak data. Before concluding, we support our theoretical results by exhaustive experiments on both synthetic and real-world graphs in Section 4.

## 2 KNOWN RESULTS

Analytically tractable models of shortest path length distributions and outbreak data are of considerable interest in the study of epidemic processes on networks. However, as networks are combinatorial structures, corresponding results are necessarily statistical [4, 7, 16, 28, 29, 35]. In a landmark paper [35], Vazquez studied the dynamics of epidemic processes in power law networks. Arguing based on branching process models, he showed that for networks whose node degree distribution has a power law exponent  $2 < \gamma < 3$ , the number of infected nodes at time  $t$  follows a *Gamma distribution*.

$$f_{GA}(t; \theta, \eta) = \frac{1}{\theta^\eta} \frac{1}{\Gamma(\eta)} t^{\eta-1} e^{-t/\theta} \quad (1)$$

where  $\Gamma(\cdot)$  is the gamma function and  $\theta > 0$  and  $\eta > 0$  are scale and shape parameters, respectively. Curiously, for power law exponents  $\gamma \geq 3$ , this result does not apply. Concerned with Erdős-Rényi graphs, Bauchhage *et al.* [7] derived a different result. Based on models of the expected number of paths of length  $t$  between arbitrary nodes [9, 14], they resorted to extreme value theory [13] to show that infection counts can be characterized by the *Weibull distribution*.

$$f_{WB}(t; \lambda, \kappa) = \frac{\kappa}{\lambda^\kappa} t^{\kappa-1} e^{-(t/\lambda)^\kappa} \quad (2)$$

where  $\lambda > 0$  and  $\kappa > 0$  are scale and shape parameters. Neither model was obtained from mere empirical observations. Both follow from basic principles, provide *physically and hence socially plausible* and comprehensible characterizations of shortest path length distributions and diffusion dynamics, and were verified empirically.

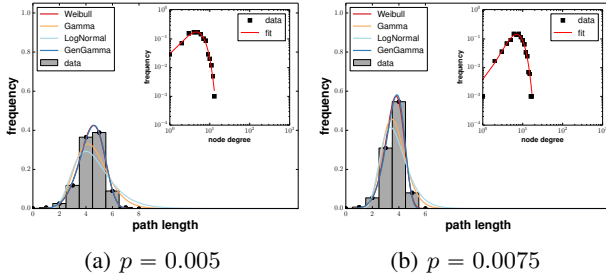

Figure 3: Qualitative examples of shortest path distribution in Erdős-Rényi graphs. Confirming [7], Weibull fits well. Yet, generalized Gamma provides better fits.

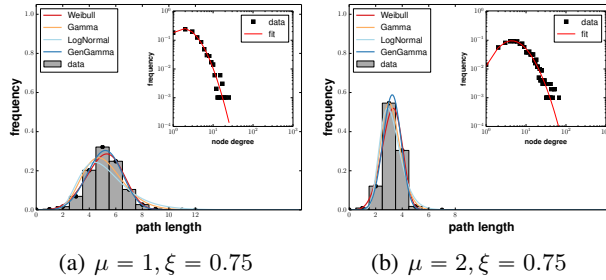

Figure 4: Qualitative examples of shortest path distribution in LogNormal graphs. For different node degree distributions, the models considered here provide more or less accurate fits. The generalized Gamma, however, always fits best (cf. Tab. 1).

Finally, Bild *et al.* [8] recently investigated information cascades and retweet networks on twitter and found that they could accurately fit their data using the *LogNormal distribution*

$$f_{LN}(t; \mu, \xi) = \frac{1}{\sqrt{2\pi} \xi t} e^{-\frac{(\log t - \mu)^2}{2\xi^2}} \quad (3)$$

where  $\mu$  and  $\xi$  are location and scale parameters. Regarding our approach in this paper, we emphasize that (3) was not found theoretically but emerged empirically. At the same time, we note that the Gamma, Weibull, and LogNormal distribution may easily confused for one another [31]. Our discussion so far therefore begs the question if the above results are contradictory or if they can be unified within a more general framework? In the following, we will show that the latter is indeed the case.

### 3 A THREE-PARAMETER DISTANCE DISTRIBUTION

We will now establish the *generalized Gamma distribution* as a comprehensive model of the shortest path distributions and outbreak data in connected networks of arbitrary topology. Different versions of the generalized Gamma dis-

tribution can be traced back to 1920s [12]. Here, we are concerned with the three-parameter version that was introduced by Stacy [33]. Its probability density function is defined for  $t \in [0, \infty)$  and given by

$$f_{GG}(t | \sigma, \alpha, \beta) = \frac{\beta}{\sigma^\alpha} \frac{1}{\Gamma(\alpha/\beta)} t^{\alpha-1} e^{-(t/\sigma)^\beta} \quad (4)$$

where  $\sigma > 0$  determines scale and  $\alpha > 0$  and  $\beta > 0$  are shape parameters. The probability density function in (4) is unimodal but may be skewed to the left or to the right. It also contains several other distributions as special cases [5, 12]. Most notably, we point out that setting  $\beta = 1$  yields the Gamma distribution in (1), equating  $\alpha = \beta$  yields the Weibull distribution in (2), letting  $\alpha/\beta \rightarrow \infty$ , the generalized Gamma distribution approaches the LogNormal distribution in (3).

These properties immediately suggest that the above results might be specific instances of a more general model. We will now prove that this is indeed the case:

**Theorem 1.** *The generalized Gamma distribution provides a physically plausible model of distance distributions and outbreak data in strongly-connected, undirected networks.*

Before proving this in the following subsections, we would like to stress that, in contrast to Vazquez [35] and Bauckhage *et al.* [7], our maximum entropy model does not make any assumption on the topology of the network — next to being strongly connected — through which a viral agent is spreading. Rather, it considers general properties of highly infectious processes as discussed in the introduction and resorts to the maximum entropy principle together with likelihood maximization techniques. Any aspects related to topological properties (e.g. degree distribution or clustering patterns) of individual networks are absorbed into the parameters of (4), which, as we shall see in the experimental section, is flexible enough to represent a wide range of different path length and spreading statistics.

#### 3.1 A MAXIMUM ENTROPY APPROACH

Let us now demonstrate that the generalized Gamma distribution provides a principled model of shortest path- and outbreak statistics in networks. We argue based on Jaynes’ *maximum entropy principle* [17]. It states that, subject to observations and contextual knowledge, the probability distribution that best represents the available information is the one of highest entropy. In particular, we resort to an approach by Wallis, cf. [18, chapter 11], which does not assume entropy as an a priori measure of uncertainty but uncovers it in the course of the argument.

To derive our analytical model of path length histograms of arbitrary networks, we consider the network spreading process in Fig. 1. Borrowing terminology from epidemiology, we note that, at onset time  $t = 0$ , most nodes in the network are *susceptible* and one node is *infected*. At time  $t + 1$ ,

Figure 5: The probability of finding a path of length  $k$  may be constant or decrease or increase with  $k$ .

nodes that were infected at  $t$  have *recovered* yet did infect their susceptible neighbors. Highly infectious *SIR* cascades like this now realize a node discovery process: the number  $n_t$  of newly infected nodes at time  $t$  corresponds to the number of nodes that are at topological distance  $d = t$  from the source.

Given these considerations, we observe that the discrete shortest path distribution of the entire network is nothing but the sum of all node count histograms  $h_s[t]$  taken over all possible source nodes. Let  $K$  denote the length of the longest shortest path starting at a source  $v_s$  and use  $n_k$  to indicate the number of nodes that are  $k$  steps away from  $v_s$ . Then,  $n = \sum_{k=0}^K n_k$  where  $n$  denotes the total number of nodes. The probability of observing a node at distance  $k$  can thus be expressed as  $p_k = n_k/n$  and we have  $1 = \sum_{k=0}^K p_k$ . Moreover, we let  $q_k$  denote the probability that there exists a shortest path of length  $k$  so that  $1 = \sum_{k=0}^K q_k$  and we emphasize that  $p_k$  and  $q_k$  will generally differ (see the didactic examples in Fig. 5). With these definitions at hand, the joint probability of observing counts  $n_k$  of infected nodes corresponds to the multinomial

$$P(n_1, \dots, n_K) = n! \prod_{k=1}^K \frac{q_k^{n_k}}{n_k!}$$

whose log-likelihood is given by

$$L = \log n! + \sum_{k=0}^K n_k \log q_k - \log n_k! \quad (5)$$

Assuming that  $n_k \gg 1$ , we may apply Stirling's formula  $\log n_k! \approx n_k \log n_k - n_k$  to simplify (5)

$$\begin{aligned} L &\approx n \log n - n + \sum_{k=0}^K n_k (\log q_k - \log n_k + 1) \\ &= n \log n + n \sum_{k=0}^K p_k (\log q_k - (\log p_k + \log n)) \\ &= -n \sum_{k=0}^K p_k \log \frac{p_k}{q_k}. \end{aligned} \quad (6)$$

As the expression in (6) is a Kullback-Leibler divergence, our considerations so far led indeed to an entropy that needs to be maximized in order to determine the most likely values  $n_k^*$  of the  $n_k$ .

However, up until now, the quantities  $q_k$  are not defined precisely enough to allow for a solution. Also, (6) accounts

only indirectly for temporal aspects of network spreading processes as any dependency on time is hidden in the index of summation  $k$ . We address both these issues by choosing the ansatz

$$q_k = A t_k^{\alpha-1} \quad (7)$$

where  $A$  is a normalization constant and  $\alpha > 0$ . This choice and its significance will be justified in detail below. For now, we continue with our main argument.

Another underspecified quantity so far is the length  $K$  of the supposed longest shortest path. However, dealing with networks of finite size, we can bypass the need of having to specify  $K$  by means of introducing the following constraint

$$\sum_{k=0}^{\infty} n_k = n \quad (8)$$

into the problem of maximizing (6). Finally, to prevent degenerate solutions (e.g. instantaneous or infinite spread), we impose a constraint on the times  $t_k$  and require their moments

$$\sum_{k=0}^{\infty} \frac{n_k}{n} t_k^\beta = c \quad (9)$$

to be finite for some  $\beta > 0$ . Using differential forms, we now express the log-likelihood in (6) and the two constraints in (8) and (9) as

$$dL = \sum_{k=0}^{\infty} \frac{\partial L}{\partial n_k} dn_k = \sum_{k=0}^{\infty} (\log A t_k^{\alpha-1} - \log n_k) dn_k,$$

$dn = \sum_{k=0}^{\infty} dn_k$ , and  $dc = \sum_{k=0}^{\infty} t_k^\beta dn_k$ , and consider the Lagrangian with multipliers  $\rho$  and  $\gamma$

$$\mathcal{L} = \sum_{k=0}^{\infty} \left[ \log \frac{A t_k^{\alpha-1}}{n_k} - \rho - \gamma t_k^\beta \right] dn_k = 0$$

in order to determine most likely infection counts  $n_k^*$  for the spreading process described above. Since at the solution the bracketed terms  $[\cdot]$  must vanish identically for every  $dn_k$ , we immediately obtain

$$n_k^* = A e^{-\rho} t_k^{\alpha-1} e^{-\gamma t_k^\beta}.$$

Plugging this result back into  $p_k = n_k/n$  yields a discrete probability mass function in the now exp-transformed space

$$\frac{n_k^*}{n} = \frac{t_k^{\alpha-1} e^{-\gamma t_k^\beta}}{\sum_{j=0}^{\infty} t_j^{\alpha-1} e^{-\gamma t_j^\beta}} \quad (10)$$

which explicitly relates infection counts  $n_k$  to time steps  $t_k$ . However, (10) still depends on the Lagrangian multiplier  $\gamma$  (now in exp-space), which is not immediately related to any available data. In order to determine  $\gamma$ , we assume the duration  $\Delta t = t_{k+1} - t_k$  of time steps to be small. This permits the following approximation

$$\sum_{k=0}^{\infty} t_k^{\alpha-1} e^{-\gamma t_k^\beta} \Delta t \approx \int_0^{\infty} t^{\alpha-1} e^{-\gamma t^\beta} dt = \gamma^{-\frac{\alpha}{\beta}} \frac{\Gamma(\alpha/\beta)}{\beta}$$

so that

$$\frac{n_k^*}{n} = \Delta t \frac{\gamma^{\frac{\alpha}{\beta}} \beta}{\Gamma(\alpha/\beta)} t_k^{\alpha-1} e^{-\gamma t_k^\beta}.$$

Plugging this into (9), tedious but straightforward algebra yields  $\gamma = \frac{\alpha}{\beta c}$  which is to say that

$$\frac{n_k^*}{n} = \Delta t \left[ \frac{\beta}{\Gamma(\alpha/\beta)} \left( \frac{\alpha}{\beta c} \right)^{\frac{\alpha}{\beta}} \right] t_k^{\alpha-1} e^{-\frac{\alpha}{\beta c} t_k^\beta}. \quad (11)$$

In order to establish the final result, we now let  $\Delta t \rightarrow 0$  which leads to

$$\frac{n_k^*}{n} \approx \int_{\Delta t} f(\tau) d\tau \approx \Delta t f(t) \quad (12)$$

where  $t_k - \frac{\Delta t}{2} \leq t \leq t_k + \frac{\Delta t}{2}$ . Direct comparison of (11) and (12) together with the substitution  $\sigma = \left(\frac{\beta c}{\alpha}\right)^{1/\beta}$  finally establishes that

$$f(t) = \frac{\beta}{\sigma^\alpha} \frac{1}{\Gamma(\alpha/\beta)} t^{\alpha-1} e^{-(t/\sigma)^\beta}$$

which is indeed the generalized Gamma distribution that was introduced in (4).

### 3.2 EXTENSIONS TO DIFFERENT TIME SCALES

So far, our derivation above was based on properties of networked *SIR* cascades for which the infection rate  $i$  as well as the recovery rate  $r$  were both assumed to be 100%. Yet, the empirical result in Section 4 indicate that the generalized Gamma distribution also accounts for the dynamics of less infectious spreading processes where  $i$  and  $r$  are smaller. Such epidemics usually last longer as it takes more time to reach all susceptible nodes and infected nodes may remain so over extended periods. In other words, such processes can be thought of as taking place on a different time scale. Here, we briefly show that the generalized Gamma distribution can also explain spreading processes on linearly or polynomially transformed time scales.

Recall that if a random variable  $X$  is distributed according to  $f(x)$ , the monotonously transformed random variable  $Y = h(X)$  has a probability function that is given by

$$g(y) = f(h^{-1}(y)) \cdot \left| \frac{d}{dy} h^{-1}(y) \right|.$$

Now, if  $t$  is generalized Gamma distributed and  $\tau = ct$  is a linearly transformed version of  $t$ , then

$$t = \frac{\tau}{c} \quad \text{and} \quad \frac{dt}{d\tau} = \frac{1}{c}$$

so that  $\tau$  is distributed according to

$$\begin{aligned} g(\tau) &= \frac{\beta}{\sigma^\alpha} \frac{1}{\Gamma(\alpha/\beta)} \left( \frac{\tau}{c} \right)^{\alpha-1} e^{-(\tau/c\sigma)^\beta} \cdot \frac{1}{c} \\ &= \frac{\beta}{\sigma'^\alpha} \frac{1}{\Gamma(\alpha'/\beta')} \tau^{\alpha'-1} e^{-(\tau/\sigma')^\beta} \end{aligned}$$

Figure 6: Causal graph of the process in Fig. 1. The adjacency matrix of a directed acyclic graph with a single source node can be brought into strictly upper triangular form and is thus nilpotent.

which is a generalized Gamma distribution with scale parameter  $\sigma' = c\sigma$ .

By the same token, if  $t$  is generalized Gamma distributed and  $\tau = t^c$  is a polynomially transformed version of  $t$ , then

$$t = \tau^{\frac{1}{c}} \quad \text{and} \quad \frac{dt}{d\tau} = \frac{1}{c} \tau^{\frac{1}{c}-1}$$

so that  $\tau$  is distributed according to

$$\begin{aligned} g(\tau) &= \frac{\beta}{\sigma^\alpha} \frac{1}{\Gamma(\alpha/\beta)} \left( \tau^{\frac{1}{c}} \right)^{\alpha-1} e^{-(\tau^{1/c}/\sigma)^\beta} \cdot \frac{1}{c} \tau^{\frac{1}{c}-1} \\ &= \frac{\beta' c}{\sigma'^{\alpha'}} \frac{1}{\Gamma(\alpha'/\beta')} \tau^{\alpha'-1} e^{-(\tau^{\beta'}/\sigma'^{\beta'})} \end{aligned}$$

which is a generalized Gamma distribution with parameters  $\sigma' = \sigma^c$ ,  $\alpha' = \frac{\alpha}{c}$ , and  $\beta' = \frac{\beta}{c}$ .

### 3.3 JUSTIFYING THE POLYNOMIAL ANSATZ (7)

While the constraints in (8) and (9) are arguably intuitive, the ansatz in (7) merits further elaboration. Note that *causal graphs* as in Fig. 6 indicate possible transmission pathways of an epidemic. In general they may be arbitrarily complex but, for the type of spreading process studied here, they are necessarily directed and acyclic. Now, in a directed, acyclic graph, the number  $N_k$  of shortest paths of lengths  $k$  starting from a source node  $v_s$  may indeed grow exponentially for a while (for instance in a tree) but the finite size of the graph causes  $N_k$  to drop to zero once  $k$  exceeds the length  $K$  of the longest shortest path; there are no shortest paths longer than  $K$ . Because of this finite size effect, a polynomial upper bound always exists for  $N_k$ ,  $k \leq K$ .

More formally, consider a network of  $n$  nodes. If  $v_s$  is the source node of an epidemic on this network and  $\mathbf{A}$  is the adjacency matrix<sup>1</sup> of the corresponding causal graph then  $(\mathbf{A}^k)_{s_j}$  denotes number of ways the epidemic agent can reach  $v_j$  from  $v_s$  in  $k$  steps and  $q_k \propto \sum_j (\mathbf{A}^k)_{s_j}$ . For causal

<sup>1</sup> $A_{ij} = 1$  if nodes  $v_i$  infects  $v_j$ , and  $A_{ij} = 0$  otherwise.

graphs,  $\mathbf{A}$  is strictly upper triangular and therefore *nilpotent*. That is,  $\exists K \leq n : \mathbf{A}^k = \mathbf{0} \ \forall k > K$ . Hence,  $\rho(\mathbf{A}) < 1$  which is to say  $\exists u > 0 : \|\mathbf{A}^k\|_F < u \ \forall k$  and therefore  $0 \leq (\mathbf{A}^k)_{sj} \leq \|\mathbf{A}^k\|_F < u$ . Accordingly,  $\sum_j (\mathbf{A}^k)_{sj} \in O(k^{\alpha-1})$  for some  $\alpha \geq 1$ . Setting  $t_k = \epsilon k$  where  $\epsilon \leq 1$  yields  $q_k \in O(t_k^{\alpha-1})$  which justifies (7).

Put in simple terms, it is sufficient to model the probability  $q_k$  of observing an epidemic path of length  $k$  as a polynomial in  $t$  rather than, say, an exponential function.

The fact that the parameter  $\alpha$  reflects aspects of network topology is easily seen from the examples in Fig. 5. Assuming the central node to be the source node of an epidemic the figure shows that  $q_k$  may be constant ( $\alpha = 1$ ), decreasing ( $\alpha < 1$ ), or increasing ( $\alpha > 1$ ) with  $k$ .

## 4 EMPIRICAL SUPPORT

We now support our theoretical results with empirical evidence. First, we present results on distance distributions of synthesized networks. Then, we report on experiments with a large number of spreading processes on synthetic graphs and, finally, we discuss results obtained for large, real-world networks.

Throughout, we fit continuous distributions to discrete histograms. That is, we apply functions  $f(t; \theta)$  to represent counts  $n_0, \dots, n_K$  which are grouped into  $K$  distinct intervals  $(t_0, t_1], (t_1, t_2], \dots, (t_{K-1}, t_\infty)$ . For this setting, it is advantageous to use multinomial likelihood estimation based on reweighted least squares in order to determine optimal model parameters  $\theta^*$  [19]. For a recent detailed exposition of this robust technique, we refer to [6]. For the fitted models, we report quantitative goodness-of-fit results in terms of the Hellinger distance

$H(h[t], f[t]) = \frac{1}{2} \sqrt{\sum_t \left( \sqrt{h[t]} - \sqrt{f[t]} \right)^2}$  between discrete empirical data  $h[t]$  and a discretized model  $f[t]$  where

$$f[t] = \begin{cases} F(t + \frac{1}{2}) & \text{if } t = 0 \\ F(t + \frac{1}{2}) - F(t - \frac{1}{2}) & \text{if } 0 < t < K \\ 1 - F(t + \frac{1}{2}) & \text{if } t = K \end{cases}$$

and  $F(\cdot)$  is the corresponding cumulative density function. We note that the Hellinger distance is bound as  $0 \leq H \leq 1$ .

**Synthetic Networks.** We created different Erdős-Rényi (ER), Barabási-Albert (BA), power law (PL), and Log-Normal (LN) graphs of  $n \in \{5,000, 10,000\}$  nodes. ER graphs are a staple of graph theory and merit investigation. To create ER graphs, we used edge probability parameters  $\pi \in \{0.005, 0.0075, 0.01\}$ . BA and PL graphs represent networks that result from preferential attachment processes and are frequently observed in biological, social, and technical contexts. To create BA graphs, we considered attachment parameters  $m \in \{1, 2, 3\}$  and exponents

Table 1: Goodness of Fit (avg. Hellinger distances) for shortest path histograms of synthetic networks

| network | parameters            | $f_{WB}$ | $f_{GA}$ | $f_{LN}$ | $f_{GG}$ |

|         | $\gamma = 2.5$        | 0.123    | 0.037    | 0.064    | 0.028    |
|         | $\gamma = 2.7$        | 0.101    | 0.044    | 0.089    | 0.028    |
|         | $\gamma = 2.9$        | 0.081    | 0.050    | 0.108    | 0.026    |
|         | $\gamma = 3.1$        | 0.070    | 0.093    | 0.137    | 0.051    |
| LN      | $\mu = 1, \xi = 0.75$ | 0.075    | 0.093    | 0.149    | 0.037    |
|         | $\mu = 1, \xi = 1.25$ | 0.082    | 0.067    | 0.113    | 0.029    |
|         | $\mu = 2, \xi = 0.75$ | 0.073    | 0.092    | 0.145    | 0.036    |
|         | $\mu = 2, \xi = 1.25$ | 0.079    | 0.062    | 0.102    | 0.026    |

of the vertex degree distributions of the PL graphs were drawn from  $\gamma \in \{2.1, 2.2, \dots, 3.2\}$ . LN graphs show log-normally distributed vertex degrees and reportedly characterize link structures within sub-communities on the web [30]. To synthesize LN graphs, parameters were chosen from  $\mu \in \{1, 1.5, \dots, 3\}$  and  $\xi \in \{0.25, 0.5, 0.75, 1\}$ . For each parametrization, we created 100 instances.

Table 1 summarizes average goodness of fit results for graphs of  $n = 10,000$  nodes and different topologies (for lack of space, we omit results for some of the parametrizations considered in our experiments). We observe that (i) in agreement with Bauchhage *et al.* [7], the Weibull distribution provides a well fitting model for the distance distribution in ER graphs; it outperforms the Gamma and the Log-Normal distribution; (ii) in agreement with Vazquez [35], the Gamma distribution provides a well fitting model for PL graphs where  $2 < \gamma < 3$ ; (iii) for PL graphs where  $\gamma \lesssim 2.2$ , the LogNormal fits well, too; (iv) for PL graphs where  $\gamma \geq 3$ , the Weibull fits better than the Gamma or the LogNormal; in this context, we note that BA graphs are power law graphs for which  $\gamma = 3$  [3]; (v) in any case, the generalized Gamma distribution provides the best fits in all cases while still being physically plausible.

Indeed, the latter is not surprising as the densities in (1)-(3) are functions of two parameters whereas the generalized gamma in (4) depends on three parameters and therefore offers greater flexibility in statistical model fitting. However, as proven above, the generalized gamma also follows from first principle and provides accurate fits across a wide variety of underlying network topologies, while the Gamma and the Weibull distribution apply to particular types of networks only. In turn and probably most important, the traditional reliance of investigating several distributions can be eliminated. Moreover, as we will demonstrate below, even without regularization, which is an interesting avenue for

future work, the parameters of the generalized Gamma indeed allow one to distinguish different graph classes.

**Spreading Processes.** Given the synthetic networks created above, we simulated *SIR* spreading processes where the infection rate varied in  $i \in \{0.5, 0.6, \dots, 0.9\}$  and the recovery rate was chosen from  $r \in \{0.5, 0.6, \dots, 0.9\}$ . For each network and each choice of  $i$  and  $r$ , we created 10 epidemics starting at randomly selected source nodes  $v_s$  and fitted the generalized Gamma to the resulting outbreak data.

Table 2 shows exemplary results obtained for PL graphs of 10,000 nodes; rows correspond to different power law exponents  $\gamma$  and columns indicate different choices of pairs  $(i, r)$ . Each panel plots the outbreak data of all the corresponding epidemics (grey dots), the corresponding empirical average taken over the individual outbreak distributions (black dots), as well as a generalized Gamma fit to these averages (blue curves). Visual inspection of these results suggests that the generalized Gamma distribution accounts very well for average outbreak dynamics in power law graphs. Though not shown in the table, this behavior was also observed for individual epidemics as well as for epidemics on other networks, hence, supporting our theoretical justification provided in Sec. 3.2.

**Real-World Networks.** The KONECT network collection [23] provides a comprehensive set of large scale, real-world network data freely available for research. Networks contained in this collection comprise (online) social networks where edges indicate social contacts or friendship relations, natural networks such as power grids or connections between airports, and bipartite networks such as typically found in the context of recommender systems. The sizes of these networks vary between  $O(10,000)$  to  $O(1,000,000)$  nodes and they show different node degree distributions and clustering coefficients. For further details, we refer to <http://konect.uni-koblenz.de/>.

Tables 3 through 5 summarize goodness-of-fit results obtained from fitting the models in (1), (2), (3), and (4) to hop count distributions of social, natural, and bipartite networks respectively. Again in agreement with the theoretical prediction in [35], we observe that the Gamma distribution provides accurate fits to path length distributions in social networks which are often reported to be power law networks with power law exponents  $2 < \gamma < 3$ . For the case of natural and bipartite networks, we find the LogNormal distribution to provide better fits than the Gamma or the Weibull distribution. We emphasize that this is an empirical finding which, to our knowledge, has not yet been justified theoretically. In this sense, the work presented in this paper can be seen as the first such justification because the LogNormal is obtained a limiting case of the generalized Gamma distribution which, as shown in Sec. 3.1, provides a physically plausible model of distance distributions in networks. In fact, just as in the previous subsections, the

generalized Gamma distribution is again found to provide the best overall fits to the data considered here. Qualitative examples of this behavior are shown in Fig. 7.

We also evaluated how the different distributions perform in predicting the average shortest path length and compared empirical means to the means of fitted models. For the Weibull, the mean is given by  $\lambda\Gamma(1 + 1/\kappa)$ , the mean of the Gamma is  $\eta\theta$ , that of the LogNormal is  $\exp(\mu - \xi^2/2)$ , and for the generalized Gamma we have  $\mathbb{E}\{t\} = \sigma \frac{\Gamma((\alpha+1)/\beta)}{\Gamma(\alpha/\beta)}$ . Using these formulas, we investigated predicted average shortest path lengths versus empirically determined ones for the networks in the KONECT collection. The results are summarized in Tab. 6, which lists mean squared square errors for the data in the figure. They suggests that w.r.t. predicting average path lengths, the Weibull performs worse

Table 6: Mean squared errors for predicted average shortest path lengths versus empirically determined ones for the networks in the KONECT collection.

|           | $f_{WB}$ | $f_{GA}$ | $f_{LN}$ | $f_{GG}$ |

| overall   | 1.745    | 1.479    | 1.303    | 0.478    |

than the Gamma which performs worse than the LogNormal which is outperformed by the generalized Gamma.

**Distinguishing between Different Graph Classes.** An interesting consequence of fitting the distance distribution using the three-parameter generalized Gamma is that it provides a non-linear mapping of path length data into three dimensions. This allows for visual analytics of the behavior of different graph topologies w.r.t. distance distributions. Fig. 8 shows exemplary distance distributions in terms 3D coordinates  $(\sigma, \alpha, \beta)$  that result from fitting generalized Gamma distributions. Looking at the Figure, it appears that distance distributions obtained from different network topologies cluster together or are confined to certain regions in this parameter space. These preliminary observations are arguably the most interesting finding in this paper as they suggest that the idea of characterizing networks in terms of continuous models of shortest path distributions can inform approaches to the problem of network inference from outbreak data. Investigating these results more deeply provides an interesting avenue for future work.

## 5 CONCLUSIONS

We considered the problem of parameterizing the distance distribution and epidemic outbreak data of strongly-connected, undirected networks. Invoking the maxi-

Figure 7: Qualitative examples of shortest path distributions on real-world networks. Path length distributions of social and natural networks are well accounted for by the Gamma distribution (a+b) whereas the Weibull provides better fits for bipartite networks that occur in recommender settings (c). In each case, however, the generalized Gamma fits best.

mum entropy principle, we showed that the generalized Gamma distribution provides a physically plausible, three-parameter distribution for these data, independent of the topology of the underlying networks. This result generalizes earlier models [7, 35] and explains recent empirical observations made w.r.t. twitter retweet networks [8]. Empirical tests confirmed our theoretical prediction and revealed that the generalized Gamma distribution accounts well for distance distributions of synthesized Erdős-Rényi, Barabási-Albert, power law, and LogNormal graphs as well as for real-world network in the KONECT collection [23]. Finally, we illustrated that the parameters of the generalized Gamma provide striking structural regularities in the resulting low-dimensional network representations.

Our results suggest several attractive avenues for future research. First of all, one should relate the shape and scale parameters of the generalized Gamma distribution to physical properties or well established features of networks. Second, one should use our theoretical results to devised informed sampling schemes for the problem of computing shortest paths (and their histograms) for large real-world networks. Finally, the results in Fig. 8 suggest a nearest-neighbour approach to network inference from outbreak data. Newly observed epidemic processes are matched to a large data base of 3D representations of outbreak data, for which the network is known; at least this provides helpful prior information for network inference approaches such as [32, 22].

## Abstract

We show new limits on the efficiency of using current techniques to make exact probabilistic inference for large classes of natural problems. In particular we show new lower bounds on knowledge compilation to SDD and DNNF forms. We give strong lower bounds on the complexity of SDD representations by relating SDD size to best-partition communication complexity. We use this relationship to prove exponential lower bounds on the SDD size for representing a large class of problems that occur naturally as queries over probabilistic databases. A consequence is that for representing unions of conjunctive queries, SDDs are not qualitatively more concise than OBDDs. We also derive simple examples for which SDDs must be exponentially less concise than FBDDs. Finally, we derive exponential lower bounds on the sizes of DNNF representations using a new quasipolynomial simulation of DNNFs by nondeterministic FBDDs.

## 1 Introduction

Weighted model counting is a fundamental problem in probabilistic inference that captures the computation of probabilities of complex predicates over independent random events (Boolean variables). Although the problem is  $\#P$ -hard in general, there are a number of practical algorithms for model counting based on DPLL algorithms and on knowledge compilation techniques. The knowledge compilation approach, though more space intensive, can be much more convenient since it builds a representation for an input predicate independent of its weights that allows the count to be evaluated easily given a particular choice of weights; that representation also can be reused to analyze more complicated predicates. Moreover,

with only a constant-factor increase in time, the methods using DPLL algorithms can be easily extended to be knowledge compilation algorithms [Huang and Darwiche, 2007]. (See [Gomes et al., 2009] for a survey.)

The representation to be used for knowledge compilation is an important key to the utility of these methods in practice; the best methods are based on restricted classes of circuits and on decision diagrams. All of the ones considered to date can be seen as natural sub-classes of the class of *Decomposable Negation Normal Form (DNNF)* formulas/circuits introduced in [Darwiche, 2001], though it is not known how to do model counting efficiently for the full class of DNNF formulas/circuits. One sub-class for which model counting is efficient given the representation is that of *d-DNNF* formulas, though there is no efficient algorithm known to recognize whether a DNNF formula is d-DNNF.

A special case of d-DNNF formulas (with a minor change of syntax) that is easy to recognize is that of *decision-DNNF* formulas. This class of representations captures all of the practical model counting algorithms discussed in [Gomes et al., 2009] including those based on DPLL algorithms. Decision-DNNFs include *Ordered Binary Decision Diagrams (OBDDs)*, which are canonical and have been highly effective representations for verification, and also *Free BDDs (FBDDs)*, which are also known as read-once branching programs. Using a quasipolynomial simulation of decision-DNNFs by FBDDs, [Beame et al., 2013, Beame et al., 2014] showed that the best decision-DNNF representations must be exponential even for many very simple 2-DNF predicates that arise in probabilistic databases.

Recently, [Darwiche, 2011] introduced another subclass of d-DNNF formulas called *Sentential Decision Diagrams (SDDs)*. This class is strictly more general than OBDDs and (in its basic form) is similarly canonical. (OBDDs use a fixed ordering of variables, while SDDs use a fixed binary tree of variables, known as a *vtree*.) There has been substantial development and growing application of SDDs to knowledge representation problems, including a recently released SDD software package [SDD, 2014]. In-

deed, SDDs hold potential to be more concise than OBDDs. [Van den Broeck and Darwiche, 2015] showed that *compressing* an SDD with a fixed vtree so that it is canonical can lead to an exponential blow-up in size, but much regarding the complexity of SDD representations has remained open.

In this paper we show the limitations both of general DNNFs and especially of SDDs. We show that the simulation of decision-DNNFs by FBDDs from [Beame et al., 2013] can be extended to yield a simulation of general DNNFs by OR-FBDDs, the nondeterministic extension of FBDDs, from which we can derive exponential lower bounds for DNNF representations of some simple functions.

For SDDs we obtain much stronger results. In particular, we relate the SDD size required to represent predicate  $f$  to the “best-case partition” communication complexity [Kushilevitz and Nisan, 1997] of  $f$ . Using this, together with reductions to the communication complexity of disjointness (set intersection), we derive the following results:

- (1) There are simple predicates given by 2-DNF formulas for which FBDD size is polynomial but for which SDD size must be exponential.
- (2) For a natural, widely-studied class of database queries known as *Unions of Conjunctive Queries (UCQ)*, the SDD size is linear iff the OBDD size is linear and is exponential otherwise (which corresponds to a query that contains an *inversion* [Jha and Suciu, 2013]).
- (3) Similar lower bounds apply to the dual of UCQ, which consists of universal, positive queries.

To prove our SDD results, we show that for any predicate  $f$  given by an SDD of size  $S$ , using its associated vtree we can partition the variables of  $f$  between two players, Alice and Bob, in a nearly balanced way so that they only need to send  $\log^2 S$  bits of communication to compute  $f$ . The characterization goes through an intermediate step involving *unambiguous* communication protocols and a clever deterministic simulation of such protocols from [Yannakakis, 1991].

*Related work:* Beyond the lower bounds for decision-DNNFs in [Beame et al., 2013, Beame et al., 2014] which give related analyses for decision-DNNFs, the work of [Pipatsrisawat and Darwiche, 2010] on structured DNNFs is particularly relevant to this paper<sup>1</sup>. [Pipatsrisawat and Darwiche, 2010] show how sizes of what they term (*deterministic*)  $\mathbf{X}$ -*decompositions* can yield lower bounds on the sizes of *structured (deterministic)* DNNFs, which include SDDs as a special case. [Pipatsrisawat, 2010] contains the full details of how this can be applied to prove lower bounds for specific predicates. These bounds are actually equivalent to lower

<sup>1</sup>We thank the conference reviewers for bringing this work to our attention.

bounds exponential in the best-partition nondeterministic (respectively, unambiguous) communication complexity of the given predicates. Our paper derives this lower bound for SDDs directly but, more importantly, provides the connection to best-partition *deterministic* communication complexity, which allows us to have a much wider range of application; this strengthening is necessary for our applications.

**Roadmap:** We give the background and some formal definitions including some generalization required for this work in Section 2. We prove our characterization of SDDs in terms of best-partition communication complexity in Section 3 and derive the resulting bounds for SDDs for natural predicates in Section 4. We describe the simulation of DNNFs by OR-FBDDs, and its consequences, in Section 5.

## 2 Background and Definitions

We first give some basic definitions of DNNFs and decision diagrams.

**Definition 2.1.** A Negation Normal Form (NNF) *circuit* is a Boolean circuit with  $\neg$  gates, which may only be applied to inputs, and  $\vee$  and  $\wedge$  gates. Further, it is Decomposable (DNNF) iff the children of each  $\wedge$  gate are reachable from disjoint sets of input variables. (Following convention, we call this circuit a “DNNF formula”, though it is not a Boolean formula in the usual sense of circuit complexity.) A DNNF formula is deterministic (d-DNNF) iff the functions computed at the children of each  $\vee$  gate are not simultaneously satisfiable.

**Definition 2.2.** A Free Binary Decision Diagram (FBDD) is a directed acyclic graph with a single source (the root) and two specified sink nodes, one labeled 0 and the other 1. Every non-sink node is labeled by a Boolean variable and has two out-edges, one labeled 0 and the other 1. No path from the root to either sink is labeled by the same variable more than once. It is an OBDD if the order of variable labels is the same on every path. The Boolean function computed by an FBDD is 1 on input  $\mathbf{a}$  iff there is a path from the root to the sink labeled 1 so that for every node label  $X_i$  on the path,  $\mathbf{a}_i$  is the label of the out-edge taken by the path. An OR-FBDD is an FBDD augmented with additional nodes of arbitrary fan-out labeled  $\vee$ . The function value for the OR-FBDD follows the same definition as for FBDDs; the  $\vee$ -nodes simply make more than one path possible for a given input. (See [Wegener, 2000].)

We now define sentential decision diagrams as well as a small generalization that we will find useful.

**Definition 2.3.** For a set  $\mathbf{X}$ , let  $\top : \{0, 1\}^{\mathbf{X}} \rightarrow \{0, 1\}$  and  $\perp : \{0, 1\}^{\mathbf{X}} \rightarrow \{0, 1\}$  denote the constant 1 function and constant 0 function, respectively.

**Definition 2.4.** We say that a set of Boolean functions  $\{p_1, p_2, \dots, p_\ell\}$ , where each  $p_i$  has domain  $\{0, 1\}^{\mathbf{X}}$ , is dis-

joint if for each  $i \neq j$ ,  $p_i \wedge p_j = \perp$ . We call  $\{p_1, p_2, \dots, p_\ell\}$  a partition if it is disjoint and  $\bigvee_{i=1}^{\ell} p_i = \top$ .

**Definition 2.5.** A vtree for variables  $\mathbf{X}$  is a full binary tree whose leaves are in one-to-one correspondence with the variables in  $\mathbf{X}$ .

We define *Sentential Decision Diagrams* (SDDs) together with the Boolean functions they represent and use  $\langle \cdot \rangle$  to denote the mapping from SDDs to Boolean functions. (This notation is extended to sets of SDDs yielding sets of Boolean functions.) At the same time, we also define a directed acyclic graph (DAG) representation of the SDD.

**Definition 2.6.**  $\alpha$  is an SDD that respects vtree  $\mathbf{v}$  rooted at  $v$  iff:

- $\alpha = \top$  or  $\alpha = \perp$ .  
Semantics:  $\langle \top \rangle = \top$  and  $\langle \perp \rangle = \perp$ .  
 $G(\alpha)$  consists of a single leaf node labeled with  $\langle \alpha \rangle$ .
- $\alpha = X$  or  $\alpha = \neg X$  and  $v$  is a leaf with variable  $X$ .  
Semantics:  $\langle X \rangle = X$  and  $\langle \neg X \rangle = \neg X$   
 $G(\alpha)$  consists of a single leaf node labeled with  $\langle \alpha \rangle$ .
- $\alpha = \{(p_1, s_1), \dots, (p_\ell, s_\ell)\}$ ,  $v$  is an internal vertex with children  $v_L$  and  $v_R$ ,  $p_1, \dots, p_\ell$  are SDDs that respect the subtree rooted at  $v_L$ ,  $s_1, \dots, s_\ell$  are SDDs that respect the subtree rooted at  $v_R$ , and  $\langle p_1 \rangle, \dots, \langle p_\ell \rangle$  is a partition.  
Semantics:  $\langle \alpha \rangle = \bigvee_{i=1}^{\ell} (\langle p_i \rangle \wedge \langle s_i \rangle)$   
 $G(\alpha)$  has a circle node for  $\alpha$  labeled  $v$  with  $\ell$  child box nodes labeled by the pairs  $(p_i, s_i)$ . A box node labeled  $(p_i, s_i)$  has a left child that is the root of  $G(p_i)$  and a right child that is the root of  $G(s_i)$ . The rest of  $G(\alpha)$  is the (non-disjoint) union of graphs  $G(p_1), \dots, G(p_\ell)$  and  $G(s_1), \dots, G(s_\ell)$  with common sub-DAGs merged. (See Figure 1.)

Each circle node  $\alpha'$  in  $G(\alpha)$  itself represents an SDD that respects a subtree of  $\mathbf{v}$  rooted at some vertex  $v'$  of  $\mathbf{v}$ ; We say that  $\alpha'$  is in  $\alpha$  and use  $\text{Sdds}(v', \alpha)$  to denote the collection of  $\alpha'$  in  $\alpha$  that respect the subtree rooted at  $v'$ . The size of an SDD  $\alpha$  is the number of nodes in  $G(\alpha)$ .

Circle nodes in  $G(\alpha)$  may be interpreted as OR gates and paired box nodes may be interpreted as AND gates. In the rest of this paper, we will view SDDs as a class of Boolean circuit. The vtree property and partition property of SDDs together ensure that this resulting circuit is a d-DNNF.

We define a small generalization of vtrees which will be useful for describing SDDs with respect to a partial assignment of variables.

**Definition 2.7.** A pruned vtree for variables  $\mathbf{X}$  is a full binary tree whose leaves are either marked stub or by a variable in  $\mathbf{X}$ , and whose leaves marked by variables are in one-to-one correspondence with the variables in  $\mathbf{X}$ .

Figure 1: An SDD with its associated vtree that computes the formula  $(A \wedge B \wedge C) \vee (\neg C \wedge D)$

We generalize SDDs so that they can respect pruned vtrees. The definition is almost identical to that for regular SDDs so we only point out the differences.

**Definition 2.8.** The definition of a pruned SDD  $\alpha$  respecting a pruned vtree  $\mathbf{v}$ , its semantics, and its graph  $G(\alpha)$ , are identical to those of an SDD except that

- if the root vertex  $v$  of  $\mathbf{v}$  is a stub then  $\langle \alpha \rangle$  must be  $\perp$  or  $\top$ , and
- if the root vertex  $v$  of  $\mathbf{v}$  is internal then we only require that  $\langle p_1 \rangle, \dots, \langle p_\ell \rangle$  are disjoint but not necessarily that they form a partition.

We now sketch a very brief overview of the communication complexity we will need. Many more details may be found in [Kushilevitz and Nisan, 1997]. Given a Boolean function  $f$  on  $\{0, 1\}^{\mathbf{X}} \times \{0, 1\}^{\mathbf{Y}}$ , one can define two-party protocols in which two players, Alice, who receives  $x \in \{0, 1\}^{\mathbf{X}}$  and Bob, who receives  $y \in \{0, 1\}^{\mathbf{Y}}$  exchange a sequence of messages  $m_1, \dots, m_C = f(x, y) \in \{0, 1\}$  to compute  $f$ . (After each bit, the player to send the next bit must be determined from previous messages.) The (deterministic) communication complexity of  $f$ ,  $CC(f(\mathbf{X}, \mathbf{Y}))$ , is the minimum value  $C$  over all protocols computing  $f$  such that all message sequences are of length at most  $C$ . The one-way deterministic communication complexity of  $f$ ,  $CC_{\mathbf{X} \rightarrow \mathbf{Y}}(f(\mathbf{X}, \mathbf{Y}))$  is the minimum value of  $C$  over all protocols where Alice may send messages to Bob, but Bob cannot send messages to Alice.

For nondeterministic protocols, Alice simply guesses a string based on her input  $x$  and sends the resulting message  $m$  to Bob, who uses  $m$  together with  $y$  to verify whether or not  $f(x, y) = 1$ . The communication complexity in this case is the minimum  $|m|$  over all protocols. Such a protocol is *unambiguous* iff for each  $(x, y)$  pair such that  $f(x, y) = 1$  there is precisely one message  $m$  that will cause Bob to output 1. A set of the form  $A \times B$  for  $A \subseteq \{0, 1\}^{\mathbf{X}}$ ,  $B \subseteq \{0, 1\}^{\mathbf{Y}}$  is called a *rectangle*. The minimum of  $|m|$  over all unambiguous protocols is the *unambiguous communication complexity* of  $f$ ; it is known to be the logarithm base 2 of the minimum number of rectangles into which one can partition the set of inputs on which  $f$  is 1.

A canonical hard problem for communication complexity is the two-party disjointness (set intersection) problem,

$\bigvee_{i=1}^n x_i \wedge y_i$  where  $x$  and  $y$  are indicator vectors of sets in  $[n]$ . It has deterministic communication complexity  $n + 1$  (and requires  $\Omega(n)$  bits be sent even with randomness, but that is beyond what we need). We will need a variant of the “best partition” version of communication complexity in which the protocol includes a choice of the best split of input indices  $\mathbf{X}$  and  $\mathbf{Y}$  between Alice and Bob.

A typical method for proving lower bounds on OBDD size for a Boolean function  $f$  begins by observing that a size  $s$  OBDD may be simulated by a  $\log s$ -bit one-way communication protocol where Alice holds the first half of the variables read by the OBDD and Bob holds the second half. In this protocol, Alice starts at the root of the OBDD and follows the (unique) OBDD path determined by her half of the input until she reaches a node  $v$  querying a variable held by Bob. She then sends the identity of the node  $v$  to Bob, who can finish the computation starting from  $v$ . Thus, if we show that  $f$  has one-way communication complexity  $CC_{\mathbf{X} \rightarrow \mathbf{Y}}(f(\mathbf{X}, \mathbf{Y}))$  at least  $C$  in the best split  $\{\mathbf{X}, \mathbf{Y}\}$  of its input variables, then any OBDD computing  $f$  must have at least  $2^C$  nodes.

Our lower bound for SDDs uses related ideas but in a more sophisticated way, and instead of providing a one-way deterministic protocol, we give an unambiguous protocol that simulates the SDD computation. In particular, the conversion to deterministic protocols requires two-way communication.

### 3 SDDs and Best-Partition Communication Complexity

In this section, we show how we can use any small SDD representing a function  $f$  to build an efficient communication protocol for  $f$  given an approximately balanced partition of input variables that is determined by its associated vtree. As a consequence, any function requiring large communication complexity under all such partitions requires large SDDs. To begin this analysis, we consider how an SDD simplifies under a partial assignment to its input variables.

#### 3.1 Pruning SDDs Using Restrictions

**Definition 3.1.** Suppose that  $\mathbf{v}$  is a pruned vtree for a set of variables  $\mathbf{X}$ , and that  $v$  is a vertex in  $\mathbf{v}$ . Let  $\text{Vars}(v)$  denote the set of variables that are descendants of  $v$  in  $\mathbf{v}$  and  $\text{Shell}(v) = \mathbf{X} \setminus \text{Vars}(v)$ . Also let  $\text{Parent}(v)$  denote the (unique) vertex in  $\mathbf{v}$  that has  $v$  as a child.

We define a construction to capture what happens to an SDD under a partial assignment of its variables.

**Definition 3.2.** Let  $\alpha$  be an SDD that respects  $\mathbf{v}$ , a vtree for the variables  $\mathbf{X}$ , and suppose that  $\alpha$  computes the function  $f$ . Let  $\mathbf{B} \subseteq \mathbf{X}$  and  $\mathbf{A} = \mathbf{X} \setminus \mathbf{B}$  and let  $\rho : \mathbf{A} \rightarrow \{0, 1\}$  be

an assignment to the variables in  $\mathbf{A}$ . Let  $\alpha|_{\rho}$  be Boolean circuit remaining after plugging the partial assignment  $\rho$  into the SDD  $\alpha$  and making the following simplifications:

1. If a gate computes a constant  $c \in \{\top, \perp\}$  under the partial assignment  $\rho$ , we can replace that gate and its outgoing edges with  $c$ .
2. Remove any children of OR-gates that compute  $\perp$ .
3. Remove any nodes disconnected from the root.

For each vtree vertex  $v \in \mathbf{v}$  that was not removed in this process, we denote its counterpart in the pruned vtree  $\mathbf{v}|_{\mathbf{A}}$  by  $v|_{\mathbf{A}}$ .

Construct the pruned vtree  $\mathbf{v}|_{\mathbf{A}}$  from  $\mathbf{v}$  as follows: for each vertex  $v$ , if  $\text{Vars}(v) \subseteq \mathbf{A}$  and  $\text{Vars}(\text{Parent}(v)) \not\subseteq \mathbf{A}$ , replace  $v$  and its subtree by a stub. We say that we have pruned the subtree rooted at  $v$ .

For  $\mathbf{A} \subseteq \mathbf{X}$ , we call  $\{\mathbf{A}, \mathbf{X} \setminus \mathbf{A}\}$  a shell partition for  $\mathbf{X}$  if there is a vtree vertex  $v \in \mathbf{v}$  such that  $\text{Shell}(v) = \mathbf{A}$ . We call  $\mathbf{A}$  the shell. If, for a restriction  $\rho : \mathbf{A} \rightarrow \{0, 1\}$ , there exists a vtree vertex  $v \in \mathbf{v}$  such that  $\text{Shell}(v) = \mathbf{A}$ , we call  $\rho$  a shell restriction.

**Proposition 3.3.** Let  $\alpha$  be an SDD that respects  $\mathbf{v}$ , a vtree for the variables  $\mathbf{X}$ , and suppose that  $\alpha$  computes the function  $f$ . Let  $\mathbf{A} \subseteq \mathbf{X}$  and  $\rho : \mathbf{A} \rightarrow \{0, 1\}$  be a partial assignment of the variables in  $\mathbf{A}$ . The pruned SDD  $\alpha|_{\rho}$  has the following properties:

- (a)  $\langle \alpha|_{\rho} \rangle = f|_{\rho}$ .
- (b)  $\alpha|_{\rho}$  is a pruned SDD respecting  $\mathbf{v}|_{\mathbf{A}}$ .
- (c)  $G(\alpha|_{\rho})$  is a subgraph of  $G(\alpha)$ .

*Proof.* (a): An SDD may be equivalently described as a Boolean circuit of alternating OR and AND gates. For any Boolean circuit in the variables  $\mathbf{X}$  that computes  $f$ , plugging in the values for the restriction  $\rho$  yields a circuit com-

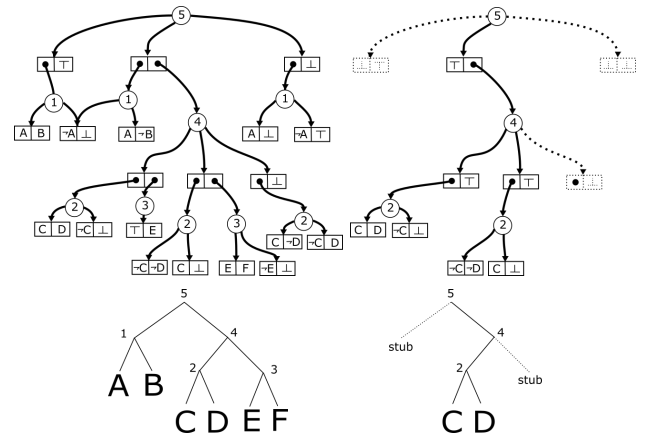

Figure 2: An SDD and its vtree, as well as the pruned pair after setting  $B$  to 0 and  $A, E, F$  to 1.

puting  $f|_\rho$ . Furthermore, the simplification steps do not change the function computed.

(b): For each  $v$  such that  $\text{Vars}(v) \subseteq \mathbf{A}$  and  $\text{Vars}(\text{Parent}(v)) \not\subseteq \mathbf{A}$ , we have replaced the subtree rooted at  $v$  by a stub and replaced the SDDs in  $\alpha$  respecting  $v$  by either  $\top$  or  $\perp$ . Thus  $\alpha|_\rho$  respects  $\mathbf{v}|_\mathbf{A}$ .

We now check that  $\alpha|_\rho$  is a pruned SDD. In particular we need to ensure that for each SDD  $\alpha' = \{(p_1, s_1), \dots, (p_\ell, s_\ell)\}$  in  $\alpha$ , the corresponding pruned SDDs that remain from  $p_1, \dots, p_\ell$  in its pruned counterpart  $\alpha'|_\rho$  represent a collection of disjoint functions. From the first part of this proposition, these are  $\langle p_{i_1} \rangle|_\rho, \dots, \langle p_{i_k} \rangle|_\rho$  for some  $k \leq n$ , where we have only included those SDDs that are consistent under  $\rho$ . Since the original set of SDDs was a partition and thus disjoint, this set of restricted (pruned) SDDs is also disjoint.

(c): The process in Definition 3.2 only removes nodes from  $G(\alpha)$  to construct  $G(\alpha|_\rho)$ . Further, it does not change the label of any SDD that was not removed.  $\square$

### 3.2 Unambiguous Communication Protocol for SDDs

The way that we will partition the input variables to an SDD between the parties Alice and Bob in the communication protocol will respect the structure of its associated vtree. The restrictions will correspond to assignments that reflect Alice's knowledge of the input and will similarly respect that structure.

Notice that a vtree cut along an edge  $(u, v)$  (where  $u$  is the parent of  $v$ ) induces a shell partition for  $\mathbf{X}$  consisting of the set  $\mathbf{B} = \text{Vars}(v)$ , and the shell  $\mathbf{A} = \mathbf{X} \setminus \mathbf{B}$ .

**Proposition 3.4.** *Let  $\alpha$  be an SDD of size  $s$  computing a function  $f : \{0, 1\}^{\mathbf{X}} \rightarrow \{0, 1\}$  that respects a vtree  $\mathbf{v}$ . Suppose that  $\{\mathbf{A}, \mathbf{B}\}$  is a shell partition for  $\mathbf{X}$  and that  $\mathbf{A}$  is its shell. Let  $b$  be the vertex in  $\mathbf{v}$  for which  $\text{Vars}(b) = \mathbf{B}$  and  $\text{Vars}(\text{Parent}(b)) \not\subseteq \mathbf{B}$ .*

*For any shell restriction  $\rho : \mathbf{A} \rightarrow \{0, 1\}$ , the set  $\langle \text{Sdds}_{\alpha|_\rho}(b|_\mathbf{A}) \rangle$  is a disjoint collection of functions.*

*Proof.* For non-shell restrictions  $\rho'$ , the collection of functions  $\langle \text{Sdds}_{\alpha|_{\rho'}}(v) \rangle$  for a vtree node  $v$  is not disjoint; we need to use the specific properties of  $\mathbf{A}$  and  $b$ . Since  $\rho$  was a shell restriction, the pruned vtree  $\mathbf{v}|_\mathbf{A}$  takes the form of a path  $v_1|_\mathbf{A}, \dots, v_k|_\mathbf{A}$  of internal vertices, where  $v_1$  is the root of  $\mathbf{v}$ , and  $v_k|_\mathbf{A} = b|_\mathbf{A}$ , with the other child of each of  $v_1|_\mathbf{A}, \dots, v_{k-1}|_\mathbf{A}$  being a stub, together with a vtree for the variables  $\mathbf{B}$  rooted at  $b$ . We will show that if  $\langle \text{Sdds}_{\alpha|_\rho}(v_i|_\mathbf{A}) \rangle$  is disjoint then so is  $\langle \text{Sdds}_{\alpha|_\rho}(v_{i+1}|_\mathbf{A}) \rangle$ . This will prove the proposition since  $\langle \text{Sdds}_{\alpha|_\rho}(v_1|_\mathbf{A}) \rangle$  only contains the function  $\langle \alpha|_\rho \rangle$  and is therefore trivially disjoint.

We will use the fact that every pruned-SDD from

$\text{Sdds}_{\alpha|_\rho}(v_{i+1}|_\mathbf{A})$  is contained in some SDD from  $\text{Sdds}_{\alpha|_\rho}(v_i|_\mathbf{A})$ . We have two cases to check:  $v_{i+1}|_\mathbf{A}$  is either a left child or a right child of  $v_i|_\mathbf{A}$ .

If  $v_{i+1}|_\mathbf{A}$  was a right child then each pruned-SDD  $\eta|_\rho$  contained in  $\text{Sdds}_{\alpha|_\rho}(v_i|_\mathbf{A})$  takes the form  $\eta|_\rho = \{(\top, s|_\rho)\}$ . Then  $\langle \text{Sdds}_{\alpha|_\rho}(v_{i+1}|_\mathbf{A}) \rangle = \langle \text{Sdds}_{\alpha|_\rho}(v_i|_\mathbf{A}) \rangle$  and is therefore disjoint by assumption.

Otherwise suppose that  $v_{i+1}|_\mathbf{A}$  is the left child of  $v_i|_\mathbf{A}$ . Let  $\eta|_\rho \in \text{Sdds}_{\alpha|_\rho}(v_i|_\mathbf{A})$ . Let  $\eta|_\rho = \{(\eta_1|_\rho, \top), \dots, (\eta_k|_\rho, \top)\}$  where  $\bigvee_{i=1}^k \langle \eta_i|_\rho \rangle = \langle \eta|_\rho \rangle$  and  $\{\langle \eta_1|_\rho \rangle, \dots, \langle \eta_k|_\rho \rangle\}$ , being a collection of primes for  $\eta|_\rho$ , is disjoint. By assumption  $\langle \text{Sdds}_{\alpha|_\rho}(v_i|_\mathbf{A}) \rangle$  is disjoint, so for any other  $\eta'|_\rho = \{(\eta'_1|_\rho, \top), \dots, (\eta'_{k'}|_\rho, \top)\} \in \text{Sdds}_{\alpha|_\rho}(v_i|_\mathbf{A})$  distinct from  $\eta|_\rho$ , we have  $\langle \eta|_\rho \rangle \wedge \langle \eta'|_\rho \rangle = \perp$ . Then for any  $i \in [k]$  and  $j \in [k']$ , we have  $\langle \eta_i|_\rho \rangle \wedge \langle \eta'_j|_\rho \rangle = \perp$ . Thus  $\langle \text{Sdds}_{\alpha|_\rho}(v_{i+1}|_\mathbf{A}) \rangle$  is disjoint.  $\square$

**Theorem 3.5.** *Let  $\alpha$  be an SDD of size  $s$  that respects a vtree  $\mathbf{v}$  and suppose that it computes the function  $f : \{0, 1\}^{\mathbf{X}} \rightarrow \{0, 1\}$ . Suppose that  $\{\mathbf{A}, \mathbf{B}\}$  is a shell partition for  $\mathbf{X}$  and that  $\mathbf{A}$  is the shell. Let  $b$  be the vertex in  $\mathbf{v}$  for which  $\text{Vars}(b) = \mathbf{B}$  and  $\text{Vars}(\text{Parent}(b)) \not\subseteq \mathbf{B}$ .*

*Consider the communication game where Alice has the variables  $\mathbf{A}$ , Bob has the variables  $\mathbf{B}$ , and they are trying to compute  $f(\mathbf{A}, \mathbf{B})$ . There is a  $\log s$ -bit unambiguous communication protocol computing  $f$ .*

*Proof.* Suppose that Alice and Bob both know the SDD  $\alpha$ . Let  $\rho : \mathbf{A} \rightarrow \{0, 1\}$  be the partial assignment corresponding to Alice's input. This is a shell restriction. Alice may then privately construct the pruned SDD  $\alpha|_\rho$ , which computes  $f|_\rho$  by Proposition 3.3. Further,  $\alpha|_\rho$  evaluates to 1 under Bob's input  $\phi : \mathbf{B} \rightarrow \{0, 1\}$  if and only if there exists a pruned-SDD  $\eta|_\rho \in \text{Sdds}_{\alpha|_\rho}(b|_\mathbf{A})$  such that  $\langle \eta|_\rho \rangle(\phi) = 1$ .

By Proposition 3.4,  $\langle \text{Sdds}_{\alpha|_\rho}(b|_\mathbf{A}) \rangle$  is disjoint. Also, since  $\rho$  is a shell restriction with shell  $\mathbf{A}$ , and  $\text{Vars}(b) = \mathbf{B} = \mathbf{X} \setminus \mathbf{A}$ , every SDD in  $\text{Sdds}_{\alpha|_\rho}(b|_\mathbf{A})$  was unchanged by  $\rho$ . In particular, this means that  $\text{Sdds}_{\alpha|_\rho}(b|_\mathbf{A}) \subseteq \text{Sdds}_\alpha(b)$  and any pruned-SDD  $\eta|_\rho$  can be viewed as some  $\eta \in \text{Sdds}_\alpha(b)$  that is also in  $\text{Sdds}_{\alpha|_\rho}(b|_\mathbf{A})$ .

For the protocol Alice nondeterministically selects an  $\eta$  from  $\text{Sdds}_{\alpha|_\rho}(b|_\mathbf{A})$  and then sends its identity as a member of  $\text{Sdds}_\alpha(b)$  to Bob. This requires at most  $\log s$  bits. Bob will output 1 on his input  $\phi$  if and only if  $\langle \eta \rangle(\phi) = 1$ , which he can test since he knows  $\alpha$  and  $b$ . This protocol is unambiguous since the fact that  $\langle \text{Sdds}_{\alpha|_\rho}(b|_\mathbf{A}) \rangle$  is disjoint means that for any input  $\phi$  to Bob there is at most one  $\eta \in \text{Sdds}_{\alpha|_\rho}(b|_\mathbf{A})$  such that  $\langle \eta \rangle(\phi) = 1$ . Since Bob knows  $\alpha$ , he also knows  $\eta$  and can therefore compute  $\langle \eta \rangle(\phi)$ . Since  $\alpha$  computes  $f$ , if  $\langle \eta \rangle(\phi) = 1$  then  $f(\phi, \rho) = 1$ . Otherwise all of the functions in  $\langle \text{Sdds}_{\alpha|_\rho}(b|_\mathbf{A}) \rangle$  evaluate to 0 on input  $\phi$  so  $f(\phi, \rho) = 0$ .  $\square$

We can relate the deterministic and unambiguous communication complexities of a function using the following result from [Yannakakis, 1991].

**Theorem 3.6** (Yannakakis). *If there is an  $g$ -bit unambiguous communication protocol for a function  $f : \{0, 1\}^{\mathbf{A}} \times \{0, 1\}^{\mathbf{B}} \rightarrow \{0, 1\}$ , then there is a  $(g+1)^2$ -bit deterministic protocol for  $f$ .*

The following  $1/3$ - $2/3$  lemma is standard.

**Lemma 3.7.** *For a vtree  $\mathbf{v}$  for  $L$  variables, if a vertex  $b$  satisfies  $\frac{1}{3}L \leq |\text{Vars}(b)| \leq \frac{2}{3}L$ , we call it a  $(1/3, 2/3)$  vertex. Every vtree contains a  $(1/3, 2/3)$  vertex.*

**Definition 3.8.** *Let  $\mathbf{X}$  be a set of variables and  $(\mathbf{A}, \mathbf{B})$  a partition of  $\mathbf{X}$ . We call the partition  $(\mathbf{A}, \mathbf{B})$  a  $(\delta, 1 - \delta)$ -partition for  $\delta \in [0, 1/2]$  if  $\min(|\mathbf{A}|, |\mathbf{B}|) \geq \delta|\mathbf{X}|$ . That is, the minimum size of one side of the partition is at least a  $\delta$ -fraction of the total number of variables.*

*The best  $(\delta, 1 - \delta)$ -partition communication complexity of a Boolean function  $f : \{0, 1\}^{\mathbf{X}} \rightarrow \{0, 1\}$  is  $\min(CC(f(\mathbf{A}, \mathbf{B})))$  where the minimum is taken over all  $(\delta, 1 - \delta)$ -partitions  $(\mathbf{A}, \mathbf{B})$ .*

**Theorem 3.9.** *If the best  $(1/3, 2/3)$ -partition communication complexity of a Boolean function  $f : \{0, 1\}^{\mathbf{X}} \rightarrow \{0, 1\}$  is  $C$ , then an SDD computing  $f$  has size at least  $2^{\sqrt{C}-1}$ .*

*Proof.* Suppose that  $\alpha$  is an SDD of size  $s$  respecting the vtree  $\mathbf{v}$  for variables  $\mathbf{X}$ , and that  $\alpha$  computes  $f$ . From Lemma 3.7 the vtree  $\mathbf{v}$  contains a  $(1/3, 2/3)$  vertex  $b$ . This  $(1/3, 2/3)$  vertex  $b$  induces a  $(1/3, 2/3)$ -partition of the variables  $\{\mathbf{A}, \mathbf{B}\}$  where  $\mathbf{B} = \text{Vars}(b)$  and  $\mathbf{A} = \text{Shell}(b)$ . Further, this partition  $\{\mathbf{A}, \mathbf{B}\}$  is a shell partition. By Theorem 3.5, there exists a  $\log s$ -bit unambiguous communication protocol for  $f(\mathbf{A}, \mathbf{B})$ . Then by Theorem 3.6, there exists a  $(\log(s) + 1)^2$ -bit deterministic communication protocol for  $f(\mathbf{A}, \mathbf{B})$ . Since the best  $(1/3, 2/3)$ -partition communication complexity of  $f$  is  $C$ , we have that  $C \leq (\log(s) + 1)^2$  which implies that  $s \geq 2^{\sqrt{C}-1}$  as stated.  $\square$

## 4 Lower Bounds for SDDs

There are a large number of predicates  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  for which the  $(1/3, 2/3)$ -partition communication complexity is  $\Omega(n)$  and by Theorem 3.9 each of these requires SDD size  $2^{\Omega(\sqrt{n})}$ . The usual best-partition communication complexity is  $(1/2, 1/2)$ -partition communication complexity. For example, the function SHIFTEDEQ which takes as inputs  $x, y \in \{0, 1\}^n$  and  $z \in \{0, 1\}^{\lceil \log_2 n \rceil}$  and tests whether or not  $y = \text{SHIFT}(x, z)$  where  $\text{SHIFT}(x, z)$  is the cyclic shift of  $x$  by  $(z)_2$  positions. However, as is typical of these functions, the same proof which shows that the  $(1/2, 1/2)$ -partition communication complexity of SHIFTEDEQ is  $\Omega(n)$  also shows

that its  $(1/3, 2/3)$ -partition communication complexity is  $\Omega(n)$ . However, most of these functions are not typical of predicates to which one might want to apply weighted model counting. Instead we analyze SDDs for formulas derived from a natural class of database queries. We are able to characterize SDD size for these queries, proving exponential lower bounds for every such query that cannot already be represented in linear size by an OBDD. This includes an example of a query called  $Q_V$  for which FBDDs are polynomial size but the best SDD requires exponential size.

### 4.1 SDD Knowledge Compilation for Database Query Lineages

We analyze SDDs for a natural class of database queries called the *union of conjunctive queries (UCQ)*. This includes all queries given by the grammar

$$q ::= R(\mathbf{x}) \mid \exists x q \mid q \wedge q \mid q \vee q$$

where  $R(\mathbf{x})$  is an elementary relation and  $x$  is a variable. For each such query  $q$ , given an input database  $D$ , the query's *lineage*,  $\Phi_q^D$ , is a Boolean expression for  $q$  over Boolean variables that correspond to tuples in  $D$ . In general, one thinks of the query size as fixed and considers the complexity of query evaluation as a function of the size of the database. The following formulas are lineages (or parts thereof) of well-known queries that are fundamental for probabilistic databases [Dalvi and Suciu, 2012, Jha and Suciu, 2013] over a particular database  $D_0$  (called the *complete bipartite graph of size  $m$*  in [Jha and Suciu, 2013]):

$$H_0 = \bigvee_{i,j \in [m]} R_i S_{ij} T_j$$

$$Q_V = \bigvee_{i,j \in [m]} R_i S_{ij} \vee S_{ij} T_j \vee R_i T_j$$

$$H_1 = \bigvee_{i,j \in [m]} R_i S_{ij} \vee S_{ij} T_j$$

$$H_{k0} = \bigvee_{i \in [m]} R_i S_{ij}^1 \quad \text{for } k \geq 1$$

$$H_{k\ell} = \bigvee_{i,j \in [m]} S_{ij}^\ell S_{ij}^{\ell+1} \quad \text{for } 0 < \ell < k$$

$$H_{kk} = \bigvee_{i \in [m]} S_{ij}^k T_j \quad \text{for } k \geq 1.$$

(The corresponding queries are represented using lower case letters  $h_0, q_V, h_1, h_{k0}, \dots, h_{kk}$  and involve unary relations  $R$  and  $T$ , as well as binary relations  $S$  and  $S^k$ . For example,  $h_0 = \exists x_0 \exists y_0 R(x_0) S(x_0, y_0) T(y_0)$ .) The following lemma will be useful in identifying subformulas of the above query lineages that can be used to compute the set disjointness function.

**Proposition 4.1.** *Let the elements of  $[m] \times [m]$  be partitioned into two sets  $A$  and  $B$ , each of size at least  $\delta m^2$ . Let  $\text{Row}(i)$  denote  $\{i\} \times [m]$  and  $\text{Col}(j)$  denote  $[m] \times \{j\}$ . Define  $W_{\text{Row}} = \{i \in [m] \mid \emptyset \neq \text{Row}(i) \cap A \text{ and } \emptyset \neq \text{Row}(i) \cap B\}$ . That is,  $\text{Row}(i)$  for  $i \in W_{\text{Row}}$  is split into two nonempty pieces by the partition. Similarly, define  $W_{\text{Col}} = \{j \in [m] \mid \emptyset \neq \text{Col}(j) \cap A \text{ and } \emptyset \neq \text{Col}(j) \cap B\}$ . Then*

$$\max(|W_{\text{Row}}|, |W_{\text{Col}}|) \geq \sqrt{\delta} \cdot m.$$

*Proof.* Suppose that both  $|W_{\text{Row}}| < m$  and  $|W_{\text{Col}}| < m$ . By definition, if  $i \notin W_{\text{Row}}$  then one of  $A$  or  $B$  contains an entire row,  $\text{Row}(i)$ , say  $A$  without loss of generality. This implies that no column  $\text{Col}(j)$  is entirely contained in  $B$ . Since  $|W_{\text{Col}}| < m$ , there is some column  $\text{Col}(j)$  that is entirely contained in  $A$ . This in turn implies that  $B$  does not contain any full row. In particular, we have that  $A$  contains all rows in  $[m] \setminus W_{\text{Row}}$  and all columns in  $[m] \setminus W_{\text{Col}}$  and thus  $B \subseteq W_{\text{Row}} \times W_{\text{Col}}$  and so  $|B| \leq |W_{\text{Row}}| \cdot |W_{\text{Col}}|$ . By assumption,  $|B| \geq \delta m^2$ . Hence  $|W_{\text{Row}}| \cdot |W_{\text{Col}}| \geq \delta m^2$  and so  $\max\{|W_{\text{Row}}|, |W_{\text{Col}}|\} \geq \sqrt{\delta} \cdot m$ .  $\square$

**Theorem 4.2.** *For  $m \geq 6$ , the best  $(1/3, 2/3)$ -partition communication complexity of  $Q_V$ ,  $H_0$ , and of  $H_1$  is at least  $m/3$ .*

*Proof.* Let  $\mathbf{X}$  be the set of variables appearing in  $Q_V$  (or  $H_1$ ) and let  $(\mathbf{A}, \mathbf{B})$  be a  $(1/3, 2/3)$ -partition of  $\mathbf{X}$ . Let  $(A, B)$  be the partition of  $[m] \times [m]$  induced by  $(\mathbf{A}, \mathbf{B})$  and define  $W_{\text{Row}}$  and  $W_{\text{Col}}$  as in Proposition 4.1. Since  $|\mathbf{X}| = m^2 + 2m$  and only elements of  $[m] \times [m]$  are relevant,  $|A|, |B| \geq (m^2 + 2m)/3 - 2m = (1 - 4/m)m^2/3 \geq m^2/9$  for  $m \geq 6$  and hence  $\max(|W_{\text{Row}}|, |W_{\text{Col}}|) \geq m/3$ . We complete the proof by showing that computing  $Q_V(\mathbf{A}, \mathbf{B})$  and  $H_1(\mathbf{A}, \mathbf{B})$  each require at least  $\max(|W_{\text{Row}}|, |W_{\text{Col}}|)$  bits of communication between Alice and Bob. We will do this by showing that for a particular subset of inputs,  $Q_V$  is equivalent to the disjointness function for a  $\max(|W_{\text{Row}}|, |W_{\text{Col}}|)$  size set.

Suppose without loss of generality that  $|W_{\text{Row}}| \geq |W_{\text{Col}}|$ . Set all  $T_j = 0$  and for each  $i \notin W_{\text{Row}}$  set  $R_i = 0$ . For each  $i \in W_{\text{Row}}$  for which  $R_i \in \mathbf{A}$ , set all  $S_{ij} \in \mathbf{A}$  to 0, let  $j_i$  be minimal such that  $S_{ij_i} \in \mathbf{B}$ , and set  $S_{ij} \in \mathbf{B}$  to 0 for all  $j > j_i$ . (Such an index  $j_i$  must exist since  $i \in W_{\text{Row}}$ .) Similarly, For each  $i \in W_{\text{Row}}$  for which  $R_i \in \mathbf{B}$ , set all  $S_{ij} \in \mathbf{B}$  to 0, let  $j_i$  be minimal such that  $S_{ij_i} \in \mathbf{A}$ , and set  $S_{ij} \in \mathbf{A}$  to 0 for all  $j > j_i$ . In particular, under this partial assignment, we have

$$Q_V = H_1 = \bigvee_{i \in W_{\text{Row}}} R_i S_{ij_i}$$

and for each  $i \in W_{\text{Row}}$ , Alice holds one of  $R_i$  or  $S_{ij_i}$  and Bob holds the other. We can reduce  $H_0$  to the same quantity by setting all  $T_j = 1$ . This is precisely the set disjointness problem on two sets of size  $|W_{\text{Row}}|$  where membership of  $i$  in each player's set is determined by the value of the unset bit indexed by  $i$  that player holds. Therefore, computing

$Q_V$  or  $H_1$  requires at least  $|W_{\text{Row}}|$  bits of communication, as desired.  $\square$

Combining this with Theorem 3.9, we immediately obtain the following:

**Theorem 4.3.** *For  $m \geq 6$ , any SDD representing  $Q_V$  or  $H_1$  requires size at least  $2\sqrt{m/3-1}$ .*

As [Jha and Suciu, 2013] has shown that  $Q_V$  has FBDD size  $O(m^2)$ , we obtain the following separation.

**Corollary 4.4.** *FBDDs can be exponentially more succinct than SDDs. In particular,  $Q_V$  has FBDD size  $O(m^2)$  but every SDD for  $Q_V$  requires size  $2\sqrt{m/3-1}$  for  $m \geq 6$ .*

We now consider the formulas  $H_{ki}$  above. Though they seem somewhat specialized, these formulas are fundamental to UCQ queries: [Jha and Suciu, 2013] define the notion of an *inversion* in a UCQ query and use it to characterize the OBDD size of UCQ queries. In particular they show that if a query  $q$  is *inversion-free* then the OBDD size of its lineage  $Q$  is linear and if  $q$  has an minimum inversion length  $k \geq 1$  then it requires OBDD size  $2^{\Omega(n/k)}$  where  $n$  is the domain size of all attributes. Jha and Suciu obtain this lower bound by analyzing the  $H_{ki}$  we defined above. (We will not define the notion of inversions, or their lengths, and instead use the definition as a black box. However, as an example, the query associated with  $H_1$  has an inversion of length 1 so its OBDD size is  $2^{\Omega(m)}$ .)

**Proposition 4.5.** [Jha and Suciu, 2013] *Let  $q$  be a query with a length  $k \geq 1$  inversion. Let  $D_0$  be the complete bipartite graph of size  $m$ . There exists a database  $D$  for  $q$ , along with variable restrictions  $\rho_i$  for all  $i \in [0, k]$ , such that  $|D| = O(|D_0|)$  and  $\Phi_q^D|_{\rho_i} = \Phi_{h_{ki}}^{D_0} = H_{ki}$*

**Theorem 4.6.** *Let  $k \geq 2$  and assume that  $m \geq 6$ . Let  $q$  be a query with a length  $k \geq 2$  inversion. Then there exists a database  $D$  for which any SDD for  $Q = \Phi_q^D$  has size at least  $2\sqrt{m/k/3-1}$ .*

*Proof.* Given a query  $q$ , let  $D$  be the database for  $q$  constructed in Proposition 4.5. Fix the vtree  $\mathbf{v}$  over  $\mathbf{X}_k$  respected by an SDD  $\alpha$  for  $\Phi_q^D$ . By Lemma 3.7, there exists a  $(1/3, 2/3)$  node  $b$  in the vtree  $\mathbf{v}$  that gives a  $(1/3, 2/3)$  partition  $\{\mathbf{A}, \mathbf{B}\}$  of  $\mathbf{X}_k$ . By Proposition 4.5, there are restrictions  $\rho_0, \dots, \rho_k$  such that  $\Phi_q^D|_{\rho_i} = H_{ki}$  for all  $i$ . Thus  $\alpha|_{\rho_i}$  is a (pruned) SDD, of size  $\leq$  that of  $\alpha$ , respecting  $\mathbf{v}|_{\rho_i}$  and computing  $H_{ki}$ . Observe that the restriction of  $\{\mathbf{A}, \mathbf{B}\}$  to the variables of  $\mathbf{X}_{ki}$  is also shell partition of  $\mathbf{v}|_{\rho_i}$  at node  $b$ .

We will show that there must exist an  $H_{ki}$  for which  $\text{CC}(H_{ki}(\mathbf{A}, \mathbf{B})) \geq m/(9k)$  and therefore by Theorem 3.6, this implies that the unambiguous communication complexity of  $H_{ki}$  is at least  $\frac{1}{3}\sqrt{m/k-1}$ . Then by Theorem 3.5, any SDD respecting  $\mathbf{v}$  that computes  $H_{ki}$  has size at least  $2^{\frac{1}{3}\sqrt{m/k-1}}$ .

Let  $W_{\text{Chain}}$  contain all pairs  $(i, j)$  for which both  $\mathbf{A} \cap \bigcup_{\ell=1}^k \{S_{ij}^\ell\} \neq \emptyset$  and  $\mathbf{B} \cap \bigcup_{\ell=1}^k \{S_{ij}^\ell\} \neq \emptyset$  and Let  $\gamma = 1/9$ . We will consider two cases: either  $|W_{\text{Chain}}| \geq \gamma \cdot m$  or  $|W_{\text{Chain}}| < \gamma \cdot m$ .

In the first case, since  $|W_{\text{Chain}}| \geq \gamma \cdot m$ , there must exist at least  $\gamma \cdot m$  tuples  $(i, j, \ell)$  for which either  $S_{ij}^\ell \in \mathbf{A}$  and  $S_{ij}^{\ell+1} \in \mathbf{B}$  or vice-versa. Call the set of these tuples  $\mathbf{T}$ . Then, since there are  $k - 1$  choices of  $\ell < k$ , there exists some  $\ell^*$  such that the set  $\mathbf{T}_{\ell^*} := \mathbf{T} \cap [m] \times [m] \times \{\ell^*\}$  contains at least  $\gamma \cdot m / (k - 1) > m / (9k)$  elements. If we set all variables of  $\mathbf{X}_{k\ell^*}$  outside of  $\mathbf{T}_{\ell^*}$  to 0, the function  $H_{k\ell^*}$  corresponds to solving a disjointness problem between Alice and Bob on the elements of  $\mathbf{T}_{\ell^*}$ . Thus the communication complexity of  $H_{k\ell^*}$  under the partition  $\{\mathbf{A}, \mathbf{B}\}$  is at least  $m / (9k)$ .

In the second case, consider the largest square submatrix  $M$  of  $[m] \times [m]$  that does not contain any member of  $W_{\text{Chain}}$ . We mimic the argument of Theorem 4.2 on this submatrix  $M$ . By definition,  $M$  has side  $m' \geq (1 - \gamma)m$ . For every  $(i, j)$  in  $M$ , either  $\mathbf{A}$  or  $\mathbf{B}$  contains all  $S_{ij}^\ell$ ; let  $A$  be those  $(i, j)$  such that these are in  $\mathbf{A}$  and  $B$  be those  $(i, j)$  for which they are in  $\mathbf{B}$ . Since  $|\mathbf{A}|, |\mathbf{B}| \geq |\mathbf{X}_k|/3 = (km^2 + 2m)/3$  and there are at most  $2m + (\gamma^2 + 2\gamma)km^2$  variables not in  $M$ ,

$$\begin{aligned} |A|, |B| &\geq [(km^2 + 2m)/3 - 2m + (\gamma^2 + 2\gamma)km^2]/k \\ &= [(1 - \gamma)^2 - 2/3 - 4/(3km)]m^2 > (m/18)^2 \end{aligned}$$

since  $k \geq 2$ . Applying Proposition 4.1, we see that  $\max(|W_{\text{Row}}|, |W_{\text{Col}}|) \geq m/18 \geq m/(9k)$ . By the same argument presented in the proof of Theorem 4.2, we have both  $\text{CC}(H_{k0}(\mathbf{A}, \mathbf{B})) \geq |W_{\text{Row}}|$  and  $\text{CC}(H_{kk}(\mathbf{A}, \mathbf{B})) \geq |W_{\text{Col}}|$  so at least one of these is at least  $m/(9k)$  and the theorem follows.  $\square$

It follows that for inversion-free UCQ queries, both SDD and OBDD sizes of any lineage are linear, while UCQ queries with inversions (of length  $k$ ) have worst-case lineage size that is exponential ( $2^{\Omega(m/k)}$  for OBDDs and  $2^{\Omega(\sqrt{m/k})}$  for SDDs). Note that the same SDD size lower bound for UCQ query lineage  $Q = \Phi_q^D$  applies to its dual  $Q^* = \Phi_q^D$  as follows: Flipping the signs on the variables in  $Q^*$  yields a function equivalent to  $\neg Q$ . So flipping the variable signs at the leaves of an SDD for  $Q^*$  we obtain an SDD of the same size for  $\neg Q$  and hence a deterministic protocol that also can compute  $Q$ .

## 5 Simulating DNNFs by OR-FBDDs

In this section, we extend the simulation of decision-DNNFs by FBDDs from [Beame et al., 2013] to obtain a simulation of general DNNFs by OR-FBDDs with at most a quasipolynomial increase in size. This simulation yields lower bounds on DNNF size from OR-FBDD lower bounds.

**Definition 5.1.** For each AND node  $u$  in a DNNF  $\mathcal{D}$ , let  $M_u$  be the number of AND nodes in the subgraph  $D_u$ . We call  $u$ 's left child  $u_l$  and its right child  $u_r$ . We will assume  $M_{u_l} \leq M_{u_r}$  (otherwise we swap  $u_l$  and  $u_r$ ).

For each AND node  $u$ , we classify the edge  $(u, u_l)$  as a light edge and the edge  $(u, u_r)$  a heavy edge. We classify every other edge in  $\mathcal{D}$  as a neutral edge.

For a DNNF  $\mathcal{D}$  or an OR-FBDD  $\mathcal{F}$ , we denote the functions that  $\mathcal{D}$  and  $\mathcal{F}$  compute as  $\Phi_{\mathcal{D}}$  and  $\Phi_{\mathcal{F}}$ .

### Constructing the OR-FBDD

For a DNNF  $\mathcal{D}$ , we will treat a leaf labeled by the variable  $X$  as a decision node that points to a 0-sink node if  $X = 0$  and a 1-sink node if  $X = 1$ , and vice-versa for a leaf labeled by  $\neg X$ . We also assume that each AND node has just two children, which only affects the DNNF size by at most polynomially.

**Definition 5.2.** Fix a DNNF  $\mathcal{D}$ . For a node  $u$  in  $\mathcal{D}$  and a path  $P$  from the root to  $u$ , let  $S(P)$  be the set of light edges along  $P$  and  $S(u) = \{S(P) \mid P \text{ is a path from the root to } u\}$ .

We will construct an OR-FBDD  $\mathcal{F}$  that computes the same boolean function as  $\mathcal{D}$ . Its nodes are pairs  $(u, s)$  where  $u$  is a node in  $\mathcal{D}$  and the set of light edges  $s$  belongs to  $S(u)$ . Its root is  $(\text{root}(\mathcal{D}), \emptyset)$ . The edges in  $\mathcal{F}$  are of three types:

*Type 1:* For each light edge  $e = (u, v)$  in  $\mathcal{D}$  and  $s \in S(u)$ , add the edge  $((u, s), (v, s \cup \{e\}))$  to  $\mathcal{F}$ .

*Type 2:* For each neutral edge  $e = (u, v)$  in  $\mathcal{D}$  and  $s \in S(u)$ , add the edge  $((u, s), (v, s))$  to  $\mathcal{F}$ .

*Type 3:* For each heavy edge  $(u, v_r)$ , let  $e = (u, v_l)$  be its sibling light edge. For each  $s \in S(u)$  and 1-sink node  $w$  in  $D_{v_l}$ , add the edge  $((w, s \cup \{e\}), (v_r, s))$  to  $\mathcal{F}$ .

We label the nodes  $u' = (u, s)$  as follows: (1) if  $u$  is a decision node in  $\mathcal{D}$  for the variable  $X$  then  $u'$  is a decision node in  $\mathcal{F}$  testing the same variable  $X$ , (2) if  $u$  is an AND-node, then  $u'$  is a no-op node, (3) if  $u$  is an OR node it remains an OR node. (4) if  $u$  is a 0-sink node, then  $u'$  is a 0-sink node, (5) if  $u$  is a 1-sink node, then: if  $s = \emptyset$  then  $u'$  is a 1-sink node, otherwise it is a no-op node.

We show an example of this construction in Figure 3.

### Size and Correctness

**Lemma 5.3.** For the DNNF  $\mathcal{D}$  let  $L$  denote the maximum number of light edges from the root to a leaf,  $M$  the number of AND nodes and  $N$  the total number of nodes. Then  $\mathcal{F}$  has at most  $NM^L$  nodes. Further, this is  $N \cdot 2^{\log^2 N}$ .

*Proof.* The nodes in  $\mathcal{F}$  are labeled  $(u, s)$ . There are  $N$  possible nodes  $u$  and at most  $M^L$  choices for the set  $s$ , as

Figure 3: A DNNF and our construction of an equivalent OR-FBDD.

each path to  $u$  has at most  $L$  light edges.

Consider a root to leaf path with  $L$  light edges. As we traverse this path, every time we cross a light edge, we decrease the number of descendant AND nodes by more than half. Thus we must have begun with more than  $2^L$  descendant AND nodes at the root so that  $N \geq M > 2^L$ . This implies that  $NM^L$  is quasipolynomial in  $N$ ,

This upper bound is quasipolynomial in  $N$ , we will show that  $M > 2^L$ . Then, since  $N \geq M$ ,  $NM^L \leq N2^{\log^2 M} \leq N2^{\log^2 N}$ .  $\square$

The proof of the following lemma is in the full paper.

**Lemma 5.4.**  $\mathcal{F}$  is a correct OR-FBDD with no-op nodes that computes the same function as  $\mathcal{D}$ .

Using the quasipolynomial simulation of DNNFs by OR-FBDDs, we obtain DNNF lower bounds from OR-FBDD lower bounds.

**Definition 5.5.** Function  $\text{PERM}_n$  takes an  $n \times n$  boolean matrix  $M$  as input and outputs 1 if and only if  $M$  is a permutation matrix. The function  $\text{ROW-COL}_n$  takes an  $n \times n$  boolean matrix  $M$  as input and outputs 1 if and only if  $M$  has an all-0 row or an all-0 column.

**Theorem 5.6.** Any OR-FBDD computing  $\text{PERM}_n$  or  $\text{ROW-COL}_n$ , must have size  $2^{\Omega(n)}$  [Wegener, 2000].

**Corollary 5.7.** Any DNNF computing  $\text{PERM}_n$  or  $\text{ROW-COL}_n$  has size at least  $2^{\Omega(\sqrt{n})}$

## 6 Discussion

We have made the first significant progress in understanding the complexity of general DNNF representations. We have also provided a new connection between SDD representations and best-partition communication complexity. Best-partition communication complexity is a standard technique used to derive lower bounds on OBDD size, where it often yields asymptotically tight results. For communication lower bound  $C$ , the lower bound for OBDD size is  $2^C$  and the lower bound we have shown for SDD size is  $2^{\sqrt{C}} - 1$ . This is a quasipolynomial difference. Are SDDs that much more efficient than OBDDs? Is there always a

quasipolynomial simulation of SDDs by OBDDs in general, matching the quasipolynomial simulation of decision-DNNFs by FBDDs? Our separation result shows an example for which SDDs are sometimes exponentially less concise than FBDDs, and hence decision-DNNFs also. Are SDDs ever more concise than decision-DNNFs?

By plugging in the arguments of [Pipatsrisawat and Darwiche, 2010, Pipatsrisawat, 2010] in place of Theorem 3.5, all of our lower bounds immediately extend to size lower bounds for structured deterministic DNNFs (d-DNNFs), of which SDDs are a special case. It remains open whether structured d-DNNFs are strictly more concise than SDDs. [Pipatsrisawat and Darwiche, 2008, Pipatsrisawat, 2010] have proved an exponential separation between structured d-DNNFs and OBDDs using the *Indirect Storage Access (ISA)* function [Breitbart et al., 1995], but the small structured d-DNNF for this function is very far from an SDD. It is immediate that, under any variable partition, the  $ISA_n$  function has an  $O(\log n)$ -bit two-round deterministic communication protocol. On the other hand, efficient one-round (i.e., one-way) communication protocols yield small OBDDs so there are two possibilities if SDDs and structured d-DNNFs have different power. Either (1) communication complexity considerations on their own are not enough to derive a separation between SDDs and structured d-DNNFs, or (2) every SDD can be simulated by an efficient one-way communication protocol, in which case SDDs can be simulated efficiently by OBDDs (though the ordering cannot be the same as the natural traversal of the associated vtree, as shown by [Xue et al., 2012]).

## Abstract

In recent years, there has been considerable progress on fast randomized algorithms that approximate probabilistic inference with tight tolerance and confidence guarantees. The idea here is to formulate inference as a counting task over an annotated propositional theory, called weighted model counting (WMC), which can be partitioned into smaller tasks using universal hashing. An inherent limitation of this approach, however, is that it only admits the inference of discrete probability distributions. In this work, we consider the problem of approximating inference tasks for a probability distribution defined over discrete and continuous random variables. Building on a notion called weighted model integration, which is a strict generalization of WMC and is based on annotating Boolean and arithmetic constraints, we show how probabilistic inference in hybrid domains can be put within reach of hashing-based WMC solvers. Empirical evaluations demonstrate the applicability and promise of the proposal.

## 1 INTRODUCTION

Weighted model counting (WMC) on a propositional knowledge base is an effective and general approach to probabilistic inference in a variety of formalisms, including Bayesian and Markov Networks. It extends the model counting task, or #SAT, which is to count the number of assignments (that is, models) that satisfy a given logical sentence (Gomes *et al.*, 2009). In WMC, one accords a weight to every model, and computes the sum of the weights of all models. The WMC formulation has recently emerged as an assembly language for probabilistic reasoning, offering a basic formalism for encoding various inference problems. State-of-the-art reasoning algorithms for Bayesian networks (Chavira and Darwiche, 2008), their relational

extensions (Chavira *et al.*, 2006), factor graphs (Choi *et al.*, 2013), probabilistic programs (Fierens *et al.*, 2013), and probabilistic databases (Suciu *et al.*, 2011) reduce their inference problem to a WMC computation. The task has been generalized to first-order knowledge bases as well (Van den Broeck *et al.*, 2011; Gogate and Domingos, 2011). Exact WMC solvers are based on knowledge compilation (Darwiche, 2004; Muise *et al.*, 2012) or DPLL search with component caching (Sang *et al.*, 2005).

However, exact inference is #P-hard (Valiant, 1979), and so, there is a growing interest in approximate model counters. Beginning with Stockmeyer (1983), who showed that approximating model counting with a tolerance factor can be achieved in deterministic polynomial time using a  $\Sigma_2^P$ -oracle, a number of more recent results show how random polynomial-time realizations are possible using an NP-oracle (e.g., a SAT solver) (Jerrum *et al.*, 1986; Karp *et al.*, 1989; Bellare *et al.*, 2000; Gomes *et al.*, 2006; Ermon *et al.*, 2013b, 2014; Chakraborty *et al.*, 2013a,b). The central idea here is the use of random parity constraints, in the form of *universal hash functions* (Sipser, 1983), that partition the model counting solution space in an inexpensive manner. Most of the recent work in the area, moreover, come with strong tolerance-confidence guarantees (introduced later), and scale well by leveraging SAT technology.

The popularity of WMC can be explained as follows. Its formulation elegantly decouples the logical or symbolic representation from the statistical or numeric one, which is encapsulated in the weight function. When building solvers, this allows us to reason about logical equivalence and reuse SAT solving technology (such as constraint propagation and clause learning). WMC also makes it more natural to reason about deterministic, hard constraints in a probabilistic context. Nevertheless, WMC has a fundamental *limitation*: it is purely Boolean. This means that the advantages mentioned above only apply to *discrete probability distributions*.

To counter this, in a companion paper (Belle *et al.*, 2015), we proposed the notion of *weighted model integration* (WMI). It is based on *satisfiability modulo theories* (SMT),

which enable us to, for example, reason about the satisfiability of linear constraints over the rationals. The WMI task is defined on the models of an SMT theory  $\Delta$ , containing mixtures of Boolean and continuous variables. For every assignment to the Boolean and continuous variables, the WMI problem defines a weight. The total WMI is computed by integrating these weights over the domain of solutions of  $\Delta$ , which is a mixed discrete-continuous space. Consider, for example, the special case when  $\Delta$  has no Boolean variables, and the weight of every model is 1. Then, the WMI simplifies to computing the volume of the polytope encoded in  $\Delta$ . Overall, weighted SMT theories admit a natural encoding of hybrid Markov and Bayesian networks, analogous to the encodings of discrete graphical networks using weighted propositional theories.

In this work, we consider the problem of approximating inference tasks for a probability distribution defined over discrete and continuous random variables. Formulated as a WMI task, we address the question as to whether fast hashing-based approximate WMC solvers can be leveraged for hybrid domains. What we show is that an NP-oracle can indeed effectively partition the model counting solution space of the more intricate mixed discrete-continuous case using universal hashing. (Of course, volume computation is still necessary, but often over very small spaces.) In this sense, hybrid domains can now be put within reach of approximate WMC solvers. In particular, the hashing approach that we consider here builds on the recent work of Chakraborty *et al.* (2014) on approximate WMC, and inherits their tolerance-confidence guarantees. In our empirical evaluations, the approximate technique is shown to be significantly faster than an exact WMI solver. We then demonstrate the practical efficacy of the system on a complex real-world dataset where we compute conditional queries over intricate arithmetic constraints that would be difficult (or impossible) to realize in existing formalisms.

Let us finally mention that current inference algorithms for hybrid graphical models often make strong assumptions on the form of the potentials, such as Gaussian distributions (Lauritzen and Jensen, 2001), or approximate using variational methods (Murphy, 1999; Lunn *et al.*, 2000), for which quality guarantees are difficult to obtain. There is also a recent focus on *piecewise-polynomial* potentials (Shenoy and West, 2011; Sanner and Abbasnejad, 2012; Wang *et al.*, 2014), which are based on generalizations of techniques such as the join-tree algorithm. Such piecewise-polynomials can also be represented in the WMI context, but in a general framework allowing arbitrary Boolean connectives and deterministic hard constraints.

## 2 PRELIMINARIES

We begin with probabilistic models, and then turn to the necessary logical background, WMC and WMI.

### 2.1 PROBABILISTIC MODELS

Let  $\mathcal{B}$  and  $\mathcal{X}$  denote sets of Boolean and real-valued random variables, that is,  $b \in \mathcal{B}$  is assumed to take values from  $\{0, 1\}$  and  $x \in \mathcal{X}$  takes values from  $\mathbb{R}$ . We let  $(\mathbf{b}, \mathbf{x}) = (b_1, \dots, b_m, x_1, \dots, x_n)$  be an element of the probability space  $\{0, 1\}^m \times \mathbb{R}^n$ , which denotes a particular assignment to the random variables from their respective domains. We let the joint probability density function be denoted by  $\text{Pr}$ . So  $\text{Pr}(\mathbf{b}, \mathbf{x})$  determines the probability of the assignment vector. When these random variables are defined by a set of dependencies, as can be represented using an *undirected graphical model* (that is, Markov network), the density function is compactly *factorized*. See Koller and Friedman (2009) for details.

### 2.2 LOGICAL BACKGROUND

*Propositional satisfiability* (SAT) is the problem of deciding whether a logical formula over Boolean variables and logical connectives can be satisfied by some truth value assignment of the Boolean variables. Given a formula  $\phi$  and assignment (or model or world)  $M$ , we write  $M \models \phi$  to denote *satisfaction*. We write  $l \in M$  to denote the literals (that is, propositions or their negations) that are satisfied at  $M$ . We often write  $\mathcal{M}(\phi)$  to mean the set of models of  $\phi$ .

A generalization to this decision problem is that of *Satisfiability Modulo Theories* (SMT). In SMT, we are interested in deciding the satisfiability of a (typically quantifier-free) first-order formula with respect to some decidable background theory  $\mathcal{T}$ , such as linear arithmetic over the rationals ( $\mathcal{LRA}$ ). Standard first-order models can be used to formulate SMT; see Barrett *et al.* (2009) for details. Moreover various background theories, like  $\mathcal{LRA}$  and linear arithmetic over the integers ( $\mathcal{LIA}$ ), can be combined. In this paper we are interested in a combination of  $\mathcal{LRA}$  and propositional logic, for which satisfaction is defined in an obvious way.

Our formulation will also use the concepts of *formula abstraction* and *refinement* (Barrett *et al.*, 2009). Here, first, a bijection is established between ground first-order atoms and a propositional vocabulary; abstraction proceeds by replacing the atoms by propositions, and refinement replaces the propositions with the atoms. In the sequel, we refer to the propositional abstraction of an SMT formula  $\phi$  as  $\phi^-$  and the refinement of  $\phi$  as  $\phi^+$ . For example, if  $\Delta = (x \leq 4) \wedge (x \leq 5)$ , then  $\Delta^- = p \wedge q$  where (say)  $p$  denotes  $x \leq 4$  and  $q$  denotes  $x \leq 5$ ; also,  $q^+ = x \leq 5$ .

### 2.3 WEIGHTED MODEL COUNTING

Weighted model counting (Chavira and Darwiche, 2008) is an extension of model counting (Gomes *et al.*, 2009). In model counting, also known as #SAT, one counts the number of satisfying assignments of a propositional sentence.

In WMC, each assignment has an associated weight and the task is to compute the sum of the weights of all satisfying assignments. WMC has applications in probabilistic inference in discrete graphical models.

**Definition 1:** Given a formula  $\Delta$  in propositional logic over literals  $\mathcal{L}$ , and a *weight function*  $w : \mathcal{L} \rightarrow \mathbb{R}$ , the *weighted model count* (WMC) is defined as:

$$\text{WMC}(\Delta, w) = \sum_{M \models \Delta} w(M)$$

where,  $w(M)$  is shorthand for  $\prod_{l \in M} w(l)$ .

Intuitively, the weight of a formula is given in terms of the total weight of its models; the weight of a model is defined in terms of the literals true in that model.

We are often interested in computing the probability of a query  $q$  given evidence  $e$  in a Boolean Markov network  $N$ , for which we use:

$$\Pr_N(q \mid e) = \frac{\text{WMC}(q \wedge e \wedge \Delta, w)}{\text{WMC}(e \wedge \Delta, w)}$$

where  $\Delta$  encodes  $N$  and  $w$  encodes the potentials; see, for example, Chavira and Darwiche (2008).

## 2.4 WEIGHTED MODEL INTEGRATION

As noted before, an inherent limitation of WMC is that it only admits the inference of discrete probability distributions. To remedy this, in a companion paper (Belle *et al.*, 2015), we introduced the notion of *weighted model integration* as a strict generalization of WMC. The main idea here is to take a logical theory with rational and Boolean variables, that is, from a combination of  $\mathcal{LR}\mathcal{A}$  and propositional logic, and annotate it with weights. As before, propositional assignments are denoted using  $M$ .

**Definition 2:** Suppose  $\Delta$  is an SMT theory over Boolean and rational variables  $\mathcal{B}$  and  $\mathcal{X}$ , and literals  $\mathcal{L}$ . Suppose  $w : \mathcal{L} \rightarrow \text{EXPR}(\mathcal{X})$ , where  $\text{EXPR}(\mathcal{X})$  are expressions over  $\mathcal{X}$ . Then the *weighted model integral* (WMI) is defined as:

$$\text{WMI}(\Delta, w) = \sum_{M \models \Delta^-} \text{VOL}(M, w)$$

$$\text{where, } \text{VOL}(M, w) = \int_{\{l^+ : l \in M\}} w(M) d\mathcal{X}.$$

The main feature of the definition is how it casts the weighted model counting problem over SMT in standard propositional logic. The intuition is as follows. The WMI of an SMT theory  $\Delta$  is defined in terms of the models of its propositional abstraction  $\Delta^-$ . For each such model, we compute its volume, that is, we integrate the weight values of the literals that are true at the model. The interval of

the integral is obtained from the refinement of each literal.<sup>1</sup> The mathematical expression for conditional probabilities is as before.

The general idea with  $\text{EXPR}(\mathcal{X})$  is that the weight function maps an expression  $e$  to its *density function*, which is usually another expression mentioning the variables in  $e$ . We note that the input language for a WMI task is easily seen to capture constraints involving discrete and continuous random variables over arbitrary Boolean connectives.

To see WMI in action, consider a simple example:

**Example 3:** Suppose  $\Delta$  is the following formula:

$$p \vee (0 \leq x \leq 10)$$

For weights, let  $w(p) = .1$ ,  $w(\neg p) = 2x$ ,  $w(q) = 1$  and  $w(\neg q) = 0$ , where  $q$  is the propositional abstraction of  $(0 \leq x \leq 10)$ . Roughly, this can be seen to say that  $x$  is uniformly distributed when  $p$  holds and otherwise it is characterized by a triangular distribution in the interval  $[0, 10]$ . There are three models of  $\Delta^-$ , for which we calculate  $\text{VOL}(\cdot, w)$ :

1.  $\text{VOL}(\{p, \neg q\}, w) = 0$  because  $w(\neg q) = 0$ ;
2.  $\text{VOL}(\{\neg p, q\}, w) = \int_{0 \leq x \leq 10} 2x dx = [x^2]_0^{10} = 100$ .
3.  $\text{VOL}(\{p, q\}, w) = \int_{0 \leq x \leq 10} .1 dx = [.1 \cdot x]_0^{10} = 1$ .

Thus,  $\text{WMI}(\Delta, w) = 100 + 1 = 101$ .

Suppose that we are interested in the probability of the query  $x \leq 3$  given that  $\neg p$  is observed. Suppose  $r$  is the abstraction of  $x \leq 3$ . First,  $\text{WMI}(\Delta \wedge \neg p, w)$  corresponds to the weight of a single interpretation, that of item 2, yielding a value of 100. Next,  $\text{WMI}(\Delta \wedge \neg p \wedge x \leq 3, w)$  also corresponds to the weight of a single interpretation  $\{\neg p, q, r\}$ , an extension to that in item 2. In this case:

$$\text{VOL}(\{\neg p, q, r\}, w) = \int_{(0 \leq x \leq 10) \wedge (x \leq 3)} 2x dx = [x^2]_0^3 = 9.$$

Therefore, the conditional probability is  $9/100 = .09$ .  $\square$

<sup>1</sup>Although the interval is defined in terms of SMT literals, this is meant to denote standard integrals in an obvious fashion:

$$\int_{x \leq 6} \phi dx \doteq \int_{-\infty}^6 \phi dx; \int_{x \geq 6} \phi dx \doteq \int_6^{\infty} \phi dx; \int_{5 \leq x \leq 6} \phi dx \doteq \int_5^6 \phi dx$$

Likewise, over connectives:

$$\int_{x \leq 6 \wedge y \geq 5} \phi dx dy \doteq \int_{x \leq 6} \int_{y \geq 5} \phi dx dy.$$

When propositions appear as intervals, they are simply ignored. See Belle *et al.* (2015) for the general definition.

The correctness of WMI and that it is a strict generalization of WMC are argued elsewhere (Belle *et al.*, 2015).<sup>2</sup>

Let us conclude this section by remarking that although the definition of WMI is very general, for most practical purposes, we restrict densities to piecewise polynomials, where  $w$  maps  $\mathcal{L}$  to polynomials over  $X$ . Such piecewise polynomials can approximate a wide variety of continuous distributions, including Gaussians (Shenoy and West, 2011; Sanner and Abbasnejad, 2012). Moreover, Baldoni *et al.* (2011) show that for a fixed number of variables, the integration is efficient, even for polynomials of increasing degree. Thus, smooth function approximations are possible in practice, and come at a reasonable cost.

### 3 APPROXIMATING WMI

In this section, we identify how to approximate  $\text{WMI}(\Delta, w)$  for an arbitrary  $\Delta$  and non-degenerate (see below)  $w$  with strong theoretical guarantees by appealing to a SAT-oracle.

#### 3.1 PROBLEM STATEMENT FOR WMC

To better understand the problem statement, let us begin with the case of WMC:

**Definition 4:** Given a propositional formula  $\Delta$  and a weight function  $w$ , an *exact algorithm* for WMC returns  $\text{WMC}(\Delta, w)$ . An *approximate algorithm* for WMC given *tolerance*  $\epsilon \in (0, 1]$  and *confidence*  $1 - \delta \in (0, 1]$ , simply called an  $(\epsilon, \delta)$ -algorithm, returns a value  $v$  such that

$$\Pr \left[ \frac{\text{WMC}(\Delta, w)}{1 + \epsilon} \leq v \leq (1 + \epsilon)\text{WMC}(\Delta, w) \right] \geq 1 - \delta$$

Intuitively, when the weight of every model is 1, an exact algorithm returns the size of the set  $\mathcal{M}(\Delta) = \{M \mid M \models \Delta\}$  while an approximate one samples from that solution space. Exact algorithms are #P-hard (Valiant, 1979) but for the approximate case random polynomial time realizations are known (Jerrum *et al.*, 1986; Karp *et al.*, 1989).<sup>3</sup>

<sup>2</sup>In an independent and recent effort, Chistikov *et al.* (2015) also introduce the notion of approximate model counting for SMT theories. The most significant difference between the proposals is that they focus only on unweighted model counting. Moreover, they define model counting as a measure on first-order models. Our approach is a simpler one based on propositional abstractions, which (as we will see) allows us to cast statements for WMI as WMC in a direct way.

<sup>3</sup>The class of  $(\epsilon, \delta)$ -algorithms that we are after follows the terminology of Karp *et al.* (1989). These can be contrasted to *bounding* counters only parameterized by confidence probabilities, such as (Kroc *et al.*, 2011).

#### 3.2 PROBLEM STATEMENT FOR WMI

To see how the above notions apply to our task, consider an SMT theory  $\Delta$  and weight function  $w$ . We observe that

$$\text{WMI}(\Delta, w) = \text{WMC}(\Delta^-, u)$$

where, for any model  $M$  of  $\Delta^-$ ,  $u$  is a weight function such that  $u(M) = \text{VOL}(M, w)$ . More precisely,  $u$  is to be seen as a weight function that does not factorize over literals and directly maps interpretations to  $\mathbb{R}$ . (This is without any loss of generality.) Thus, our problem statement becomes:

**Definition 5:** An  $(\epsilon, \delta)$ -algorithm for a WMI problem over  $\Delta$  and  $w$  is an  $(\epsilon, \delta)$ -algorithm for WMC over  $\Delta^-$  and weight function  $u$ , where for any model  $M$  of  $\Delta^-$ ,  $u(M) = \text{VOL}(M, w)$ .

The idea is that by treating the volumes of models as weights over propositional interpretations, we can view WMI simply in terms of WMC. Theoretical results can then be imported for our purposes.

Given an  $(\epsilon, \delta)$ -algorithm for WMC, there are two caveats, however. First, weights of interpretations need to be actually computed using integration during inference, but (usually) over a small number of literals and their polynomial potentials true in a model. Second, such an algorithm samples feasible satisfying assignments for  $\Delta^-$ , but these need not be  $\mathcal{T}$ -consistent. For example, if  $p$  denotes  $x \leq 3$  and  $q$  denotes  $x \leq 5$ , then the interpretation  $\{p, \neg q\}$  is not a model in  $\mathcal{LRA}$  on refinement. In the formal machinery, the weight of this model is easily seen to be 0 (that is, the interval of the integral will be an empty set), and so these models can freely appear in the problem statement. In practice, these theory inconsistency models are rejected in the WMC calculation, and once found, the algorithm can be made to refine its search of feasible solutions by incorporating these models as blocked clauses.

#### 3.3 APPROACH

In sum, what we are after is an  $(\epsilon, \delta)$ -algorithm for  $\text{WMC}(\Delta, w)$  for a propositional theory  $\Delta$  and weight function  $w$ . Consider classical model counting, that is, where the weight of every model is 1, which is #P-hard. Bellare *et al.* (2000) were the first to show that satisfying assignments can be generated uniformly in random polynomial-time using only an NP-oracle (e.g., a SAT solver), improving and complementing earlier results (Jerrum *et al.*, 1986; Karp *et al.*, 1989; Stockmeyer, 1983). Adapting these techniques further, Chakraborty *et al.* (2013a,b) introduce a scalable approximate model counter. See Gomes *et al.* (2006) and Ermon *et al.* (2013b) for closely related proposals.

### 3.3.1 Counting by Hashing

The central idea in Bellare *et al.* (2000) and Chakraborty *et al.* (2013b) is the use of *universal hash functions* (Sipser, 1983):

**Definition 6 :** A family of functions  $\mathcal{H} = \{h \mid \{0, 1\}^n \rightarrow \{0, 1\}^m\}$  is called *uniform*, written  $h \stackrel{R}{\leftarrow} \mathcal{H}$ , if it holds that for any  $y \in \{0, 1\}^m$ , the random variable  $h(y)$  is uniformly distributed in  $\{0, 1\}^n$ .

**Definition 7 :** A family of functions  $\mathcal{H} = \{h \mid \{0, 1\}^n \rightarrow \{0, 1\}^m\}$  is called *t-wise independent* if it holds that for any  $x_1, \dots, x_t \in \{0, 1\}^m$ , any  $y_1, \dots, y_t \in \{0, 1\}^n$ , and any  $h \stackrel{R}{\leftarrow} \mathcal{H}$ , we have:

$$\Pr[h(y_1) = x_1 \wedge \dots \wedge h(y_t) = x_t] = 2^{-m \cdot t}$$

For the sake of clarity, we denote this family as  $\mathcal{H}(n, m, t)$ . Now, suppose  $x \in \{0, 1\}^m$  and  $h \stackrel{R}{\leftarrow} \mathcal{H}(n, m, t)$ . Let  $h^{-1}(x) = \{y \in \{0, 1\}^n \mid h(y) = x\}$ . Then, the idea is that for any propositional language over  $n$  variables,  $\mathcal{M}(\Delta) \subseteq \{0, 1\}^n$  and  $x \in \{0, 1\}^m$ , the set  $\mathcal{M}(\Delta) \cap h^{-1}(x)$  partitions  $\mathcal{M}(\Delta)$  into a set of well-balanced *cells*, each one induced by a particular choice of  $h$ . Thus, by iterating over different samples of  $h \stackrel{R}{\leftarrow} \mathcal{H}(n, m, t)$ , we can perform a small number of computations on the cells and leverage that as an estimate for the solution space as a whole.

The work of Chakraborty *et al.* (2013b) uses an efficient family of hash functions, denoted  $\mathcal{H}_{\text{xor}}(n, m, 3)$  below. Given  $h \stackrel{R}{\leftarrow} \mathcal{H}(n, m, 3)$  and  $y \in \{0, 1\}^n$ , let  $h(y)[k]$  denote the  $k$ th component of the vector obtained by applying  $h$  to  $y$ , and  $y[k]$  denote the  $k$ th component of the string  $y$ . The family of hash functions of interest is defined as

$$\mathcal{H}_{\text{xor}}(n, m, 3) = \{h \mid h(y)[i] = a_{i,0} \oplus \left(\bigoplus_{l=1}^n a_{i,l} \cdot y[l]\right), \\ a_{i,j} \in \{0, 1\}, 1 \leq i \leq m, 0 \leq j \leq n\}$$

where  $\oplus$  denotes the XOR operation. By choosing values of  $a_{i,j}$  randomly and independently, we can effectively choose a random hash function from the family. Gomes *et al.* (2006) show that this family of hash functions is 3-wise independent.

### 3.3.2 WMC by Hashing

As argued by Ermon *et al.* (2013a), the one major limitation when applying approximate model counters for probabilistic inference is that weights play an important role in deeming which samples are interesting. Therefore, uniformly sampling from  $\mathcal{M}(\phi)$  is not appealing, and would lead to poor estimates of conditional probabilities. The approach taken in Ermon *et al.* (2013a) is to reformulate the inference task by an embedding for which uniform sampling suffices.

While this is an attractive option, it requires a factored representation of the probability distribution and appeals to solutions of optimization problems from a MPE query (that is, finding the most likely state). In our setting, these requirements are problematic. For one thing, note that even if the original input problem uses a factored representation, we only possess a WMC problem with a weight function for interpretations that (possibly) lacks any structure. For another, MPE queries will involve computing integrals (recall that weights are computed during inference) for a large number of states, a task we would like to avoid unless necessary.

Nonetheless, extending earlier results (Bellare *et al.*, 2000; Chakraborty *et al.*, 2013b), Chakraborty *et al.* (2014) (CFMSV henceforth) show how approximate model counters can be applied to weighted model counting problems by means of a parameter called *tilt*.

**Definition 8:** Suppose  $\Delta$  is a propositional theory and  $w$  is a weight function mapping  $\mathcal{M}(\Delta)$  to strictly positive numbers. Let  $w_{\max} = \max_M w(M)$  and let  $w_{\min} = \min_M w(M)$ . We define the *tilt*  $\theta$  to be the ratio  $w_{\max}/w_{\min}$ .

For our purposes, we adapt the notion as follows:

**Definition 9:** Suppose  $\Delta$  is a SMT theory over literals  $\mathcal{L}$  and continuous variables  $\mathcal{X}$  and  $w$  is a weight function mapping  $\mathcal{L}$  to  $\text{EXPR}(\mathcal{X})$ . Let  $w_{\max} = \max_M \text{VOL}(M, w)$  and let  $w_{\min} = \min_M \text{VOL}(M, w)$ . We define the *tilt*  $\theta$  to be the ratio  $w_{\max}/w_{\min}$ .

The idea is that in approximate model counting, the number of hash functions to sample (and thus, the number of cells to construct of  $\mathcal{M}(\Delta)$ ) is guided by the confidence parameter  $\delta$ . In the approach of Chakraborty *et al.* (2014), the tilt of a problem is used to additionally ensure that an appropriate number of cells are constructed in the weighted case. While the approach requires the modeler to provide an upper bound on the tilt, the parameter is agnostic about the form of the weight function, which is desirable in our setting. Nonetheless, when the tilt is large (i.e., when the weight of an interpretation is small relative to others), it would mean that a large number of cells are constructed, which may be inefficient, and alleviating this is an interesting avenue for the future. In practice, the problems we encountered had small tilts. (In our experimental evaluations, an upper bound of 5-10 was provided for the tilt.)

## 3.4 ALGORITHM

Putting it all together, we present the pseudocode for WMI computation. It can be seen as a simple reworking of CFMSV to solve WMI.<sup>4</sup> For the sake of completeness, we

<sup>4</sup>In that sentiment, we believe an important feature of our formulation is that other WMC approaches can be adapted for WMI along the same lines.

---

**Algorithm 1** WEIGHTMC( $\phi, u, \epsilon, \delta, \theta$ )

---

```
1:  $w_{\max} \leftarrow 1$ 
2:  $\text{pivot} \leftarrow 2 \times \lceil e^{3/2} \left(1 + \frac{1}{\epsilon}\right)^2 \rceil$ 
3:  $\text{iter} \leftarrow \lceil 35 \log_2(3/\delta) \rceil$ 
4: for  $i : 1, \dots, \text{iter}$  do
5:    $(\mathcal{M}, c, w_{\max}) \leftarrow \text{WEIGHTMCCORE}(\phi, u, \text{pivot}, \theta, w_{\max})$ 
6:   store  $(c, w_{\max})$  if  $\mathcal{M} \neq \emptyset$ 
7: end for
8: return the median of  $c \times w_{\max}$  for stored tuples
```

---

---

**Algorithm 2** WEIGHTMCCORE( $\phi, u, \text{pivot}, \theta, w_{\max}$ )

---

```
1:  $i \leftarrow 0$ ;  $\text{vol} \leftarrow 0$ ;  $n \leftarrow$  number of variables in  $\phi$ 
2: repeat
3:    $i \leftarrow i + 1$ 
4:   Choose  $h \xleftarrow{R} \mathcal{H}_{\text{xor}}(n, i, 3)$ 
5:   Choose  $x \xleftarrow{R} \{0, 1\}^i$ 
6:    $(\mathcal{M}, \text{vol}, w_{\max}) \leftarrow \text{BOUNDEDWEIGHTSAT}(\phi, (h(b_1, \dots, b_n) = x), u, \text{pivot}, \theta, w_{\max})$ 
7: until  $(0 < \text{vol}/w_{\max} \leq \text{pivot}$  or  $i = n)$ 
8: if  $(\text{vol}/w_{\max} > \text{pivot}$  or  $\mathcal{M} = \emptyset)$  then return  $(\emptyset, \text{vol}, w_{\max})$ 
9: else return  $(\mathcal{M}, \text{vol} \cdot 2^{i-1}/w_{\max}, w_{\max})$ 
10: end if
```

---

present the essential components of the CFMSV algorithm, called WEIGHTMC. Interested readers are referred to that work for full details. First, given an SMT theory  $\Delta$ , weight function  $w$ , tolerance  $\epsilon$ , confidence  $\delta$  and an upper bound on the tilt  $\theta$ , we compute:<sup>5</sup>

$$\text{WMI}(\Delta, w, \epsilon, \delta, \theta) = \text{WEIGHTMC}(\Delta^-, u, \epsilon, \delta, \theta)$$

where  $u$  is the weight function mapping interpretations to numbers and is calculated using:

$$u(M) = \text{VOL}(M, w).$$

The WEIGHTMC procedure is given in Algorithm 1. Basically, the given parameters  $\delta$  and  $\epsilon$  are used to determine the number of times WEIGHTMCCORE is invoked and the number of cells to induce on  $\mathcal{M}(\Delta^-)$ , respectively. What the procedure returns is the median of the volume estimates, obtained from WEIGHTMCCORE over these iterations. For any given iteration, if no model is found, then the estimates from WEIGHTMCCORE are ignored.

The procedure WEIGHTMCCORE applied to a propositional formula  $\phi$ , detailed in Algorithm 2, partitions models of  $\phi$  into cells. This is achieved by choosing 3-wise independent hash functions, and adding random parity constraints. The resulting logical formula is conjoined with

---

<sup>5</sup>CFMSV's WEIGHTMC procedure also includes a parameter called the *independent support* of a propositional theory  $\phi$  over variables  $\mathcal{B}$ . The support of  $\phi$  is  $\mathcal{B}$ , and the independent support  $\mathcal{I} \subseteq \mathcal{B}$  uniquely determine the truth values of variables from  $\mathcal{B} - \mathcal{I}$ . By choosing hash functions only on the independent support, rather than the full set of variables in  $\mathcal{B}$ , significant performance improvements can be gained. But since this is inessential to understanding the conceptual ideas of the algorithm, we omit further discussion on this matter.

---

**Algorithm 3** BOUNDEDWEIGHTSAT( $\phi, \chi, u, \text{pivot}, \theta, w_{\max}$ )

---

```
1:  $w_{\min} \leftarrow w_{\max}/\theta$ ;  $\text{vol} \leftarrow 0$ ;  $\mathcal{M} = \emptyset$ ;  $\gamma = \phi \wedge \chi$ 
2: repeat
3:    $M \leftarrow \text{SOLVESAT}(\gamma)$ 
4:   if  $M = \text{UNSAT}$  then
5:     break
6:   end if
7:    $\text{CONS} \leftarrow \text{CONSISTENT}(\mathcal{T}, \{l^+ \mid l \in M\})$ 
8:   if  $\text{CONS} = \text{INCONSISTENT}$  then
9:      $\phi \leftarrow \text{ADDBLOCKCLAUSE}(\phi, M)$ 
10:  else
11:     $\mathcal{M} \leftarrow \mathcal{M} \cup M$ 
12:     $\gamma \leftarrow \text{ADDBLOCKCLAUSE}(\gamma, M)$ 
13:     $\text{CACHE}[M] \leftarrow u(M)$  if  $\text{CACHE}[M] = \{\}$ 
14:     $\text{vol} \leftarrow \text{vol} + \text{CACHE}[M]$ 
15:     $w_{\min} \leftarrow \min(w_{\min}, \text{CACHE}[M])$ 
16:  end if
17: until  $\text{vol}/(w_{\min} \cdot \theta) > \text{pivot}$ 
18: return  $(\mathcal{M}, \text{vol}, w_{\min} \cdot \theta)$ 
```

---

$\phi$ , for which BOUNDEDWEIGHTSAT is invoked. The number of iterations of BOUNDEDWEIGHTSAT is bound by the number of propositional variables in  $\phi$ , or when the current tilt exceeds an  $\epsilon$ -based parameter. Among other things, BOUNDEDWEIGHTSAT returns the models of  $\phi$  conjoined with a random parity constraint, and unless this is empty, volume estimates in WEIGHTMCCORE are returned to WEIGHTMC. Both WEIGHTMCCORE and WEIGHTMC are minor adaptations of the procedures from CFMSV in the following sense: in the CFMSV modules, the weights are directly used; for example, line 7 in Algorithm 2 would explicitly refer to  $u(\mathcal{M}) = \sum_{M \in \mathcal{M}} u(M)$ . In our setting, computing  $u(\mathcal{M})$  involves integration which we would not want to repeat for every iteration. Thus, weights of (sets of) models are themselves returned when required. It is easy to see that the analysis of these procedures is unaffected by this adaptation.

Finally, we turn to BOUNDEDWEIGHTSAT in Algorithm 3, where a more significant adaptation of the CFMSV scheme occurs. First, one would observe that, different from CFMSV, the parity constraint  $\chi$  is provided separate from the input formula (for reasons justified below). Nonetheless, the procedure essentially performs a bounded version of model counting on  $\gamma = \phi \wedge \xi$ , as would CFMSV, where a  $(\theta, \epsilon)$ -derived parameter determines this bound. As soon as no model is found, the procedure exits with the current estimates. If a model  $M$  is found, however, unlike CFMSV, we need to additionally ensure the refinement of this assignment is consistent w.r.t. the background theory  $\mathcal{T}$ . If it is not  $\mathcal{T}$ -consistent, then we can prevent this model from being considered for all iterations by adding it as a block clause to our input propositional formula  $\phi$ . (Recall also that such a model would have zero volume, leading to an infinite tilt if it were to be considered.) On the other hand, if it is theory consistent, we compute its volume and then add it as a block clause to  $\gamma$ . (This achieves the model counting of  $\gamma$ .) In particular, we calculate  $u(M) = \text{VOL}(M, w)$  where

$w$  is the actual weight function from the WMI problem, and cache this result. So, integration is performed only once for the model  $M$ . The procedure then returns the total volume of the set of models  $\mathcal{M}$  identified.

What is perhaps interesting to realize of this adaptation of CFMSV is that it also does not affect the analysis of the procedures. Note that, if the problem instance is a propositional theory, then  $\Delta^- = \Delta$ , and line 7 of Algorithm 3 is trivially true because  $\mathcal{T}$  is propositional logic. Consequently, the test in line 8 is trivially false. More formally:

**Proposition 10:** *Suppose  $\phi$  is a propositional formula,  $u$  is a weight function,  $\epsilon, \delta \in (0, 1]$ , and  $\theta$  is an upper bound on the tilt. Then  $\text{WEIGHTMC}(\phi, u, \epsilon, \delta, \theta)$  from CFMSV’s original formulation returns  $c$  iff the current adaptation does.*

This allows us, very easily, to leverage the strong guarantees of CFMSV (our rewording):

**Theorem 11:** [CFMSV] *Suppose  $\phi, u, \epsilon, \delta, \theta$  are as above. Then  $\text{WEIGHTMC}(\phi, u, \epsilon, \delta, \theta)$  is an  $(\epsilon, \delta)$ -algorithm for  $\text{WMC}(\phi, u)$ . Given a SAT-oracle, it runs in time polynomial in  $\log_2(1/\delta), \theta, |\phi|$  and  $1/\epsilon$  relative to the oracle.*

From which we obtain:

**Corollary 12:** *Suppose  $\Delta$  is an SMT theory,  $w$  is a weight function, and  $\epsilon, \delta, \theta$  are as above. Suppose  $u$  is the derived weight function for  $\Delta^-$ . Then,  $\text{WEIGHTMC}(\Delta^-, u, \epsilon, \delta, \theta)$  is an  $(\epsilon, \delta)$ -algorithm for  $\text{WMI}(\Delta, w)$ . Suppose we are given an oracle to the weight function  $u$  and a SAT-oracle. Then,  $\text{WEIGHTMC}(\Delta^-, u, \epsilon, \delta, \theta)$  runs in time polynomial in  $\log_2(1/\delta), \theta, |\Delta^-|$  and  $1/\epsilon$  relative to the oracles.*

Thus, we can inherit existing results for this WMC solver (and perhaps others). The oracle to  $u$  computes the volumes of  $\mathcal{T}$ -consistent models. Each instance of  $\text{VOL}(M, w)$  involves the following (Belle *et al.*, 2015):

**Proposition 13:** *Suppose  $\Delta$  is an SMT theory over continuous variables  $\mathcal{X}$ ,  $M$  a model of  $\Delta^-$ , and  $w$  is as above. Let  $k$  be the maximum degree of the polynomials in  $\{w(l) \mid l \in M\}$ . Then  $\text{VOL}(M, w)$  integrates polynomials of degree  $k \cdot |M|$ .*

Basically, for any model  $M$  of  $\Delta^-$ ,  $\text{VOL}(M, w)$  is formulated as the integration of the polynomial potentials of the literals true at  $M$ , which would be a product of  $|M|$  polynomials, each of degree  $k$ . As mentioned earlier, Baldoni *et al.* (2011) show that when the number of variables is fixed (as determined by  $|\mathcal{X}|$ ), integration is efficient. In practice, moreover, when encoding factored representations and piecewise polynomials, it is often the case that negated atoms are assigned constant weights and so we encounter polynomials of degree  $k \cdot n$  where  $n \ll |M|$ . In essence, what we usually encounter are a small number of polynomial potentials corresponding to atoms that are true in the model.

## 4 EMPIRICAL EVALUATIONS

In this section, we discuss results on an implementation of the approximate inference system. The inference system builds on an implementation of  $\text{WEIGHTMC}$  from CFMSV, which uses  $\text{CRYPTOMINISAT v2}$  to handle XOR clauses efficiently.<sup>6</sup> The  $\text{BOUNDEDWEIGHTSAT}$  module appeals to the Z3 SMT solver v4.3.2 for testing theory consistency,<sup>7</sup> and the  $\text{LATE}$  software v1.6 for computing integrals.<sup>8</sup> All experiments were run using a system with 1.7 GHz Intel Core i7 and 8GB RAM. Moreover, to maintain consistency with CFMSV and their parameterization, experiments were run for  $\epsilon = .8, \delta = .2$  and  $\theta$  was assumed to be 5.

Figure 1: scaling behavior

### 4.1 SCALING BEHAVIOR

In large domains over arbitrary polynomial potentials, approximate inference can be assumed to offer significant savings. To test this, we used a benchmark from our prior work (Belle *et al.*, 2015). In that work, we randomly generated SMT theories and weight functions, involving intricate dependencies and hard constraints. These included weighted sentences of the form:

$$\begin{aligned} x^3 & f_1 \Leftrightarrow [x + 3y \leq 3] \\ .001y^2 - .11y + 2.5 & f_2 \Leftrightarrow [p \vee (x \geq 0 \wedge y \geq 0)] \\ .1 & f_3 \Leftrightarrow (\neg p \vee \neg q) \end{aligned}$$

(that is, the LHS is the weight function for the expression in the RHS) with additional hard constraints of the sort:

$$(f_1 \wedge f_2) \Rightarrow \neg f_3.$$

In our prior work, an exact WMI solver was implemented using a block-clause strategy: in each iteration, if a theory-consistent model is found, a clause over the negations of

<sup>6</sup><http://www.msoos.org/cryptominisat2/>

the literals in the assignment is added as an additional constraint, and in this way, all models are enumerated. Using the above benchmark weighted SMT theories, we plot the approximate WMI system against the exact WMI implementation. To further contrast this to the simpler setting of classical propositional logic, we also ran experiments for an exact WMC and the approximate WMC of CFMSV for the input problem  $\Delta^-$  (that is, the propositional abstraction). Figure 1 illustrates that for small problems, exact computations are usually faster, both in the propositional and SMT setting, the former observation already reported in CFMSV. In large domains, however, exact WMC already fares poorly against the approximate version, and in the WMI setting, exact computations become infeasible, and cannot compete with the approximate module for increasing problem sizes.

## 4.2 REAL-WORLD DATASET

To demonstrate the expressivity and usefulness of the approach in a complex real-world scenario, we consider the following novel application involving conditional queries over arithmetic constraints. It uses a data series released by the UK government that provides average journey time,

speed and traffic flow information on all motorways, known as the Strategic Road Network, in England.<sup>9</sup> Motorways are split into junctions, and each information record refers to a specific junction, day and time period. In the following we consider the 2012 dataset, with over 7 million entries, and focus on the surroundings of the A6 motorway. Figures 2a and 2b show the portion of the network with at most two and three junctions respectively from A6. We extract statistics on journey time across each junction. For the sake of simplicity, we model a junction’s journey time as a uniform distribution between the observed minimum and maximum travel time.

Consider a planning problem for a supply system for motorway service stations. The operations center (located, say, somewhere along A6) receives supply requests from a number of stations, and needs to predict whether the delivery vehicle will be able to reach all stations and return within a certain amount of time. Travel time between every pair of stations, and between stations and the operations center, is computed in terms of shortest paths across the network. We compute shortest paths for both minimum and maximum travel times, so as to get a distribution for the shortest path duration w.r.t. every pair of relevant points (stations and operations center), which, as noted, is uniform between these two extremes. Given a certain route between stations, the probability of completing it within the desired time can be computed by integrating over travel time distributions between consecutive stops. However, the optimal route can not be fixed a-priori (as in standard TSP problems), as the vehicle also performs deliveries between stations and to the center, depending on the current needs. These deliveries enforce various constraints on the allowed routes. The overall probability is thus obtained by summing over all valid routes, given the known constraints.

Consider, for example, the case in which stations at A14, A1304, A43, and A5199 need to be visited before returning to the operations center. Figure 2a depicts this case, showing the portion of the network with at most two junctions away from A6. (The nodes to be visited are colored green.) The probability of beginning from the operations center at 8 a.m. and completing the route by 9 a.m., considering all possible paths, is:

$$\Pr(T < 3600) = 0.765,$$

computed using the approximate WMI module, where  $T$  is the overall time measured in seconds. Now suppose a constraint says that station A14 should be reached only after visiting A1304 (owing to a delivery request between these two stations). The probability then needs to be updated according to this evidence, which rules out part of the possible routes. Nonetheless, the probability of completing the task is almost unchanged:

$$\Pr(T < 3600 \mid t_{A14} > t_{A1304}) = 0.770,$$

<sup>9</sup><http://data.gov.uk/dataset/dft-eng-srn-routes-journey-times>

Figure 3: Probabilistic reasoning about the Strategic Road Network surrounding motorway A6. Figures 3a-3c plot cycle lengths of 5 (dotted red), 6 (finely dotted blue) and 7 (solid green), relating constraints to time, problem size and volume computations respectively.

where the minor increase is due to some slightly suboptimal routes being disallowed. Suppose further an additional constraint specifies that station A1304 should not be visited before 8:30 a.m. (say, because the package to deliver will not be available until then). This additional evidence brings success probability down to:

$$\Pr(T < 3600 \mid t_{A14} > t_{A1304} \wedge t_{A1304} \geq 1800) = 0.557.$$

Finally, suppose a last constraint were to require the station A5199 to be also visited after 8:30 a.m. (say, when a package to be delivered to the operations center will be made available). This additional constraint makes it infeasible to complete the route in the required time:

$$\Pr(T < 3600 \mid t_{A14} > t_{A1304} \wedge t_{A1304} \geq 1800 \wedge t_{A5199} \geq 1800) = 0.$$

Note that for such carefully constructed small-size problems in the 2-neighborhood case, exact and approximate procedures return the very same results in about the same time. (The exact procedure, however, quickly becomes infeasible for increasing cycle lengths.)

Using this example, which is to be seen as a cycle of length 5: A6–A14–A1304–A43–A5199–A6, as a template we randomly generated a number of test problems on the more complex 3-neighborhood setting, and plot an excerpt on extensive results on the dataset. These test problems are diverse in their modeling power: ranging from inequality constraints (e.g.,  $t_{A5199} \geq 1800$ ) to ordering constraints (e.g., A5199 after A1304), and Boolean combinations thereof, often leading to more than 300 complex SMT formulas. (Intuitively, if a SMT formula has  $n$  SMT literals, these can possibly denote joint piecewise potentials of  $n$  continuous random variables.) The figures depict the behaviors for cycles of length 5, 6 and 7, ordered by constraints against the time taken, the problem size (which is the number of complex SMT formulas in the theory), and the number of calls of  $\text{VOL}(\cdot, \cdot)$ . Besides demonstrating the

scalability of approximate WMI in such a setting, one also observes that while additional constraints increases the size of the theory, and thus, the number of random variables and volume computations, the time taken for conditional queries does not necessarily increase because suboptimal paths are eliminated (and so, marginalization is easier). To the best of our knowledge, a probabilistic inference system for hybrid specifications against intricate Boolean combinations of propositional and arithmetic constraints has not been deployed on such a scale previously.

## 5 CONCLUSIONS

We introduced a novel way to leverage a fast hashing-based approximate WMC methodology for inference with discrete and continuous random variables. On the one hand, SAT technology can now be exploited in challenging inference and learning tasks in hybrid domains. On the other, strong tolerance-confidence guarantees can be inherited in this more complex setting. WMI and weighted SMT theories allow a natural encoding of hybrid graphical networks while also admitting the specification of arithmetic constraints in conditional queries, all of which are difficult to realize in traditional representations. We demonstrated its practical efficacy in a complex novel application, and we believe, in general, the ideas of our approach would put hybrid domains within the reach of other WMC solvers.

## Abstract

We address the problem of learning Bayesian networks from discrete, unmatched case-control data using specialized conditional independence tests. Those tests can also be used for learning other types of graphical models or for feature selection. We also propose a post-processing method that can be applied in conjunction with any Bayesian network learning algorithm. In simulations we show that our methods are able to deal with selection bias from case-control data.

## 1 INTRODUCTION

Most Bayesian network learning algorithms assume i.i.d. data. In many studies, such as **case-control** studies, this is not the case. In case-control studies data are selected based on one or multiple variables, usually using a comparable number of samples from different values of those variables, leading to non i.i.d. data. Such data are also called **artificially balanced** in the machine learning literature. Case-control sampling is often used in epidemiological or biomedical studies [Breslow, 1996], particularly when studying a disease that is relatively rare. Their goal is usually to identify differences between patients (cases) and healthy individuals (controls), such as identifying differentially expressed genes between the two groups from gene expression data. Case-control sampling is especially important when cases are very rare, as much fewer samples have to be collected compared to cross-sectional studies, significantly reducing the time and cost for obtaining the data.

We address the problem of learning Bayesian networks from discrete case-control data. This is challenging because case-control data do not necessarily represent a sample from the general population. In general, non i.i.d. sampling may lead to **selection bias**, which could alter the (conditional) independence relations in the data; case-

control sampling is a special case of such sampling. Because of that, one cannot usually use methods designed for i.i.d. data.

To the best of our knowledge, there has been only one previous approach to learn Bayesian networks from case-control data by Cooper [2000]. The idea is to use a Bayesian method to integrate over all possible values for all non-sampled cases and controls, assuming that those numbers are known a priori. This method is very impractical, mainly due to its high computational cost. There is a vast literature on methods for case-control data ([Rothman et al., 2008] contains a review of many methods, as well as relevant references) but they are mostly concerned with modeling the outcome (on which selection is based on), and thus are not applicable for modeling other measured variables or for Bayesian network learning.

Learning from case-control data is important for the following reasons. First, a lot of case-control datasets have accumulated over the years and such methods could be used to identify novel associations or possibly even causal relations. For instance, the NCBI GEO database contains thousands of biological datasets [Edgar et al., 2002, Barrett et al., 2013], many of which stem from case-control studies. In addition, this would allow co-analysis of data collected under different experimental designs. Currently, there exist several methods for learning causal networks from multiple heterogeneous datasets [Cooper and Yoo, 1999, Tillman and Spirtes, 2011, Hyttinen et al., 2013, Triantafillou and Tsamardinos, 2014]. Those methods are able to use observational and experimental i.i.d. data. Extending them for other types of data, such as case-control data, is a natural next step.

In this paper we define the problem and show the implications of case-control sampling on the observed independencies. We propose different conditional independence tests for discrete data, as well as a post-processing method that can be used with any Bayesian network learning algorithm. Finally, we investigate the behavior of our methods in various, simulated experiments and show that they are able to handle selection bias from case-control data.

## 2 PRELIMINARIES

We will briefly introduce the basic theory and notation used throughout the paper. Interested readers may refer to Pearl [2000] or Spirtes et al. [2000].

We use upper-case and lower-case letters to refer to random variables (e.g.  $X$ ) and values of those variables (e.g.  $x$ ), and bold letters to refer to sets of variables or values. Let  $\mathbf{V}$  be a set of random variables. A **Bayesian Network** (BN) over  $\mathbf{V}$  is a pair  $\mathcal{B} = \langle \mathcal{G}, \mathcal{P} \rangle$ , where  $\mathcal{G}$  is a **Directed Acyclic Graph** (DAG) representing conditional independencies between variables  $\mathbf{V}$ , and  $\mathcal{P}$  is the joint probability distribution of  $\mathbf{V}$ . We will use the terms variable and node interchangeably. The graph and distribution are connected through the **Markov Condition**: a variable is conditionally independent of all its non-descendants given its parents. The **skeleton**  $\mathcal{G}_S$  of a BN  $\mathcal{G}$  is the undirected graph which can be constructed by ignoring the orientations of  $\mathcal{G}$ . A triple of nodes  $\langle X, Y, Z \rangle$  is called a **collider** in  $\mathcal{G}$ , if  $X \rightarrow Y \leftarrow Z$  is in  $\mathcal{G}$ . Two variables  $X$  and  $Y$  are  **$d$ -separated** given a (possibly empty) set of variables  $\mathbf{Z}$  if and only if for all paths between  $X$  and  $Y$  one of the following is true: (a) there is a collider  $U \rightarrow V \leftarrow W$  on that path and neither  $V$  nor any of its descendants is in  $\mathbf{Z}$ , or (b) there is a consecutive triple  $\langle U, V, W \rangle$  that is not a collider and  $V$  is in  $\mathbf{Z}$ . If  $X$  and  $Y$  are not  $d$ -separated given  $\mathbf{Z}$  they are  **$d$ -connected**. We assume the **Faithfulness Condition** that (together with the Markov Condition) implies that *there is a  $d$ -connecting path between  $X$  and  $Y$  given  $\mathbf{Z}$ , if and only if  $X$  and  $Y$  are statistically dependent given  $\mathbf{Z}$* . We denote conditional dependence and independence of two variables  $X$  and  $Y$  given  $\mathbf{Z}$  as  $Dep(X; Y | \mathbf{Z})$  and  $Ind(X; Y | \mathbf{Z})$  respectively.

## 3 PROBLEM DEFINITION

In this work we consider discrete data from **unmatched case-control** studies. In unmatched studies samples are assumed to be sampled in an i.i.d. fashion from the respective subpopulations. We assume that the data have been selected based on a set of *measured* variables  $\mathbf{T}$ ; we will call those variables **selection variables**. In case  $\mathbf{T}$  contains only a single variable, we will refer to it as  $T$ . We denote with  $S$  a binary variable that indicates whether a sample has been selected or not. In our case, we assume that  $S$  only depends on  $\mathbf{T}$ ; their relation can be modeled by nodes with directed edges from each  $\mathbf{T}$  to  $S$ .

**Assumption 1.**  $S$  depends only on  $\mathbf{T}$  and all variables in  $\mathbf{T}$  have been measured.

Case-control sampling induces a type of **selection bias**. Selection bias arises if samples are less probably to be sampled based on some criteria. When analyzing such data it may happen that **spurious dependencies** are identified which do not exist in the general population, but are

Figure 1: Conditioning on  $S = 1$  introduces a spurious dependence between  $X$  and  $Y$ .

due to the selection process. The reason for that is that the data  $\mathcal{D}$  are collected from the conditional distribution  $P(\mathcal{D} | S = 1)$ . Consider the example shown in Figure 1. Although  $X$  and  $Y$  are independent in the general population, a naive analysis that does not account for the sampling process would identify a spurious dependence between them. This happens because the data are selected conditional on  $S = 1$ ,  $d$ -connecting  $X$  and  $Y$  through  $T$ , as  $S$  is a descendant of  $T$  and  $T$  is a collider on the path  $X \rightarrow T \leftarrow Y$ .

The question is if and when it is possible to estimate the joint probability distribution of a set of variables  $\mathbf{X}$  in the general population,  $P(\mathbf{X})$ , from data collected with case-control sampling, that is following  $P(\mathbf{X} | S = 1)$ . Bareinboim et al. [2014] address the general problem of recoverability of conditional distributions when data are collected under selection. They show that the conditional distribution  $P(Y | X)$  is not recoverable when data are collected with case-control sampling. This result can be trivially extended to the case of estimating the joint distribution of a set of variables. Fortunately, they show that it is possible to recover the population distribution if the joint distribution of  $\mathbf{T}$  is known. Then,  $P(\mathbf{X})$  can be estimated as follows.

$$\begin{aligned} P(\mathbf{X}) &= \sum_{\mathbf{t}} P(\mathbf{X} | \mathbf{T} = \mathbf{t}) P(\mathbf{T} = \mathbf{t}) \\ &= \sum_{\mathbf{t}} P(\mathbf{X} | \mathbf{T} = \mathbf{t}, S = 1) P(\mathbf{T} = \mathbf{t}) \end{aligned} \quad (1)$$

The second equality follows by Assumption 1. The conditional probability  $P(\mathbf{X} | \mathbf{T} = \mathbf{t}, S = 1)$  can be directly estimated from  $\mathcal{D}$ . Thus, in order to estimate  $P(\mathbf{X})$  for any set of variables we only need the joint probability distribution of  $\mathbf{T}$  in the general population. This could either be provided as prior knowledge by a domain expert or from the literature, or estimated from an external data source.

**Assumption 2.** The joint probability distribution of  $\mathbf{T}$  in the general population is known.

Notice that there are cases where the equality  $P(\mathbf{X}) = P(\mathbf{X} | S = 1)$  holds. For example, if none of the variables in  $\mathbf{X}$  is dependent with  $\mathbf{T}$ ,  $P(\mathbf{X})$  can be directly estimated from  $\mathcal{D}$ . We will further investigate the conditions under which this holds in the next section.

We conclude with some comments on our assumptions. Assumption 1 is reasonable and probably holds for most case-control studies. In case it is violated additional spurious dependencies may be introduced. Regarding Assumption 2: although it may be restrictive in some cases, prior information about the joint distribution is often available. In fact, many methods for analyzing case-control data require such prior information. For example, in logistic regression models for an outcome that has been selected on (e.g. disease), such knowledge is necessary in order to estimate the intercept of the model, although it is not needed in order to estimate the remaining parameters [Breslow and Day, 1980].

## 4 IMPLICATIONS OF CONDITIONING ON S

In the previous section we saw an example where conditioning on  $S = 1$  introduces a spurious dependence. Next, we will further investigate how the dependencies and independencies are affected after conditioning on  $S = 1$ . Most of those results are based on previous results by Spirtes et al. [2000] (see Section 9.3). Those results are general, allowing for  $S$  to be in any position in the graph. We will show their consequences for the special case of case-control sampling.

First we investigate whether conditioning on  $S = 1$  removes any dependencies that exist in the general population. Spirtes et al. [2000] have characterized all situations where this happens.

**Corollary 1** (Adapted from [Spirtes et al., 2000]). *If  $Dep(X; Y|\mathbf{Z})$ , then  $Ind(X; Y|\mathbf{Z}, S = 1)$  holds if and only if there exists a path  $U$  between  $X$  and  $Y$  such that (a) every collider on  $U$  has a descendant in  $\mathbf{Z}$ , (b) no non-collider in  $U$  is in  $\mathbf{Z}$ , and (c)  $S$  is a non-collider on every such path.*

In our case there is no such path because the third condition can never be satisfied, as  $S$  does not have any outgoing edges. Because of that,  $S$  can only be a collider on all such paths. Therefore, *conditioning on  $S = 1$  does not remove any dependencies.*

The next corollary characterizes the cases where a conditional independence may turn into a dependence.

**Corollary 2** (Adapted from [Spirtes et al., 2000]). *If  $Ind(X; Y|\mathbf{Z})$ , then  $Dep(X; Y|\mathbf{Z}, S = 1)$  holds if and only if there exists a path  $U$  between  $X$  and  $Y$  such that (a) no non-collider on  $U$  is in  $\mathbf{Z} \cup \{S\}$ , (b) every collider on  $U$  has a descendant in  $\mathbf{Z} \cup \{S\}$ , and (c) some collider on  $U$  does not have a descendant in  $\mathbf{Z}$ .*

Based on this result, we will characterize all cases where a spurious dependence will appear in the graph after conditioning on  $S = 1$  that cannot be removed by conditioning

on any set of variables. We proceed by stating and proving the result.

**Theorem 1.** *Let  $X, Y$  be two variables. If  $\exists \mathbf{Z} Ind(X; Y|\mathbf{Z})$ , then  $\forall \mathbf{Z}' Dep(X; Y|\mathbf{Z}', S = 1)$  holds if and only if there is a node  $W$  such that (a)  $X \rightarrow W \leftarrow Y$ , and (b)  $W = S$  or  $W$  is an ancestor of  $S$ .*

*Proof.*

**Sufficiency:** Follows trivially, as conditioning on  $S$  d-connects  $X$  and  $Y$  through  $W$ .

**Necessity:** We will show this by contradiction. Assume that there is no  $W$  satisfying both conditions. From Corollary 2 we know that for some  $\mathbf{Z}$  satisfying both  $Ind(X; Y|\mathbf{Z})$  and  $Dep(X; Y|\mathbf{Z}, S = 1)$ , there is a path  $U$  between  $X$  and  $Y$  with at least one collider  $V$  on  $U$  that is also an ancestor of  $S$ . The only case where this holds is if there is at least one node between  $X$  and  $V$  or  $Y$  and  $V$  on  $U$ . But then at least one of those nodes has to be a non-collider and we could d-separate  $X$  and  $Y$  by conditioning on any such noncollider, contradicting our assumptions.  $\square$

In words, this theorem characterizes all cases where two variables  $X$  and  $Y$  can be d-separated in the population graph, but cannot d-separated by any set after conditioning on  $S$ . We will later use this to learn Bayesian networks from case-control data.

## 5 CONDITIONAL INDEPENDENCE TESTING

As we saw in the previous section, conditioning on  $S$  may introduce spurious dependencies in the data. Because of that, one cannot use independence tests designed for i.i.d. data. In this section we will describe various conditional independence tests for case-control data.

### 5.1 TEST STATISTIC

As a test statistic we consider the conditional mutual information (CMI)  $I(X; Y|\mathbf{Z})$ , which is defined as:

$$I(X; Y|\mathbf{Z}) = \sum_{x, y, \mathbf{z}} P(x, y, \mathbf{z}) \log \frac{P(x, y, \mathbf{z})P(\mathbf{z})}{P(x, \mathbf{z})P(y, \mathbf{z})} \quad (2)$$

Assuming that we know the distribution of  $\mathbf{T}$ , we can use Equation 1 to compute  $I(X; Y|\mathbf{Z})$  for any variables  $X, Y$  and  $\mathbf{Z}$ . For the case of i.i.d. data the CMI is closely related to the  $G$ -statistic used by the  $G$ -test:

$$G(X; Y|\mathbf{Z}) = 2 \cdot N \cdot I(X; Y|\mathbf{Z}) \quad (3)$$

where  $N$  is the sample size. Under the null hypothesis this statistic is asymptotically  $\chi^2$  distributed with  $(|X| - 1)(|Y| - 1)|Z|$  degrees of freedom.

Unfortunately, the  $G$ -test cannot be trivially applied to case-control data. Intuitively, the reason is that  $N$  case-control samples are not always equivalent to  $N$  samples from an i.i.d. dataset. We will show the intuition behind this with an example <sup>1</sup>.

**Example 1.** Assume that  $\mathbf{T}$  contains a single binary variable  $T$  and we sample  $N = 1000$  samples, 500 for each value of  $T$ , and that  $P(T = 0) = 0.2$ . The probability of  $\mathbf{X}$  given by Equation 1 is  $P(\mathbf{X}) = P(\mathbf{X}|T = 0) \cdot 0.2 + P(\mathbf{X}|T = 1) \cdot 0.8$ . If we use  $N$  as our sample size, we essentially assume that we have estimated  $P(\mathbf{X}|T = 0)$  and  $P(\mathbf{X}|T = 1)$  using 200 and 800 samples respectively even though we used 500 for each of them. As a result, we **overestimate and underestimate the variance in the estimation of  $P(\mathbf{X}|T = 1)$  and  $P(\mathbf{X}|T = 0)$  respectively, which can lead to false results.**

Next we consider various strategies to deal with this.

## 5.2 UNDERSAMPLING

The trivial approach is to use a subset of the samples such that the proportion of values of  $\mathbf{T}$  in the resulting dataset coincides with the distribution of  $\mathbf{T}$ . For Example 1 we could use 125 samples with  $T = 0$  and 500 samples with  $T = 1$ , as  $125/625 = 0.2$  and  $500/625 = 0.8$ , and perform a standard independence test. In general, one can use at most  $N = \min_{\mathbf{t}} N(\mathbf{T} = \mathbf{t}) / P(\mathbf{T} = \mathbf{t})$  samples, where  $N(\mathbf{T} = \mathbf{t})$  is the number of samples with  $\mathbf{T} = \mathbf{t}$  (proof omitted).

There are several downsides to this approach. First, undersampling often ignores a significant amount of samples (375 in the previous example), possibly reducing the power of the test. Second, the result may vary a lot, depending on the selected samples. One possibility to reduce this variance is to create multiple datasets by undersampling, perform a test on each such dataset and combine the results somehow (e.g. taking the median p-value). Finally, undersampling may be problematic if the marginal distribution of  $T$  contains extreme values. In the previous example, if  $P(\mathbf{X}|T = 0)$  was 0.01, only 5 samples with  $T = 0$  could be used to (approximately) satisfy the marginals. In practice, those values will often be even more extreme.

## 5.3 A PERMUTATION TEST

Permutation tests are non-parametric procedures for statistical significance testing. The basic idea is that, under the

<sup>1</sup>We have also conducted several, anecdotal simulations which confirm this problem.

null hypothesis, one can permute the data in an appropriate way to generate another, permuted dataset. *Specifically, for a permutation test to be exact, the permutation has to be performed in a way that preserves the distribution of the observations under the null hypothesis* [Good, 2004]. Then, the test statistic computed on that dataset is a sample from its null distribution. Because the number of all permutations is usually astronomically large, making complete enumeration infeasible, one usually resorts to Monte Carlo approximations that sample a relatively small number of permutations (usually between 1000 and 10000). The  $p$ -value is computed as the proportion of permutation statistics that are at least as extreme as the statistic on the original data.

**Permutation Testing for Discrete Data.** For conditional independence testing the null hypothesis is that  $X$  and  $Y$  are conditionally independent given  $\mathbf{Z}$ . This means that conditional independence holds for any value  $\mathbf{z}$  of  $\mathbf{Z}$ . A permuted dataset can be created by randomly permuting the columns of  $X$  and  $Y$  for each value  $\mathbf{z}$  of  $\mathbf{Z}$  [Tsamardinos and Borboudakis, 2010]. For example, if  $Z$  is a binary variable, a permuted dataset is created by splitting the original dataset  $\mathcal{D}$  into two datasets,  $\mathcal{D}_{Z=0}$  and  $\mathcal{D}_{Z=1}$ , randomly permuting the columns of  $X$  and  $Y$  on each of them and then combining the resulting datasets. This results in an exact test, as the conditional distribution of  $X$  and  $Y$  for each value of  $\mathbf{Z}$  remains fixed.

We use the same procedure for discrete case-control data using the CMI as our test statistic. It is important to note that *this permutation approach does not always preserve the distribution of  $X$  and  $Y$  under the null* when applied to case-control data. We show this with the following example. Let  $X$  be a discrete variable,  $T$  a binary variable and  $P(T = 0) = 0.2$ . Now, assume that for some value  $x$  of  $X$  we have 100 samples with  $T = 0$  and 50 samples with  $T = 1$  in the original dataset, and 50 and 100 respectively for some permuted dataset. Then,  $P(x) = 100/500 \cdot 0.2 + 50/500 \cdot 0.8 = 0.12$  for the original dataset but  $P(x) = 50/500 \cdot 0.2 + 100/500 \cdot 0.8 = 0.18$  for the permuted dataset. Let  $Y$  be another discrete variable with the same marginals as  $X$ . Then, the joint distribution of  $X$  and  $Y$  under the null is  $P(x, y) = 0.12 \cdot 0.12$  in the original dataset and  $P(x, y) = 0.18 \cdot 0.18$  in the permuted dataset. Thus, their joint distribution under the null is not invariant for this type of permutations.

We conducted various simulations to investigate the behavior of this test and, although this approach does not result in an exact test, they suggest that it works reasonably well in practice; the results are presented in Section 7.

## 5.4 AN ASYMPTOTIC TEST

An interesting observation that we made is that, under the null hypothesis, the permutation distribution of the  $G$ -

---

**Algorithm 1** Estimate Effective Sample Size

---

**Input:**  $P(\mathbf{T}), N(\mathbf{T}), N, K$ **Output:**  $N_{ESS}$

  - 8:  $N_{ESS} \leftarrow \text{Median}(1/2 \cdot Stats' / Stats)$
  - 9:  $N_{ESS} \leftarrow \text{Min}(N_{ESS}, N)$
- 

statistic computed on the case-control data, for some unknown number of samples  $N$ , seems to also follow a  $\chi^2$  distribution with  $(|X| - 1)(|Y| - 1)|\mathbf{Z}|$  degrees of freedom. We observed this behavior for a large number of different: (i) conditional and unconditional tests, (ii) probability distributions of  $\mathbf{T}$ , and (iii) types of discrete variables  $X$ ,  $Y$  and  $\mathbf{Z}$ . We conjecture that this is always the case.

**Conjecture 1.** *The  $G$ -statistic  $G(X; Y|\mathbf{Z})$  as defined by Equation 3 and computed for case-control data using Equations 1 and 2 is asymptotically distributed as a  $\chi^2$  random variable with  $(|X| - 1)(|Y| - 1)|\mathbf{Z}|$  degrees of freedom for some unknown number of samples  $N$ .*

We will call this unknown number of samples the **effective sample size** and denote it as  $N_{ESS}$ . Based on this conjecture, we will devise a simple procedure to estimate  $N_{ESS}$ .

Let  $\mathcal{D}$  be a dataset obtained from case-control sampling,  $P(\mathbf{T})$  be the joint distribution of  $\mathbf{T}$ ,  $N(\mathbf{T})$  be the number of samples in  $\mathcal{D}$  for each value of  $\mathbf{T}$ , and  $N$  be the total number of samples in  $\mathcal{D}$ . Suppose that we generate a large number  $K$  of independent random variables  $X$  and  $Y$ , each of  $N$  samples, assuming that the first  $N(\mathbf{T} = \mathbf{t}_0)$  samples correspond to  $\mathbf{T} = \mathbf{t}_0$ , the next  $N(\mathbf{T} = \mathbf{t}_1)$  to  $\mathbf{T} = \mathbf{t}_1$  and so on, and then compute their mutual information. Let  $Stats$  contain all statistics in ascending order. If  $K$  is large enough we would expect the  $i$ -th value in  $Stats$ ,  $Stats_i$ , to correspond to a  $p$ -value of  $i/(K - 1)$ . According to Conjecture 1 the  $G$ -statistic for some  $N_{ESS}$  of any two independent random variables follows a  $\chi^2$  distribution. Thus, for each such  $p$ -value, we can use the inverse  $\chi^2$  cumulative distribution to compute its corresponding statistic  $Stats'$ . We know that  $Stats_i = I(X_i; Y_i)$  and that  $Stats'_i \simeq 2 \cdot N_{ESS} \cdot I(X_i; Y_i)$ . Thus, we can estimate  $N_{ESS}$  as  $N_{ESS} \simeq 1/2 \cdot Stats'_i / Stats_i$ . Because the procedure is not exact, we suggest to compute this value for each pair of  $Stats$  and  $Stats'$  values, and use the median value as an estimate for  $N_{ESS}$ . Naturally, this value cannot be larger than  $N$ , so we use the minimum of those values. The procedure is shown in Algorithm 1.

The method only needs to be applied once before analyzing

a dataset, adding only a constant computational overhead. As a result, the cost of analyzing a case-control dataset is essentially identical to analyzing any other dataset, up to a constant additive factor.

## 6 BAYESIAN NETWORK LEARNING

We propose two different strategies for learning Bayesian networks from case-control data.

One is to use a test suited for case-control data with any existing constraint-based method. This strategy also allows one to learn other graphs such as Maximal Ancestral Graphs [Richardson and Spirtes, 2002], or to perform feature selection using a conditional independence based method [Tsamardinos et al., 2006].

Another approach is to learn a network using an independence test suited for i.i.d. data and perform a **post-processing** step to correct the graph by identifying and removing spurious dependencies using an independence test for case-control data. Theorem 1 characterizes all cases where a spurious dependence will be identified. Of course, we cannot directly apply Theorem 1 as we do not know the real DAG. Instead, we will use the skeleton of the DAG without any orientations. The next corollary characterizes all potentially spurious edges in a skeleton.

**Corollary 3.** *Let  $G_S$  be the skeleton of a DAG  $\mathcal{G}$ . An edge between variables  $X$  and  $Y$  is **potentially spurious**, if and only if there is a node  $W$  such that (a)  $X, Y$  and  $W$  are adjacent and form a triangle, and (b)  $W = S$  or there is a potentially directed path from  $W$  to  $S$  (the path cannot go through  $X$  or  $Y$ ). As  $S$  will not be in  $\mathcal{G}$  we have to check if  $W \in \mathbf{T}$  or if  $W$  is a potential ancestor of any variable in  $\mathbf{T}$ .*

This result follows from Theorem 1 and is stated without proof. This directly suggests how to use it with existing learning algorithms. After identifying  $\mathcal{G}$ , take its skeleton  $G_S$ , check for triples  $X, Y, W$  that satisfy those criteria, and finally try to remove potentially spurious edges by performing a series of independence tests with an appropriate method. Note that  $W$  never has to be conditioned on in those tests as it either is a collider and would  $d$ -connect  $X$  and  $Y$  or, if not, the edge between  $X$  and  $Y$  can not be spurious and should not be removed. The second condition can be checked by removing all edges at  $X$  and  $Y$  and checking whether  $W$  and  $\mathbf{T}$  are connected by a path.

We have to point out that this approach may not be optimal. Instead of the skeleton, there may be a way to partially orient the graph and further narrow down the cases where Corollary 3 applies. For example, if the edge from  $W$  to  $X$  is oriented towards  $X$ , then the edge between  $X$  and  $Y$  cannot be due to a spurious dependence, but applying Corollary 3 on the skeleton will try to remove it. However, this is not trivial; a naive application of the PC rules may

Figure 2: (a) Graphical representation of noisy model. (b) Collider model for the first set of experiments.

result in false orientations due to the presence of spurious edges. We did not further investigate this possibility.

## 7 EXPERIMENTAL EVALUATION

We performed simulations to investigate the behavior of the proposed independence tests in different situations. We consider only a single selection variable  $T$ . When we generate data, we select an equal number of samples for each value of  $T$  (that is,  $T$  is uniformly distributed in the case-control data). For a given Bayesian network we compute the marginal distribution of  $T$  using an exact inference algorithm implemented in the Bayes Net toolbox [Murphy, 2001]. We used  $K = 100000$  to estimate the effective sample size.

First, we evaluate the tests in simple Noisy-MAX and Noisy-SUM scenarios. Then, we investigate the sensitivity of the tests with respect to the prior distribution of  $T$ . Finally, we compare the proposed Bayesian network learning strategies on the INSURANCE network [Binder et al., 1997]. We used MATLAB to conduct the simulations and create the figures (the code is available at <http://www.mensxmachina.org/>).

### 7.1 NOISY-MAX AND NOISY-SUM

We use the model proposed by [Srinivas, 1993], a generalization of the Noisy-OR model [Pearl, 1988], to generate data from a Noisy-MAX or Noisy-SUM distribution. Those models are members of the family of independence of causal influences (ICI) models [Heckerman and Breese, 1994]. A graphical representation of noisy models is shown in Figure 2. The nodes  $X'_i$  are called **inhibitor** nodes and are used to introduce noise in the model. Noisy-MAX distributions in particular are interesting as they have been shown to be very common in practice [Zagorecki and Druzdzel, 2006].

#### 7.1.1 Setup

In all our experiments the inhibitor nodes take the same number of values as their parents and their distribution is:  $P(X'_i = 0 | X_i = 0) = 1$ ,  $P(X'_i = k | X_i = k) = 1 - e$  and

$P(X'_i = k | X_i \neq k) = e / (|X_i| - 1)$ , where  $e$  is the noise parameter. The value of  $W$  is a deterministic function of its parent values (MAX or SUM).

We use two different cases for our evaluation. The first is a simple collider graph (see Figure 2 (b)). Here we test whether  $X$  and  $Y$  are unconditionally independent. We use this to evaluate the ability of the tests to handle the case of spurious dependencies. The second is a chain graph ( $X \rightarrow X' \rightarrow T \rightarrow T' \rightarrow Y$ ), with two additional nodes – inhibitor node pairs, one into  $T$  and one into  $Y$ . For this case we test whether  $X$  and  $Y$  are unconditionally and conditionally independent given  $T$ . This is done to investigate the behavior of the tests in case no spurious dependencies are present.

For the collider case we generated data from the Noisy-MAX and Noisy-SUM distributions, and for the chain graph we generated data from the Noisy-MAX distribution. The parameters we used are: noise  $e \in \{0, 0.3, 0.7\}$ , sample size  $N \in \{250, 1000\}$ , range of values  $r \in \{2, 4\}$  for  $X$  and  $Y$ . We used 6 independence tests:  $G^2$  test, Permutation  $G^2$  test,  $G^2_{cc}$  test for case-control data, Permutation  $G^2_{cc}$  test for case-control data, Undersampling  $G^2_u$  test, Bootstrapping and Undersampling  $G^2_u$  test using the median  $p$ -value. For the permutation tests we used 1000 permutations, and for the bootstrapping test we used 500 samples.

#### 7.1.2 Results

The results for the collider and chain graphs are shown in Figures 3 and 4. In each figure we show the empirical CDF function of the  $p$ -values. In case independence holds, the  $p$ -values should be uniformly distributed and the CDF should be on the diagonal. In case of dependence, we would ideally have low  $p$ -values only. We use  $\text{Test}(X; Y)$  and  $\text{Test}(X; Y | T)$  to refer to the unconditional and conditional tests of  $X$  and  $Y$ . The first and last two columns of each group of figures correspond to data with  $r = 2$  and  $r = 4$  respectively.

**$G^2$  and Permutation  $G^2$ .** For the collider graph both tests identify a spurious dependence, as expected, unless the noise is too high or the sample size is too low. For the chain graph, where case-control sampling does not affect the independencies, both tests perform well. The asymptotic test does not always produce calibrated  $p$ -values for the test  $\text{Test}(X; Y | T)$ , agreeing with previous results [Tsamardinos and Borboudakis, 2010]. The simulations confirm that tests designed for i.i.d. data should not be applied on case-control data.

**$G^2_{cc}$  and Permutation  $G^2_{cc}$**  For the collider graph, both tests produce  $p$ -values close to the ideal uniform distribution (black diagonal line), or overestimate the  $p$ -value; this can be seen especially in the noiseless Noisy-SUM case. Although this is not ideal, it is still useful, as the significance level upper bounds the actual type I error. Unfortu-

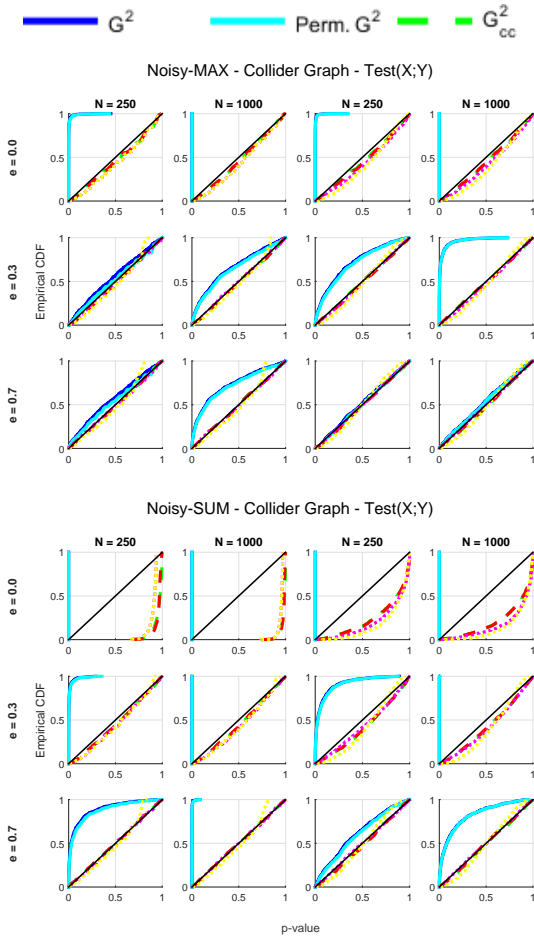

Figure 3: Results for the collider graph.

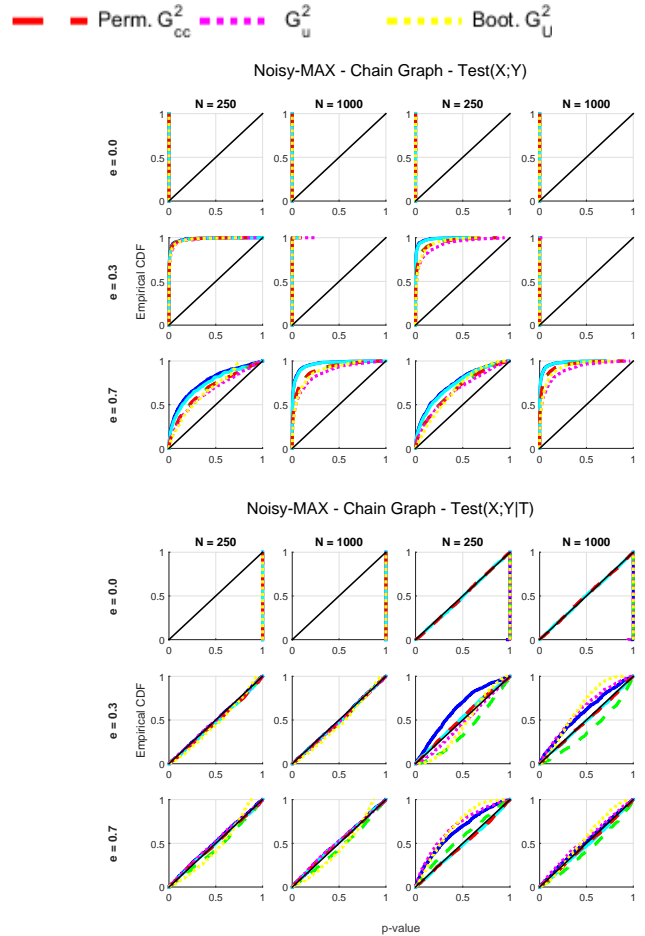

Figure 4: Results for the chain graph.

nately, we were not able to identify the circumstances under which this happens. For the chain graph, both tests perform reasonably well. In comparison to the  $G^2$  and Permutation  $G^2$  tests, the specialized tests have less power. Nevertheless, they will still be useful for network learning using the post-processing method, as it combines the best of both worlds. Again, the permutation test produces calibrated  $p$ -values for  $\text{Test}(X; Y|T)$ , whereas the asymptotic one does not.

**$G^2_u$  and Bootstrapping  $G^2_u$ .** Again, both tests perform similarly to the other specialized tests. However, undersampling exhibits a large variance, as it highly depends on the selected samples. The bootstrapping version reduces this variance, but its distribution has a heavy tail close to one. This bias may be the result of taking the median  $p$ -value. We discourage the use of the bootstrapping method, but there may be other similar approaches that do not exhibit this behavior.

**Comparison of  $G^2_{cc}$  and Permutation  $G^2_{cc}$**  Figure 5 (a,b) shows that the  $G^2_{cc}$  and Permutation  $G^2_{cc}$  produce almost identical  $p$ -values on the unconditional tests. In Figure 5

(c,d) we compare the asymptotic and permutation tests for the conditional case with noisy data and  $r = 4$  (Figure 4, bottom right). We see that in this case the  $G^2_{cc}$  does not produce the same  $p$ -values as the permutation  $G^2_{cc}$  test. However, the same behavior can be observed for the standard  $G^2$  test and the permutation  $G^2$  test. Also, for both cases, the  $p$ -values of the asymptotic tests are highly correlated with the ones of the permutation tests. The results suggest that the  $G^2_{cc}$  test is a reasonable approximation to the permutation version.

## 7.2 SENSITIVITY TO $P(T)$

We conducted a small experiment to investigate the sensitivity of the tests to the distribution of  $T$ . We simulated 1000 datasets from a Noisy-MAX collider graph with binary variables  $X$  and  $Y$ , with  $e = 0$  and  $N \in \{250, 1000\}$ . The distribution of  $T$  is  $P(T = 0) = 0.25$  and  $P(T = 1) = 0.75$  and we selected 500 samples for each value of  $T$ . In order to measure the sensitivity of the methods to the specified marginal distribution we computed the area under the empirical CDF of the  $p$ -values. Values close to 0.5

Figure 5: Comparison of the  $p$ -values from the  $G^2_{cc}$  and Permutation  $G^2_{cc}$  tests (a) on all tests for the collider graph (b) on the unconditional tests for the chain graph. Comparison on noisy data with  $r = 4$  of (c)  $G^2_{cc}$  vs Permutation  $G^2_{cc}$  (d)  $G^2$  vs Permutation  $G^2$ .

Figure 6: Sensitivity of methods to prior distribution.

indicate that the  $p$ -values are uniformly distributed (this is not always true, but should be reasonable in our case due to the convexity/concavity and monotonicity of the CDF; see Figure 3 for  $e = 0$  and  $N = 1000$ ). The results are summarized in Figure 6. We only show results from  $P(T = 0) = 0$  to  $0.5$ . We see that the methods are sensitive to the correct specification of the prior distribution, and that their sensitivity highly depends on the sample size. For  $N = 250$ , small deviations are acceptable, whereas for  $N = 1000$  even deviations of  $0.05$  significantly reduce the ability of the tests to detect spurious dependencies. Of course, this can not be generalized and it may highly vary for different distributions, but it indicates that those methods have to be used with care.

### 7.3 INSURANCE NETWORK

We evaluated our methods on the INSURANCE network [Binder et al., 1997]. It contains 27 nodes and 52 edges. This network is appropriate for our purposes as it has many nodes for introducing spurious dependencies that also have

Table 1: Characteristics of the selection variables. The second row shows the number of spurious dependencies induced by selecting on those variables. The last four rows show their marginal distribution.

| Node       | 18    | 19    | 20      | 21    | 25    | 26    |
|------------|-------|-------|---------|-------|-------|-------|
| Spurious   | 6     | 13    | 6       | 14    | 9     | 5     |
| $P(T = 0)$ | 0.001 | 0.788 | 0.844   | 0.541 | 0.888 | 0.965 |
| $P(T = 1)$ | 0.999 | 0.09  | 0.08    | 0.286 | 0.054 | 0.018 |
| $P(T = 2)$ | -     | 0.09  | 0.077   | 0.12  | 0.036 | 0.011 |
| $P(T = 3)$ | -     | 0.032 | 1.2e-05 | 0.052 | 0.023 | 0.007 |

relatively extreme distributions.

#### 7.3.1 Setup

We selected 6 nodes from the INSURANCE network as selection variables. The selection variables as well as their characteristics are shown in Table 1.

**Algorithms.** For Bayesian network learning we used the PC algorithm with Heuristic 3, as described in [Spirtes et al., 2000] (Section 5.4.2), except with an additional modification that sets an upper limit on the size of the conditioning set for each test. This is necessary especially for lower sample sizes, as conditioning on many variables tends to give very high  $p$ -values. In our simulations we set that parameter to 3 (maximum in-degree in the network). The significance level was set to  $0.05$  for all tests. We used 5 different methods to learn the network from case-control data: (a)  $G^2$  test, (b)  $G^2_{cc}$  test for case-control data, (c) Undersampling  $G^2_u$  test, (d)  $G^2$  test + post-processing with  $G^2_{cc}$  and (e)  $G^2$  test + post-processing with  $G^2_u$ . Methods (a-c) did not apply the post-processing step. Whenever the  $G^2_u$  test was used, undersampling was performed only once for each dataset. In addition, we also ran the PC algorithm with the  $G^2$  test on i.i.d. data to compare our methods against (Reference). The reference results should be close to the best achievable performance for a given sample size.

**Data.** Again, we generated data with equal proportions of each value of  $T$ . For each selection variable, as well as for the reference case, we generated 100 datasets for each of three different sample sizes  $N \in \{1000, 10000, 100000\}$ .

#### 7.3.2 Results

The results are summarized in Table 2. For each method we report the extra edges (“+”) and missing edges (“-”), averaged over all 100 runs.

**PC with  $G^2$  test.** We observe that ignoring the sampling and using PC with the standard  $G^2$  test performs very well for  $N = 1000$  and does not identify many spurious edges. However, as expected, it identifies a significant amount of extra edges with larger sample sizes.

**PC with  $G^2_{cc}$  and  $G^2_u$  tests.** The case-control tests with

out post-processing identify fewer extra edges at the cost of missing some edges. This happens both, because they are conservative and because of lower power than their i.i.d. counterparts, as we saw in previous experiments. Again, this improves with more samples but they do not seem to significantly outperform the  $G^2$  test, at least in those experiments. Increasing the significance level may improve the situation.

**PC with  $G^2$  test + post-processing with  $G_{cc}^2$  and  $G_u^2$  tests.** The best results, in terms of total number of errors, are achieved when post-processing is applied. For  $N = 1000$  they perform similarly to the  $G^2$  method without post-processing. This is expected, as the first step does not identify many extra edges and thus, post-processing is rarely applied. For larger sample sizes almost no spurious edges are identified, but a few more edges than  $G^2$  without post-processing are missed. This happens because the post-processing rule is erroneously applied to edges that are not due to spurious dependencies and removes them.

Compared to the previous two methods without post-processing, slightly more edges are found but fewer edges are missed. This agrees with the simulations on the simple collider and chain graphs, which showed that the  $G^2$  test is more powerful and therefore misses fewer edges than the  $G_u^2$  and  $G_{cc}^2$  tests.

Finally, the results are similar to the reference results, demonstrating the effectiveness of the proposed methods.

**Comparison of  $G_u^2$  and  $G_{cc}^2$ .** In all simulations the  $G_u^2$  test performs very similar to the  $G_{cc}^2$  test, with the latter being marginally better on average. Note however that averaging may hide the variance of the  $G_u^2$  test. In any case, undersampling is an alternative that can be generalized to other types of data, and should be further investigated.

## 8 CONCLUSION

We proposed methods to learn Bayesian networks from discrete, unmatched case-control data. We showed that one can first learn a network by ignoring the case-control sampling and then apply a post-processing step to remove spurious edges using a specialized test for case-control data. To do this the joint distribution of the selection variables must be available. In case it is not correctly specified the tests may fail to remove spurious edges. Finally, the trivial approach of undersampling seems to be a reasonable alternative, with the advantage that it easily generalizes to other types of data, such as continuous data with discrete selection variables. A drawback however is that it exhibits a large variance as it highly depends on the selected samples.

There is a lot of room for improvement and extensions. First, the proposed post-processing method could be improved to reduce the number of false removals of edges. Second, it is important to investigate additional case-control samplings, such as those from matched or nested studies. Finally, devising methods for other types of data, such as continuous data, would further broaden the scope. One possible approach would be to use or extend the ideas by Kuroki and Cai [2006] for recovering the population covariance matrix. Another possibility is to find a way to perform undersampling multiple times and combine the results appropriately.

## Abstract

We propose a family of efficient algorithms for learning the parameters of a Bayesian network from incomplete data. Our approach is based on recent theoretical analyses of missing data problems, which utilize a graphical representation, called the missingness graph. In the case of MCAR and MAR data, this graph need not be explicit, and yet we can still obtain closed-form, asymptotically consistent parameter estimates, without the need for inference. When this missingness graph is explicated (based on background knowledge), even partially, we can obtain even more accurate estimates with less data. Empirically, we illustrate how we can learn the parameters of large networks from large datasets, which are beyond the scope of algorithms like EM (which require inference).

## 1 INTRODUCTION

When learning the parameters of a Bayesian network from data with missing values, the conventional wisdom among machine learning practitioners is that there are two options: use *expectation maximization* (EM) or *gradient methods* (to optimize the likelihood); see, e.g., Darwiche (2009), Koller and Friedman (2009), Murphy (2012), Barber (2012). Both of these approaches, however, suffer from the following disadvantages, which prevent them from scaling to large networks and datasets; see also Thiesson, Meek, and Heckerman (2001). First, they are *iterative*, and hence may need many passes over a potentially large dataset. Next, these algorithms may get stuck in *local optima*, which means that, in practice, one must run these algorithms multiple times with different initial seeds, and hope that one of them leads to a good optimum. Last, but not least, these methods *require inference* in the network, which places a hard limit

---

\*Both authors contributed equally to this work. Gvdb is also affiliated with KU Leuven, Belgium.

on the networks where EM and gradient methods can even be applied, namely for networks where exact inference is tractable, i.e., they have small enough treewidth, or sufficient local structure (Chavira & Darwiche, 2006, 2007).

Recently, Mohan, Pearl, and Tian (2013) showed that the joint distribution of a Bayesian network is recoverable from incomplete data, including data that falls under the classical *missing at random* assumption (MAR), but also for a broad class of data that is not MAR. Their analysis is based on a graphical representation for missing data problems, called the *missingness graph*, where one explicates the *causal mechanisms* that are responsible for the missingness in an incomplete dataset. Using this representation, they provide a way to decide whether a given query (e.g., a joint marginal) is recoverable, and if so, they provide a *closed-form* expression (in terms of the observables) for an asymptotically consistent estimate.

Building on the theoretical foundations set by Mohan et al. (2013), we propose a family of practical and efficient algorithms for estimating the parameters of a Bayesian network from incomplete data. For the cases of both MCAR and MAR data, where the missingness graph need not be explicit, we start by deriving the closed-form parameter estimates, as implied by Mohan et al. (2013). We next show how to obtain better estimates, by exploiting a factorized representation that allows us to aggregate distinct, yet asymptotically equivalent estimates, hence utilizing more of the data. We also show how to obtain improved estimates, when the missingness graph is only partially explicated (based on domain or expert knowledge). As in Mohan et al. (2013), all of our estimation algorithms are asymptotically consistent, i.e., they converge to the true parameters of a network, in the limit of infinite data.

As we show empirically, our parameter estimation algorithms make learning from incomplete data viable for larger Bayesian networks and larger datasets, that would otherwise be beyond the scope of algorithms such as EM and gradient methods. In particular, our algorithms (1) are non-iterative, requiring only a single pass over the data, (2) provide estimates in closed-form, and hence do not suffer from

Figure 1: Datasets and DAGs.

local optima, and (3) require no inference, which is the primary limiting factor for the scalability of algorithms such as EM. We note that these advantages are also available when learning Bayesian networks from *complete* data.

## 2 TECHNICAL PRELIMINARIES

In this paper, we use upper case letters ( $X$ ) to denote variables and lower case letters ( $x$ ) to denote their values. Variable sets are denoted by bold-face upper case letters ( $\mathbf{X}$ ) and their instantiations by bold-face lower case letters ( $\mathbf{x}$ ). Generally, we will use  $X$  to denote a variable in a Bayesian network and  $\mathbf{U}$  to denote its parents. A network parameter will therefore have the general form  $\theta_{x|\mathbf{u}}$ , representing the probability  $\Pr(X=x|\mathbf{U}=\mathbf{u})$ .

Given an incomplete dataset  $\mathcal{D}$ , we want to learn the parameters of the Bayesian network  $\mathcal{N}$  that the dataset originated from. This network induces a distribution  $\Pr(\mathbf{X})$ , which is in general unknown; instead, we only have access to the dataset  $\mathcal{D}$ .

### 2.1 MISSING DATA: AN EXAMPLE

As an illustrative example, consider Figure 1(a), depicting a dataset  $\mathcal{D}$ , and the directed acyclic graph (DAG)  $\mathcal{G}$  of a Bayesian network, both over variables  $X$  and  $Y$ . Here, the value for variable  $X$  is always observed in the data, while the value for variable  $Y$  can be missing. In the graph, we denote a variable that is always observed with a double-circle. Now, if we happen to know the mechanism that causes the value of  $Y$  to become missing in the data, we can include it in our model, as in Figure 1(b). Here, we use a variable  $R_Y$  to represent the mechanism that controls whether the value of variable  $Y$  is missing or observed. Further, we witness the value of  $Y$ , or its missingness, through a proxy variable  $Y^*$ , as an observation. Such a graph, which explicates the missing data process, is called a *missingness graph*.

In our example, we augmented the dataset and graph with new variables  $R_Y$ , representing the causal mechanism that dictates the missingness of the value of  $Y$ . This mechanism can be active ( $Y$  is unobserved), denoted by  $R_Y=\text{unob}$ . Otherwise, the mechanism is passive ( $Y$  is observed), de-

noted by  $R_Y=\text{ob}$ . Variable  $Y^*$  acts as a proxy on the value of  $Y$ , which may be an observed value  $y$ , or a special value (mi) when the value of  $Y$  is missing. The value of  $Y^*$  thus depends functionally on variables  $R_Y$  and  $Y$ :

$$Y^* = f(R_Y, Y) = \begin{cases} \text{mi} & \text{if } R_Y = \text{unob} \\ Y & \text{if } R_Y = \text{ob} \end{cases}$$

That is, when  $R_Y=\text{unob}$ , then  $Y^*=\text{mi}$ ; otherwise  $R_Y=\text{ob}$  and the proxy  $Y^*$  assumes the observed value of  $Y$ .

Figure 2: An MNAR missingness graph.

Figure 2 highlights a more complex example of a missingness graph, with causal mechanisms  $R_X$  and  $R_Y$  that depend on other variables. In Section 2.3, we highlight how different missing data problems (such as MCAR and MAR) lead to different types of missingness graphs.

### 2.2 LEARNING WITH MISSINGNESS GRAPHS

Given a Bayesian network with DAG  $G$ , and an incomplete dataset  $\mathcal{D}$ , we can partition the variables  $\mathbf{X}$  into two sets: the fully-observed variables  $\mathbf{X}_o$ , and the partially-observed variables  $\mathbf{X}_m$  that have missing values in  $\mathcal{D}$ . As in our example above, one can take into account knowledge about the processes responsible for the missingness in  $\mathcal{D}$ . More specifically, we can incorporate the causal mechanisms that cause the variables  $\mathbf{X}_m$  to have missing values, by introducing (1) variables  $\mathbf{R}$  representing the *causal mechanisms* that are responsible for missingness in the data, and (2) variables  $\mathbf{X}_m^*$  that act as *proxies* to the variables  $\mathbf{X}_m$ . This augmented Bayesian network, which we refer to as the *missingness graph*  $\mathcal{N}^*$ , has variables  $\mathbf{X}_o, \mathbf{X}_m^*, \mathbf{R}$  that are fully-observed, and variables  $\mathbf{X}_m$  that are only partially-observed. The missingness graph  $\mathcal{N}^*$  thus induces a distribution  $\Pr(\mathbf{X}_o, \mathbf{X}_m, \mathbf{X}_m^*, \mathbf{R})$ . Using the missingness graph, we want to draw conclusions about the partially-observed variables, by reasoning about the fully-observed ones.

Missingness graphs can serve as a powerful tool for analyzing missing data problems; see, e.g., Thoemmes and Mohan (2015), Francois and Leray (2007), Darwiche (2009), Koller and Friedman (2009). As Mohan et al. (2013) show, one can exploit the conditional independencies that missingness graphs encode, in order to extract *asymptotically consistent* estimates for missing data problems, including MNAR ones, whose underlying assumptions would put it out of the scope of existing techniques.<sup>1</sup> Mohan et al.

<sup>1</sup>Note that maximum-likelihood estimation is asymptotically consistent, although a consistent estimator is not necessarily a maximum-likelihood estimator; see, e.g., Wasserman (2011).

(2013) identify conditions on  $\mathcal{N}^*$  that allow the original, partially-observed distribution  $\Pr(\mathbf{X}_o, \mathbf{X}_m)$  to be identified from the fully-observed distribution  $\Pr(\mathbf{X}_o, \mathbf{X}_m^*, \mathbf{R})$ . However, in practice, we only have access to a dataset  $\mathcal{D}$ , and the corresponding *data distribution* that it induces:

$$\Pr_{\mathcal{D}}(\mathbf{x}_o, \mathbf{x}_m^*, \mathbf{r}) = \frac{1}{N} \mathcal{D}\#(\mathbf{x}_o, \mathbf{x}_m^*, \mathbf{r}),$$

where  $N$  is the number of instances in dataset  $\mathcal{D}$ , and where  $\mathcal{D}\#(\mathbf{x})$  is the number of instances where instantiation  $\mathbf{x}$  appears in the data.<sup>2</sup> However, the data distribution  $\Pr_{\mathcal{D}}$  tends to the true distribution  $\Pr$  (over the fully-observed variables), as  $N$  tends to infinity.

Building on the theoretical foundations set by Mohan et al. (2013), we shall propose a family of efficient and scalable parameter estimation algorithms from incomplete data. In essence, we will show how to query the observed data distribution  $\Pr_{\mathcal{D}}$ , in order to make inferences about the true, underlying distribution  $\Pr(\mathbf{X}_o, \mathbf{X}_m)$  (in particular, we want the conditional probabilities that parameterize the given Bayesian network). As we shall discuss, in many cases the missingness graph need not be explicit. In other cases, when there is knowledge about the missingness graph, even just partial knowledge, we can exploit it, in order to obtain more accurate parameter estimates.

### 2.3 CATEGORIES OF MISSINGNESS

An incomplete dataset is categorized as *Missing Completely At Random* (MCAR) if all mechanisms  $\mathbf{R}$  that cause the values of variables  $\mathbf{X}_m$  to go missing, are marginally independent of  $\mathbf{X}$ , i.e., where  $(\mathbf{X}_m, \mathbf{X}_o) \perp\!\!\!\perp \mathbf{R}$ . This corresponds to a missingness graph where no variable in  $\mathbf{X}_m \cup \mathbf{X}_o$  is a parent of any variable in  $\mathbf{R}$ . For example, if all mechanisms  $\mathbf{R}$  are root nodes, then the problem is MCAR. Note that the missingness graph of Figure 1(b) implies an MCAR dataset.

An incomplete dataset is categorized as *Missing At Random* (MAR) if missingness mechanisms are conditionally independent of the partially-observed variables given the fully-observed variables, i.e., if  $\mathbf{X}_m \perp\!\!\!\perp \mathbf{R} \mid \mathbf{X}_o$ . This corresponds to a missingness graph where variables  $\mathbf{R}$  are allowed to have parents, as long as none of them are partially-observed. In the example missingness graph of Figure 1(b), adding an edge  $X \rightarrow R_Y$  results in a graph that yields MAR data. This is a stronger, variable-level definition of MAR, which has previously been used in the machine learning literature (Darwiche, 2009; Koller & Friedman, 2009), in contrast to the event-level definition of MAR that is prevalent in the statistics literature (Rubin, 1976).

<sup>2</sup>Note that the data distribution is well-defined over the variables  $\mathbf{X}_o, \mathbf{X}_m^*$ , and  $\mathbf{R}$ , as they are fully-observed in the augmented dataset, and that  $\Pr_{\mathcal{D}}$  can be represented compactly in space linear in  $N$ , as we need not explicitly represent those instantiations  $\mathbf{x}$  that were not observed in the data.

Table 1: Summary of Estimation Algorithms

| Algorithm | Description (Section Number)                  |
|-----------|---|
| D-MCAR    | Direct Deletion for MCAR data (3.1)           |
| D-MAR     | Direct Deletion for MAR data (3.2)            |
| F-MCAR    | Factored Deletion for MCAR data (3.3)         |
| F-MAR     | Factored Deletion for MAR data (3.3)          |
| I-MAR     | Informed Deletion for MAR data (5.1)          |
| IF-MAR    | Informed Factored Deletion for MAR data (5.1) |

An incomplete dataset is categorized as *Missing Not At Random* (MNAR) if it is not MAR (and thus not MCAR). For example, the DAG in Figure 2 corresponds to an MNAR missingness graph. This is because the mechanism  $R_X$  has a partially-observed variable as a parent; further, mechanism  $R_Y$  has a partially-observed parent  $X$ .

## 3 CLOSED-FORM LEARNING

We now present algorithms to learn the parameters of a Bayesian network  $\mathcal{N}$  from data  $\mathcal{D}$ . We first consider the classical missing data assumptions, with no further knowledge about the missingness graph that generated the data.

To estimate the conditional probabilities  $\theta_{x|\mathbf{u}}$  that parameterize a Bayesian network, we estimate the joint distributions  $\Pr(X, \mathbf{U})$ , which are subsequently normalized, as a conditional probability table. Hence, it suffices, for our discussion, to estimate marginal distributions  $\Pr(\mathbf{Y})$  for families  $\mathbf{Y} = \{X\} \cup \mathbf{U}$ . We let  $\mathbf{Y}_o = \mathbf{Y} \cap \mathbf{X}_o$  denote the observed variables in  $\mathbf{Y}$ , and  $\mathbf{Y}_m = \mathbf{Y} \cap \mathbf{X}_m$  denote the partially-observed variables. Further, we let  $\mathbf{R}_{\mathbf{Z}} \subseteq \mathbf{R}$  denote the missingness mechanisms for the partially-observed variables  $\mathbf{Z}$ . Through  $\mathcal{D}$ , we have access to the data distribution  $\Pr_{\mathcal{D}}$  over the variables in the missingness dataset. Appendix D illustrates our learning algorithms on a concrete dataset and Table 1 gives an overview of the different estimation algorithms in this paper.

### 3.1 DIRECT DELETION FOR MCAR

The statistical technique of *listwise deletion* is perhaps the simplest technique for performing estimation with MCAR data: we simply delete all instances in the dataset that contain missing values, and estimate our parameters from the remaining dataset, which is now complete. Of course, with this technique, we potentially ignore large parts of the dataset. The next simplest technique is perhaps pairwise deletion, or available-case analysis: when estimating a quantity over a pair of variables  $X$  and  $Y$ , we delete just those instances where variable  $X$  or variable  $Y$  is missing.

Consider now the following, more general, deletion technique, which is expressed in the terms of causal missingness mechanisms. In particular, to estimate the marginals  $\Pr(\mathbf{Y})$  of a set of (family) variables  $\mathbf{Y}$ , from the data dis-

tribution  $\Pr_{\mathcal{D}}$ , we can use the estimate:

$$\begin{aligned} \Pr(\mathbf{Y}) &= \Pr(\mathbf{Y}_o, \mathbf{Y}_m | \mathbf{R}_{\mathbf{Y}_m} = \text{ob}) \quad \text{by } \mathbf{X}_o, \mathbf{X}_m \perp\!\!\!\perp \mathbf{R} \\ &= \Pr(\mathbf{Y}_o, \mathbf{Y}_m^* | \mathbf{R}_{\mathbf{Y}_m} = \text{ob}) \quad \text{by } \mathbf{X}_m = \mathbf{X}_m^* \text{ when } \mathbf{R} = \text{ob} \\ &\approx \Pr_{\mathcal{D}}(\mathbf{Y}_o, \mathbf{Y}_m^* | \mathbf{R}_{\mathbf{Y}_m} = \text{ob}) \end{aligned}$$

That is, we can estimate  $\Pr(\mathbf{Y})$  by using the subset of the data where every variable in  $\mathbf{Y}$  is observed (which follows from the assumptions implied by MCAR data). Since the data distribution  $\Pr_{\mathcal{D}}$  tends to the true distribution  $\Pr$ , this implies a consistent estimate for the marginals  $\Pr(\mathbf{Y})$ . In contrast, the technique of listwise deletion corresponds to the estimate  $\Pr(\mathbf{Y}) \approx \Pr_{\mathcal{D}}(\mathbf{Y}_o, \mathbf{Y}_m^* | \mathbf{R}_{\mathbf{X}_m} = \text{ob})$ , and the technique of pairwise deletion corresponds to the above, when  $\mathbf{Y}$  contains two variables. To facilitate comparisons with more interesting estimation algorithms that we shall subsequently consider, we refer to the more general estimation approach above as *direct deletion*.

### 3.2 DIRECT DELETION FOR MAR

In the case of MAR data, we cannot use the simple deletion techniques that we just described for MCAR data—the resulting estimates would not be consistent. However, we show next that it is possible to obtain consistent estimates from MAR data, using a technique that is as simple and efficient as direct deletion. Roughly, we can view this technique as deleting certain instances from the dataset, but then re-weighting the remaining ones, so that a consistent estimate is obtained. We shall subsequently show how to obtain even better estimates by factorization.

Again, to estimate network parameters  $\theta_{x|u}$ , it suffices to show how to estimate family marginals  $\Pr(\mathbf{Y})$ , now under the MAR assumption. Let  $\mathbf{X}'_o = \mathbf{X}_o \setminus \mathbf{Y}_o$  denote the fully-observed variables outside of the family variables  $\mathbf{Y}$  (i.e.,  $\mathbf{X}_o = \mathbf{Y}_o \cup \mathbf{X}'_o$ ). We have

$$\begin{aligned} \Pr(\mathbf{Y}) &= \sum_{\mathbf{X}'_o} \Pr(\mathbf{Y}_o, \mathbf{Y}_m, \mathbf{X}'_o) \\ &= \sum_{\mathbf{X}'_o} \Pr(\mathbf{Y}_m | \mathbf{Y}_o, \mathbf{X}'_o) \Pr(\mathbf{Y}_o, \mathbf{X}'_o) \end{aligned}$$

Hence, we reduced the problem to estimating two sets of probabilities. Estimating the probabilities  $\Pr(\mathbf{Y}_o, \mathbf{X}'_o)$  is straightforward, as variables  $\mathbf{Y}_o$  and  $\mathbf{X}'_o$  are fully observed in the data. The conditional probabilities  $\Pr(\mathbf{Y}_m | \mathbf{Y}_o, \mathbf{X}'_o)$  contain partially observed variables  $\mathbf{Y}_m$ , but they are conditioned on all fully observed variables  $\mathbf{X}_o = \mathbf{Y}_o \cup \mathbf{X}'_o$ . The MAR definition implies that each subset of the data that fixes a value for  $\mathbf{X}_o$  is locally MCAR. Like the MCAR case, we can estimate each conditional probability as

$$\Pr(\mathbf{Y}_m | \mathbf{Y}_o, \mathbf{X}'_o) = \Pr(\mathbf{Y}_m^* | \mathbf{Y}_o, \mathbf{X}'_o, \mathbf{R}_{\mathbf{Y}_m} = \text{ob}).$$

This leads to the following estimation algorithm,

$$\Pr(\mathbf{Y}) \approx \sum_{\mathbf{X}'_o} \Pr_{\mathcal{D}}(\mathbf{Y}_m^* | \mathbf{Y}_o, \mathbf{X}'_o, \mathbf{R}_{\mathbf{Y}_m} = \text{ob}) \Pr_{\mathcal{D}}(\mathbf{Y}_o, \mathbf{X}'_o)$$

---

#### Algorithm 1 F-MCAR( $y, \mathcal{D}$ )

---

**Input:**

$y$ : A state of query variables  $\mathbf{Y}$

$\mathcal{D}$ : An incomplete dataset with data distribution  $\Pr_{\mathcal{D}}$

**Auxiliary:**

CACHE: A global cache of estimated probabilities

**Function:**

- 1: **if**  $y = \emptyset$  **then return** 1
  - 2: **if**  $\text{CACHE}[y] \neq \text{nil}$  **then return**  $\text{CACHE}[y]$
  - 3:  $\mathcal{E} \leftarrow \emptyset$  // Initialize set of estimates
  - 4: **for each**  $y \in \mathbf{y}$  **do**
  - 5:    $\mathbf{u} \leftarrow \mathbf{y} \setminus \{y\}$  // Factorize with parents  $\mathbf{u}$
  - 6:   **add**  $\Pr_{\mathcal{D}}(y | \mathbf{u}, \mathbf{R}_y = \text{ob}) \cdot \text{F-MCAR}(\mathbf{u}, \mathcal{D})$  **to**  $\mathcal{E}$
  - 7:  $\text{CACHE}[y] \leftarrow \text{Aggregate estimates in } \mathcal{E}$  // E.g., mean
  - 8: **return**  $\text{CACHE}[y]$
- 

Figure 3: Factorization Lattice of  $\Pr(X, Y, Z)$

which uses only the fully-observed variables of the data distribution  $\Pr_{\mathcal{D}}$ . Note that the summation requires only a single pass through the data, i.e., for only those instantiations of  $\mathbf{X}'_o$  that appear in it. Again,  $\Pr_{\mathcal{D}}$  tends to the true distribution  $\Pr$ , as the dataset size tends to infinity, implying a consistent estimate of  $\Pr(\mathbf{Y})$ .

### 3.3 FACTORED DELETION

We now propose a class of deletion algorithms that exploit more data than direct deletion. In the first step, we generate multiple but consistent estimates for the query so that each estimate utilizes different parts of a dataset to estimate the query. In the second step, we aggregate these estimates to compute the final estimate and thus put to use almost all tuples in the dataset. Since this method exploits more data than direct deletion, it obtains a better estimate of the query.

**Factored Deletion for MCAR** Algorithm 1 implements factored deletion for MCAR. Let the query of interest be  $\Pr(\mathbf{Y})$ , and let  $Y^1, Y^2, \dots, Y^n$  be any ordering of the  $n$

variables in  $\mathbf{Y}$ . Each ordering yields a unique factorization:

$$\Pr(\mathbf{Y}) = \prod_{i=1}^n \Pr(Y^i | Y^{i+1}, \dots, Y^n)$$

We can estimate each of these factors independently, on the subset of the data in which all of its variables are fully observed (as in direct deletion), i.e.,

$$\Pr(Y^i | Y^{i+1}, \dots, Y^n) = \Pr(Y^i | Y^{i+1}, \dots, Y_m^n, \mathbf{R}_{\mathbf{Z}^i} = \text{ob})$$

where  $\mathbf{Z}^i$  is the set of partially-observed variables in the factor. When  $|\mathbf{Y}_m| > 1$ , we can utilize much more data than direct deletion. See Appendix D, for an example.

So far, we have discussed how a consistent estimate of  $\Pr(\mathbf{Y})$  may be computed given a factorization. Now we shall detail how estimates from each factorization can be aggregated to compute more accurate estimates of  $\Pr(\mathbf{Y})$ . Let  $k$  be the number of variables in a family  $\mathbf{Y}$ . The number of possible factorizations is  $k!$ . However, different factorizations share the same sub-factors, which we can estimate once, and reuse across factorizations. We can organize these computations using a lattice, as in Figure 3, which has only  $2^k$  nodes and  $k \cdot 2^{k-1}$  edges. Our algorithm will compute as many estimates as there are edges in this lattice, which is only on the order of  $O(n \log n)$ , where  $n$  is the number of parameters being estimated for a family  $Y$  (which is also exponential in the number of variables  $k$ ). To emphasize the distinction with direct deletion, which uses only those instances in the data where *all* variables in  $\mathbf{Y}$  are observed, factored deletion uses any instance in the data where *at least one* variable in  $\mathbf{Y}$  is observed.

More specifically, our factored deletion algorithm first estimates the conditional probabilities on the edges of the lattice, each estimate using the subset of the data where its variables are observed. Second, it propagate the estimates, bottom-up. For each node, there are several alternative estimates available, on its incoming edges. There are various ways of aggregating these estimates, such as mean, median, and propagating the lowest-variance estimate.<sup>3</sup>

**Factored Deletion for MAR** Algorithm 2 implements factored deletion for MAR. Let  $Y_m^1, Y_m^2, \dots, Y_m^n$  be any ordering of the  $n$  partially observed variables  $\mathbf{Y}_m \subseteq \mathbf{Y}$  and let  $\mathbf{X}'_o = \mathbf{X}_o \setminus \mathbf{Y}_o$  denote the fully-observed variables outside of  $\mathbf{Y}$ . Given an ordering, we have the factorization:

$$\Pr(\mathbf{Y}) = \sum_{\mathbf{X}'_o} \Pr(\mathbf{Y}_o, \mathbf{X}'_o) \prod_{i=1}^n \Pr(Y_m^i | \mathbf{Z}^{i+1}, \mathbf{X}_o)$$

where  $\mathbf{Z}^i_m = \{Y_m^j | i \leq j \leq n\}$ . We then proceed in a manner similar to factored deletion for MCAR to estimate individual factors and aggregate estimates to compute  $\Pr(\mathbf{Y})$ . For equations and derivations, please see Appendix A.

<sup>3</sup>In initial experiments, all aggregations performed similarly. Reported results use an inverse-variance weighting heuristic.

---

## Algorithm 2 F-MAR( $\mathbf{y}, \mathcal{D}$ )

---

**Input:**

$\mathbf{y}$ : A state of query variables  $\mathbf{Y}$ , consisting of  $\mathbf{y}_o$  and  $\mathbf{y}_m$   
 $\mathcal{D}$ : An incomplete dataset with data distribution  $\Pr_{\mathcal{D}}$

**Function:**

```

1:  $e \leftarrow 0$  // Estimated probability
2: for each  $\mathbf{x}_o$  appearing in  $\mathcal{D}$  that agrees with  $\mathbf{y}_o$  do
3:    $\mathcal{D}_{\mathbf{x}_o} \leftarrow$  subset of  $\mathcal{D}$  where  $\mathbf{x}_o$  holds
4:    $e \leftarrow e + \Pr_{\mathcal{D}}(\mathbf{x}_o) \cdot \text{F-MCAR}(\mathbf{y}_m, \mathcal{D}_{\mathbf{x}_o})$ 
5: return  $e$ 

```

---

## 4 EMPIRICAL EVALUATION

To evaluate the learning algorithms we proposed, we simulate partially observed datasets from Bayesian networks, and re-learn their parameters from the data.<sup>4</sup>

In our first sets of experiments, we compare our parameter estimation algorithms with EM, on relatively small networks for MCAR and MAR data. These experiments are intended to observe general trends in our algorithms, in terms of their computational efficiency, but also in terms of the quality of the parameter estimates obtained. Our main empirical contributions are presented in Section 4.3, where we demonstrate the scalability of our proposed estimation algorithms, to larger networks and datasets, compared to EM (even when using approximate inference algorithms).

We consider the following algorithms:

**D-MCAR & F-MCAR:** direct deletion and factored deletion for MCAR data.

**D-MAR & F-MAR:** direct deletion and factored deletion for MAR data.

**EM- $k$ -JT:** EM with  $k$  random restarts, jointree inference.

**F-MAR + EM-JT:** EM seeded with F-MAR estimates, jointree inference.

Remember that D-MCAR and F-MCAR are consistent for MCAR data only, while D-MAR and F-MAR are consistent for general MAR data. EM is consistent for MAR data, but only if it converges to maximum-likelihood estimates.

We evaluate the learned parameters in terms of their *likelihood* on independently generated, fully-observed test data, and the *Kullback–Leibler divergence* (KLD) between the original and learned Bayesian networks. We report per-instance log-likelihoods (which are divided by dataset size). We evaluate the learned models on unseen data, so all learning algorithms assume a symmetric Dirichlet prior

<sup>4</sup>An implementation of our system is available at <http://reasoning.cs.ucla.edu/deletion>.

(a) KL Divergence vs. Dataset Size

(b) KL Divergence vs. Time

Figure 4: Learning the `alarm` network from MCAR data.

on the network parameters with a concentration parameter of 2 (which corresponds to Laplace smoothing).

#### 4.1 MCAR DATA

First, we consider learning from *MCAR data*, evaluating the quality of the parameters learned by each algorithm. We simulate training sets of increasing size, from a given Bayesian network, selecting 30% of the variables to be partially observed, and removing 70% of their values completely at random. All reported numbers are averaged over 32 repetitions with different learning problems. When no number is reported, a 5 minute time limit was exceeded.

To illustrate the trade-off between data and computational resources, Figure 4 plots the KLDs as a function of dataset size and time; further results are provided in Table 5 of Appendix B. First, we note that in terms of the final estimates obtained, there is no advantage in running EM with restarts: EM-1-JT and EM-10-JT learn almost identical models. This indicates that the likelihood landscape for MCAR data has few local optima, and is easy to optimize. Hence, EM may be obtaining maximum-likelihood estimates in these cases. In general, maximum-likelihood estimators are more statistically efficient (asymptotically) than other estimators, i.e., they require fewer samples. However, other estimators (such as method-of-moments) can be more computationally efficient; see, e.g., Wasserman (2011). We also observe this trend here. EM obtains better estimates with smaller datasets, with smaller KLDs. However, direct and factored deletion (D-MCAR and F-MCAR) are both orders-of-magnitude faster, and can scale to much larger

datasets, than EM (which requires inference). Further, F-MCAR needs only a modest amount of additional data to obtain comparable estimates.

To compare our direct and factored methods, we see that F-MCAR is slower than D-MCAR, as it estimates more quantities (one for each lattice edge). F-MCAR learns better models, however, as it uses a larger part of the available data. Finally, D-MAR performs worse than F-MCAR and D-MCAR, as it assumes the weaker MAR assumption. All learners are consistent, as all KLDs converge to zero.

#### 4.2 MAR DATA

Next, we consider the more challenging problem of learning from *MAR data*, which we generate as follows: (1) select an  $m$ -fraction of the variables to be partially observed, (2) add a missingness mechanism variable  $R_X$  for each partially-observed variable  $X$ , (3) assign  $p$  parents to each  $R_X$ , randomly selected from the set of observed variables, giving preference to neighbors of  $X$  in the network, (4) sample parameters for the missingness mechanism CPTs from a Beta distribution, (5) sample a complete dataset with  $R_X$  values, and (6) hide values of  $X$  accordingly.

For our first MAR experiment, we use a small network that is tractable enough for EM to scale to large dataset sizes, so that we can observe trends in this regime. Figure 5(a) shows KLD for the `fire alarm` network, which has only 6 variables (and hence, the complexity of inference is negligible). The missing data mechanisms were generated with  $m = 0.3$ ,  $p = 2$ , and a Beta distribution with shape parameters 1.0 and 0.5. All numbers are averaged over 64 repetitions with different random learning problems.<sup>5</sup>

There is a significant difference between EM, with and without restarts, indicating that the likelihood landscape is challenging to optimize (compared to MCAR, which we just evaluated). EM-10-JT performs well for small dataset sizes, but stops converging after around 1,000 instances. This could be due to all restarts getting stuck in local optima. The KLD of F-MAR starts off between EM-1-JT and EM-10-JT for small sizes, but quickly outperforms EM. For the largest dataset sizes, it learns networks whose KLD is two orders of magnitude smaller than EM-10-JT. The KLD improves further when we use F-MAR estimates to seed EM. This approach is on par with EM-10 for small datasets, while still converging for large dataset sizes. However, note that using F-MAR to seed EM will not be practical for larger networks, where inference becomes a

<sup>5</sup>On our chosen parameters: (1) the number of repetitions was chosen to produce smooth learning curves; (2) a Beta distribution with shape parameter 1 is uniform, and with parameter 0.5, it is slightly biased (so that it acts more like an MAR, and less like an MCAR, mechanism); (3)  $m = 0.3$  corresponds to a low amount of missing data, and later  $m = 0.9$  corresponds to high amount; and (4)  $p = 2$  encourages sparsity and keeps the CPTs small, although setting  $p$  to 1 or 3 does not change the results.

Figure 5: Learning small, tractable Bayesian networks from MAR data. The legend is given in sub-figure (b).

bottleneck. D-MCAR and F-MCAR are not consistent for MAR data, and indeed converge to a biased estimate with a KLD around 0.1. Finally, we observe that the factorized algorithms generally outperform their direct counterparts.

For our second MAR experiment, we work with the classical `alarm` network, which has 37 variables. The missing data mechanisms were generated with  $m = 0.9$ ,  $p = 2$ , and a Beta distribution with shape parameters 0.5. All reported numbers are averaged over 32 repetitions, and when no number is reported, a 10 minute time limit was exceeded.

Figures 5(b) and 5(c) show test set likelihood as a function of dataset *size* and learning *time*. EM-10-JT performs well for very small dataset sizes, and again outperforms EM-1-JT. However, inference time is non-negligible and EM-1-JT fails to scale beyond 1,000 instances, whereas EM-10-JT scales to 10,000 (as one would expect). The closed-form learners dominate all versions of EM as a function of time, and scale to dataset sizes that are two orders of magnitude larger. EM seeded by F-MAR achieves similar quality to EM-10-JT, while being significantly faster than EM learners with random seeds. D-MAR and F-MAR are more computationally efficient, and can scale to much larger dataset sizes. Further, as seen in Figure 5(c), they can obtain good likelihoods even before the EM methods report their first likelihoods.

### 4.3 SCALING TO LARGER NETWORKS

In our last set of experiments of this section, we evaluate our algorithms on their ability to scale to larger networks, with higher treewidths, where exact inference is more challenging.<sup>6</sup> Again, inference is the main factor that limits the scalability of algorithms such as EM, to larger networks and datasets (EM invokes inference as a sub-routine, once per data instance, per iteration). Tables 2 & 3 report results on four networks, where we simulated MAR datasets, as in the previous set of experiments. Each method is given a time limit of 5 or 25 minutes. Appendix C provides results on additional settings. We consider the following methods:

<sup>6</sup>The `grid` network has 400 variables, `munin1` has 189 variables, `water` has 32 variables, and `barley` has 48 variables.

**EM-JT** The EM-10-JT algorithm used in anytime fashion, which returns, given a time limit, the best parameters found in any restart, even if EM did not converge.

**EM-BP** A variant of EM-JT that uses (loopy) belief propagation for (approximate) inference (in the E-step).

We see that EM-JT, which performs exact inference, does not scale well to these networks. This problem is mitigated by EM-BP, which performs *approximate* inference, yet we find that it also has difficulties scaling (dashed entries indicate that EM-JT and EM-BP did not finish 1 iteration of EM). In contrast, F-MAR, and particularly D-MAR, can scale to much larger datasets. This efficiency is due to the relative simplicity of the D-MAR and F-MAR estimation algorithms: they are not iterative and require only a single pass over the data. In contrast, with EM-BP, the EM algorithm is not only iterative, but the BP algorithm that EM-BP invokes as a sub-routine, is itself an iterative algorithm. As for accuracy, F-MAR typically obtains the best likelihoods (in bold) for larger datasets, while EM-BP can perform better on smaller datasets. We also evaluated D-MCAR and F-MCAR, although they are not in general consistent for MAR data. We find that they scale even further, and can also produce good estimates in terms of likelihood.

## 5 EXPLOITING MISSINGNESS GRAPHS

We have so far made very general assumptions about the structure of the missingness graph, capturing the MCAR and MAR assumptions. In this section, we show how to exploit additional knowledge about the missingness graph to further improve the quality of our estimates. Having deeper knowledge of the nature of the missingness mechanisms will even enable us to obtain consistent estimators for datasets that are not MAR (in some cases).

### 5.1 INFORMED DELETION FOR MAR

Consider any MAR dataset, and a missingness graph where each  $R \in \mathbf{R}$  depends every observed variable in  $\mathbf{X}_o$ . This would be an MAR missingness graph that assumes

the least, in terms of conditional independencies, about the causal mechanisms  $\mathbf{R}$ . If we know more about the nature of the missingness (i.e., the variables that the  $\mathbf{R}$  depend on), we can exploit this to obtain more accurate estimates. Note that knowing the parents of an  $R$  is effectively equivalent to knowing the Markov blanket of  $R$  (Pearl, 1987), which can be learned from data (Tsamardinos, Aliferis, Statnikov, & Statnikov, 2003; Yaramakala & Margaritis, 2005). With sufficient domain knowledge, an expert may be able to specify the parents of the  $\mathbf{R}$ . It suffices even to identify a set of variables that just *contains* the Markov blanket.

Suppose that we have such knowledge of the missing data mechanisms of an MAR problem, namely that we know the subset  $\mathbf{W}_o$  of the observed variables  $\mathbf{X}_o$  that suffice to separate the missing values from their causal mechanisms, i.e., where  $\mathbf{X}_m \perp\!\!\!\perp \mathbf{R} \mid \mathbf{W}_o$ . We can exploit this knowledge in our direct deletion algorithm, to obtain improved parameter estimates. In particular, we can reduce the scope of the summation in our direct deletion algorithm from the variables  $\mathbf{X}'_o$  (the set of variables in  $\mathbf{X}_o$  that lie outside the family  $\mathbf{Y}$ ), to the variables  $\mathbf{W}'_o$  (the set of variables in  $\mathbf{W}_o$  that lie outside the family  $\mathbf{Y}$ ), yielding the algorithm:

$$\Pr(\mathbf{Y}) \approx \sum_{\mathbf{W}'_o} \Pr_{\mathcal{D}}(\mathbf{Y}_m^* | \mathbf{Y}_o, \mathbf{W}'_o, \mathbf{R}_{\mathbf{Y}_m} = \text{ob}) \Pr_{\mathcal{D}}(\mathbf{Y}_o, \mathbf{W}'_o)$$

Again, we need only consider, in the summation, the instantiations of  $\mathbf{W}'_o$  that appear in the dataset.

We refer to this algorithm as *informed direct deletion*. By reducing the scope of the summation, we need to estimate fewer sub-terms  $\Pr_{\mathcal{D}}(\mathbf{Y}_m^* | \mathbf{Y}_o, \mathbf{W}'_o, \mathbf{R}_{\mathbf{Y}_m} = \text{ob})$ . This results in a more efficient computation, but further, each individual sub-expression can be estimated on more data. Moreover, our estimates remain consistent. We can similarly replace  $\mathbf{X}_o$  by  $\mathbf{W}_o$  in the factored deletion algorithm, to obtain an *informed factored deletion* algorithm.

**Empirical Evaluation** Here, we evaluate the benefits of informed deletion. In addition to the MAR assumption, with this setting, we assume that we know the set of parents  $\mathbf{W}_o$  of the missingness mechanism variables. To gen-

erate data for such a mechanism, we select a random set of  $s$  variables to form  $\mathbf{W}_o$ . We further employ the sampling algorithm previously used for MAR data, but now insist that the parents of  $\mathbf{R}$  variables come from  $\mathbf{W}_o$ . Table 4 shows likelihoods and KLDs on the `alarm` network, for  $s = 3$ , and other settings as in the MAR experiments. Informed D-MAR (ID-MAR) and F-MAR (IF-MAR) consistently outperform their non-informed counterparts.

## 5.2 LEARNING FROM MNAR DATA

A missing data problem that is not MAR is classified as MNAR. Here, the parameters of a Bayesian network may not even be identifiable. Further, maximum-likelihood estimation is in general not consistent, so EM and gradient methods can yield biased estimates. However, if one knows the mechanisms that dictate missingness (in the form of a missingness graph), it becomes possible again to obtain consistent estimates, in some cases (Mohan et al., 2013).

For example, consider the missingness graph of Figure 2, which is an MNAR problem, where both variables  $X$  and  $Y$  are partially observed, and the missingness of each variable depends on the value of the other. Here, it is still possible to obtain consistent parameter estimates, as  $\Pr(X, Y) =$

$$\frac{\Pr(R_X = \text{ob}, R_Y = \text{ob}) \Pr(X^*, Y^* | R_X = \text{ob}, R_Y = \text{ob})}{\Pr(R_X = \text{ob} | Y^*, R_Y = \text{ob}) \Pr(R_Y = \text{ob} | X^*, R_X = \text{ob})}$$

For a derivation, see Mohan et al. (2013). Such derivations for recovering queries under MNAR are extremely sensitive to the structure of the missingness graph. Indeed, the class of missingness graphs that admit consistent estimation has not yet been fully characterized.

## 6 RELATED WORK

When estimating the parameters of a Bayesian network, maximum-likelihood (ML) estimation is the typical approach, where for incomplete data, the common wisdom among machine learning practitioners is that one needs to use Expectation-Maximization (EM) or gradient methods (Dempster, Laird, & Rubin, 1977; Lauritzen, 1995); see also, e.g., Darwiche (2009), Koller and Friedman (2009), Murphy (2012), Barber (2012). Again, such methods do not scale to large datasets or large networks as (1) they are iterative, (2) they suffer from local optima, and most notably, (3) they require inference in a Bayesian network. Considerable effort has been expended in improving on EM across these dimensions, in order to, for example, (1) accelerate the convergence of EM, and to intelligently sample subsets of a dataset, e.g., Thiesson et al. (2001), (2) escape local optima, e.g., (Elidan, Ninio, Friedman, & Shuurmans, 2002), and (3) use approximate inference algorithms in lieu of exact ones when inference is intractable, e.g., Ghahramani and Jordan (1997), Caffo, Jank, and Jones

(2005). Further, while EM is suitable for data that is MAR (the typical assumption in practice), there are some exceptions, such as work on recommender systems that explicitly incorporate missing data mechanisms (Marlin & Zemel, 2009; Marlin, Zemel, Roweis, & Slaney, 2007, 2011).

In the case of complete data, the parameter estimation task simplifies considerably, in the case of Bayesian networks: maximum-likelihood estimates can be obtained inference-free and in closed-form, using just a single pass over the data:  $\theta_{x|\mathbf{u}} = \Pr_{\mathcal{D}}(x|\mathbf{u})$ . In fact, the estimation algorithms that we proposed in this paper also obtain the same parameter estimates in the case of complete data, although we are not concerned with maximum-likelihood estimation here—we simply want to obtain estimates that are consistent (as in estimation by the method of moments).

Other inference-free estimators have been proposed for other classes of graphical models. Abbeel, Koller, and Ng (2006) identified a method for closed-form, inference-free parameter estimation in factor graphs of bounded degree from complete data. More recently, Halpern and Sontag (2013) proposed an efficient, inference-free method for consistently estimating the parameters of noisy-or networks with latent variables, under certain structural assumptions. From the perspective of maximum-likelihood learning, where evaluating the likelihood (requiring inference) seems to be unavoidable, the ability to consistently estimate parameters—without the need for inference—greatly extends the accessibility and utility of such models. For example, it opens the door to practical structure learning algorithms, under incomplete data, which is a notoriously difficult problem in practice (Abbeel et al., 2006; Jernite, Halpern, & Sontag, 2013).

## 7 CONCLUSIONS

In summary, we proposed a family of efficient and scalable algorithms for learning the parameters of Bayesian networks, from MCAR and MAR datasets, and sometimes MNAR datasets. Our parameter estimates are asymptotically consistent, and further, they are obtained inference-free and in closed-form. We further introduced and discussed some improved approaches for parameter estimation, when given additional knowledge of the missingness mechanisms underlying an incomplete dataset. Empirically, we demonstrate the practicality of our method, showing that it can scale to much larger datasets, and much larger Bayesian networks, than EM.

## Abstract

The problem of feature selection is critical in several areas of machine learning and data analysis. Here we consider feature selection for supervised learning problems, where one wishes to select a small set of features that facilitate learning a good prediction model in the reduced feature space. Our interest is primarily in filter methods that select features independently of the learning algorithm to be used and are generally faster to implement than wrapper methods. Many common filter methods for feature selection make use of mutual information based criteria to guide their search process. However, even in simple binary classification problems, mutual information based methods do not always select the best set of features in terms of the Bayes error. In this paper, we develop a filter method that directly aims to select the optimal set of features for a general performance measure of interest. Our approach uses the Bayes error with respect to the given performance measure as the criterion for feature selection and applies a greedy algorithm to optimize this criterion. We demonstrate application of this method to a variety of learning problems involving different performance measures. Experiments suggest the proposed approach is competitive with several state-of-the-art methods.

## 1 INTRODUCTION

The problem of feature selection is critical in several areas of machine learning and data analysis, particularly for learning prediction models with good generalization ability and for reducing the running time of learning algorithms [1–3]. In this paper, we consider feature selection for supervised learning problems, where one wishes to select a small set of features that facilitate learning a good

prediction model in the reduced feature space. Our focus is primarily on filter methods that select features independently of the learning algorithm to be used, typically by greedily maximizing some suitable feature selection criterion. These methods are generally faster in practice and easier to implement than other approaches to feature selection such as wrapper or embedded methods.

Over the years, there has been much work on designing filter methods for feature selection, many of which make use of mutual information based criteria to guide their search process [4–7]. However, these methods do not explicitly consider the performance measure used to evaluate a model in the learning problem. In fact, even in the case of simple binary classification, one can construct settings where the popular mutual information criterion does not yield the best set of features in terms of the Bayes 0-1 classification error (as we shall shortly see with an example) [8]. Clearly, there is a need for filter methods that are tailored to directly optimize a given performance measure of interest.

In this paper, we develop a *Bayes optimal* filter method for a general performance measure. Our approach directly aims to find the optimal set of features in terms of the Bayes error for the given loss or performance measure, thus allowing for the possibility of learning a good model in the reduced feature space. We show that the mutual information criterion mentioned above is a special case of our setting when the loss function of interest is the logarithmic loss for class probability estimation. We use a greedy forward selection algorithm for approximately optimizing the Bayes criterion for the given performance measure, and demonstrate application of this method to various learning problems involving different performance measures. Experiments on several learning tasks suggest that the proposed approach is competitive with the state-of-the-art methods.

Indeed in the simpler setting of classification with the 0-1 error, there have been some works that have suggested the use of Bayes error as a criterion for feature selection/transformation [8–13]. Of these, only Yang and Hu (2012) provide an experimental evaluation of a filter method for optimizing the Bayes 0-1 error [13]; however,

---

<sup>†</sup>Work done while at Indian Institute of Science, Bangalore.

even here, the objective eventually optimized is different from the Bayes optimal criterion for the 0-1 error (we elaborate on this in Section 3.1). On the other hand, we provide in this paper the first systematic study of Bayes optimal filter methods for general performance measures, going well beyond the simple setting of 0-1 classification, and handling a variety of learning settings, including those with complex performance measures such as the F-measure.

## 1.1 RELATED WORK

Filter methods have received much attention from the machine learning/data mining/artificial intelligence communities, resulting in various hand-crafted filter criteria and heuristic techniques for optimizing the proposed objectives [4–7, 14–21]. Predominant among these are methods that use the mutual information (MI) between a given feature subset and the output label as a measure of *relevance* of the feature subset to the given learning task, often with additional information theoretic terms to account for *redundancy* among the features in the given subset [4–7, 16–21]. While there have been arguments made to justify the use of MI as a criterion for binary classification by establishing lower/upper bounds on MI in terms of the 0-1 Bayes error [21–24], these bounds are tight only for certain settings; in general, the optimal feature subset for the MI criterion need not be the same as that for the 0-1 Bayes error.

There has also been some work on designing filter methods for specific learning tasks, such as text retrieval [25], class imbalanced classification [26], and ranking [27]. However, the feature selection criteria proposed therein are either based on heuristics and do not explicitly promote feature subsets that are Bayes optimal for the given problem, or as in the case of [25], require a certain (binary) representation of the features and do not apply to general settings.

Apart from filter methods, other popular families of feature selection techniques include *wrapper methods*, where the quality of a subset of features is determined by explicitly learning a model on the feature subset and evaluating its accuracy on a held-out sample [2, 28, 29]; and *embedded methods*, which combine model learning and feature selection into a single step, such as using sparse regularization in the learning problem [30]. While both these approaches allow us to incorporate different loss functions during feature selection, filter methods are computationally cheaper as they decouple feature selection from model learning, and are typically simpler to implement in practice.

**Organization.** Section 2 gives preliminaries, together with an example illustrating that the MI feature selection criterion can be suboptimal for binary classification. Section 3 describes the proposed Bayes feature selection method, followed by examples of how it can be applied to different learning problems and performance measures. Section 4 gives results of experiments on several learning tasks.

## 2 PRELIMINARIES AND BACKGROUND

**Notation.** For  $n \in \mathbb{Z}_+$ , we denote  $[n] = \{1, \dots, n\}$ . For a vector  $\mathbf{x} = (x_1, \dots, x_n) \in \mathbb{R}^n$  and set  $\mathcal{J} = \{j_1, \dots, j_k\} \subseteq [n]$  with  $j_1 < \dots < j_k$ , we denote  $\mathbf{x}_{\mathcal{J}} = (x_{j_1}, \dots, x_{j_k}) \in \mathbb{R}^k$ . For random variables  $X$  and  $Y$ , we denote by  $H(X)$  the entropy of  $X$ , by  $H(Y|X)$  the conditional entropy of  $Y$  given  $X$ , and by  $I(X; Y)$  the mutual information between  $X$  and  $Y$ . For a predicate  $\phi$ , we denote by  $\mathbf{1}(\phi)$  the indicator of  $\phi$ , which takes the value 1 if  $\phi$  is true and 0 otherwise. For any  $z \in \mathbb{R}$ ,  $\text{sign}(z) = 1$  if  $z > 0$  and  $-1$  otherwise.

**Problem Setup.** Let  $\mathcal{X} \subseteq \mathbb{R}^n$  be an  $n$ -dimensional instance space. We will be interested in feature selection for *supervised learning problems*, where there is some label space  $\mathcal{Y}$  and prediction space  $\hat{\mathcal{Y}}$ ; one receives a training sample  $S = ((\mathbf{x}^1, y^1), \dots, (\mathbf{x}^m, y^m)) \in (\mathcal{X} \times \mathcal{Y})^m$ , and the goal is to learn a prediction model  $h : \mathcal{X} \rightarrow \hat{\mathcal{Y}}$ .<sup>1</sup> Typically, one assumes all examples (both training examples and future test examples) are drawn i.i.d. from some probability distribution  $D$  on  $\mathcal{X} \times \mathcal{Y}$ , and the goal is to learn a prediction model with good prediction performance (according to a suitable performance measure) on future examples from  $D$ . We will denote by  $(X, Y)$  a random variable drawn from  $D$ . Often, performance is measured via a loss function  $\ell : \mathcal{Y} \times \hat{\mathcal{Y}} \rightarrow \mathbb{R}_+$ ; the goal then is to learn a model  $h$  minimizing the expected loss on a new example from  $D$ , which we refer to as the  $\ell$ -error of  $h$  w.r.t.  $D$ :  $\text{er}_D^\ell[h] = \mathbf{E}_{(X, Y) \sim D}[\ell(Y, h(X))]$ . The smallest achievable  $\ell$ -error over all possible prediction models is called the *Bayes  $\ell$ -error* for  $D$ :  $\text{er}_D^{\ell, *} = \inf_{h: \mathcal{X} \rightarrow \hat{\mathcal{Y}}} \text{er}_D^\ell[h]$ . For example, in binary classification, one has  $\mathcal{Y} = \hat{\mathcal{Y}} = \{\pm 1\}$ , and the loss function of interest is often the 0-1 loss  $\ell_{0-1} : \{\pm 1\} \times \{\pm 1\} \rightarrow \mathbb{R}_+$  defined as  $\ell_{0-1}(y, \hat{y}) = \mathbf{1}(\hat{y} \neq y)$ . For problems with binary labels  $\mathcal{Y} = \{\pm 1\}$ , we will denote by  $p = \mathbf{P}(Y = 1)$  the overall probability of label +1 under  $D$ , and by  $\eta : \mathcal{X} \rightarrow [0, 1]$  the associated class probability function:  $\eta(\mathbf{x}) = \mathbf{P}(Y = 1 | X = \mathbf{x})$ . Here the Bayes 0-1 error has the form  $\text{er}_D^{0-1, *} = \mathbf{E}_X[\min(\eta(X), 1 - \eta(X))]$ .

The *feature selection problem* we are interested in is to select a subset of features  $\mathcal{J} \subseteq [n]$  of some specified size  $k \in [n]$  (usually  $k \ll n$ ), such that one can then learn a good prediction model in the reduced  $k$ -dimensional feature space  $\mathcal{X}_{\mathcal{J}} = \{\mathbf{x}_{\mathcal{J}} | \mathbf{x} \in \mathcal{X}\} \subseteq \mathbb{R}^k$ .<sup>2</sup> Specifically, given a training sample  $S \in (\mathcal{X} \times \mathcal{Y})^m$  as above, one works with the reduced training sample  $S_{\mathcal{J}} = ((\mathbf{x}_{\mathcal{J}}^1, y^1), \dots, (\mathbf{x}_{\mathcal{J}}^m, y^m)) \in (\mathcal{X}_{\mathcal{J}} \times \mathcal{Y})^m$ , and learns a prediction model  $h_{\mathcal{J}} : \mathcal{X}_{\mathcal{J}} \rightarrow \hat{\mathcal{Y}}$  in the reduced space  $\mathcal{X}_{\mathcal{J}}$ . We will denote by  $D_{\mathcal{J}}$  the marginal distribution of  $D$  on  $\mathcal{X}_{\mathcal{J}} \times \mathcal{Y}$ ; for problems with binary la-

<sup>1</sup>Often  $\hat{\mathcal{Y}} = \mathcal{Y}$ , but this is not always the case.

<sup>2</sup>In this paper, we assume for simplicity that the target feature subset size  $k$  is given as part of the problem. However, the methods developed easily extend to settings where  $k$  is unknown.

bels  $\mathcal{Y} = \{\pm 1\}$ , we will also denote by  $\eta_{\mathcal{J}} : \mathcal{X}_{\mathcal{J}} \rightarrow [0, 1]$  the class probability function on the reduced feature space  $\mathcal{X}_{\mathcal{J}}$ :  $\eta_{\mathcal{J}}(\mathbf{z}) = \mathbf{P}(Y = 1 | X_{\mathcal{J}} = \mathbf{z})$ , where  $X_{\mathcal{J}}$  contains components of the random vector  $X$  corresponding to indices in  $\mathcal{J}$ . Clearly, if the examples in  $S$  are drawn i.i.d. from  $D$ , then the examples in  $S_{\mathcal{J}}$  can be viewed as being drawn i.i.d. from  $D_{\mathcal{J}}$ . In the loss function setting, the performance of a model  $h_{\mathcal{J}}$  learned in the reduced feature space is measured via its  $\ell$ -error w.r.t.  $D_{\mathcal{J}}$ :  $\text{er}_{D_{\mathcal{J}}}^{\ell}[h_{\mathcal{J}}] = \mathbf{E}_{(Z, Y) \sim D_{\mathcal{J}}}[\ell(Y, h_{\mathcal{J}}(Z))] = \mathbf{E}_{(X, Y) \sim D}[\ell(Y, h_{\mathcal{J}}(X_{\mathcal{J}}))]$ .

**Feature Selection as (Approximate) Optimization.** We will view feature selection methods as (approximately) optimizing some objective or criterion  $C_D : 2^{[n]} \rightarrow \mathbb{R}$ , which typically depends on distribution  $D$ . Given such a criterion  $C_D$  and a target feature subset size  $k$ , one aims to select

$$\mathcal{J}^* \in \underset{\substack{\mathcal{J} \subseteq [n] \\ |\mathcal{J}| = k}}{\text{argmax}} C_D(\mathcal{J}). \quad (1)$$

Of course, in practice, one does not know the distribution  $D$ , and so instead uses an approximate version of the criterion  $C_D$  based on the training sample  $S$ , which we shall denote as  $\widehat{C}_S : 2^{[n]} \rightarrow \mathbb{R}$ . Moreover, the combinatorial optimization problem (over  $\binom{n}{k}$  subsets) is generally computationally hard, and so one settles for an approximate search strategy, such as a greedy approach. We shall elaborate further on both these approximations below.

**Filter Methods and Mutual Information (MI) Criterion.** In a filter method for feature selection, the choice of the feature subset does not depend on the particular learning algorithm to be used in the reduced feature space, i.e. the criterion  $C_D$  is independent of the particular learning algorithm to be used. A popular filter criterion that is widely used in feature selection for supervised learning is the *mutual information* (MI) criterion, defined as the mutual information between the selected features and the labels:

$$C_D^{\text{MI}}(\mathcal{J}) = I(X_{\mathcal{J}}; Y), \quad (2)$$

where  $(X, Y)$  denotes a random variable distributed according to  $D$ . The motivation for using the MI criterion is that it is expected to preserve the information necessary for learning a good prediction model. Indeed, in the case of binary classification, monotonic functions of the mutual information  $I(X; Y)$  are known to both upper and lower bound the Bayes error  $\text{er}_D^{0-1,*}$  [21–24]. However, as seen below, even in the case of binary classification, there are situations where the MI criterion does *not* select an optimal set of features:

**Example 1** (Suboptimality of MI criterion for binary classification with 0-1 error). *Consider a binary classification problem on a 2-dimensional instance space with binary features:  $\mathcal{X} = \{0, 1\}^2$ ,  $\mathcal{Y} = \{\pm 1\}$ . Let  $D$  be a probability distribution on  $(\mathcal{X} \times \mathcal{Y})$  under which  $\mathbf{P}(Y = 1) = 0.3$ , the random variables  $X_1, X_2$  (components of the random*

*vector  $X$ ) are conditionally independent given the label  $Y$ , and the class-conditional distributions are given by*

$$\begin{aligned} \mathbf{P}(X_1 = 1 | Y = 1) &= 0.4; & \mathbf{P}(X_1 = 1 | Y = -1) &= 0.1; \\ \mathbf{P}(X_2 = 1 | Y = 1) &= 0.9; & \mathbf{P}(X_2 = 1 | Y = -1) &= 0.4. \end{aligned}$$

*Clearly,  $\mathbf{P}(X_1 = 1) = 0.19$ ,  $\mathbf{P}(X_2 = 1) = 0.55$ ,  $\eta_{\{1\}}(0) = 0.22$ ,  $\eta_{\{1\}}(1) = 0.63$ ,  $\eta_{\{2\}}(0) = 0.07$  and  $\eta_{\{2\}}(1) = 0.49$ . Now consider selecting a single feature for use in learning a binary classifier (thus here  $n = 2$ ,  $k = 1$ ). It can be verified that under the above distribution,*

$$\begin{aligned} C_D^{\text{MI}}(\{1\}) &= I(X_1; Y) = 0.08 \\ C_D^{\text{MI}}(\{2\}) &= I(X_2; Y) = 0.17. \end{aligned}$$

*Therefore the MI criterion would select feature 2 and learn a classifier in the feature space  $\mathcal{X}_{\{2\}}$ . One can also compute the Bayes 0-1 errors in  $\mathcal{X}_{\{1\}}$  and  $\mathcal{X}_{\{2\}}$ ; these can be verified to be*

$$\text{er}_{D_{\{1\}}}^{0-1,*} = 0.25; \quad \text{er}_{D_{\{2\}}}^{0-1,*} = 0.30.$$

*Thus even if one uses the best possible learning algorithm in the feature space  $\mathcal{X}_{\{2\}}$  selected by the MI criterion, the best classifier one can learn will have 0-1 error 0.30. On the other hand, if we had selected feature 1, we could potentially have learned a classifier with 0-1 error 0.25!*

The above example suggests looking directly for a feature subset that yields low Bayes error with respect to a given performance measure of interest.

### 3 BAYES OPTIMAL FEATURE SELECTION

Motivated by the above discussion, we now develop a filter method for feature selection that is tailored to optimize a general performance measure of interest. In particular, rather than selecting a feature subset by maximizing the mutual information with the labels, our approach optimizes *the information most relevant to the supervised learning task at hand*, with the aim of learning as good a prediction model in the reduced feature space as possible in terms of the given loss or performance measure. More formally, for a supervised learning problem with label space  $\mathcal{Y}$ , prediction space  $\widehat{\mathcal{Y}}$ , and with loss function  $\ell : \mathcal{Y} \times \widehat{\mathcal{Y}} \rightarrow \mathbb{R}_+$ , we will be interested in selecting a feature subset that minimizes the Bayes  $\ell$ -error in the reduced feature space, or equivalently, maximizes the following criterion:

$$C_D^{\text{Bayes}, \ell}(\mathcal{J}) = -\text{er}_{D_{\mathcal{J}}}^{\ell,*}. \quad (3)$$

Note that this is different from a wrapper method, which looks for a feature subset that maximizes prediction performance of a model learned by a particular algorithm; here, we are instead interested in finding the best feature subset for a given performance measure of interest, *without being tied to any particular learning algorithm*.

### 3.1 EXAMPLES OF BAYES CRITERION FOR VARIOUS LEARNING PROBLEMS AND PERFORMANCE MEASURES

Here we give several examples of the above Bayes criterion for specific learning problems/performance measures. We shall see that for the case of binary class probability estimation with the logarithmic loss, the Bayes criterion effectively reduces to the MI criterion (Example 5); thus the MI criterion can be viewed as finding a good feature space for class probability estimation. Similarly, for regression with squared error, the Bayes criterion is exactly the criterion optimized in the forward regression feature selection algorithm for sparse linear regression (Example 6). We begin with the simple case of binary classification with 0-1 error.

**Example 2** (Bayes criterion for binary classification with 0-1 error). *Let  $\mathcal{Y} = \hat{\mathcal{Y}} = \{\pm 1\}$ , with  $\ell_{0-1} : \{\pm 1\} \times \{\pm 1\} \rightarrow \mathbb{R}_+$  defined as  $\ell_{0-1}(y, \hat{y}) = \mathbf{1}(\hat{y} \neq y)$ . Then*

$$C_D^{\text{Bayes}, 0-1}(\mathcal{J}) = -\mathbf{E}_X \left[ \min(\eta_{\mathcal{J}}(X_{\mathcal{J}}), 1 - \eta_{\mathcal{J}}(X_{\mathcal{J}})) \right].$$

As noted earlier, the filter method provided by Yang and Hu (2012) [13] for optimizing the Bayes 0-1 error eventually optimizes an objective different from the above one; while the authors initially discuss a feature selection criterion of the above form, they end up prescribing and analyzing a variant  $-\mathbf{E}_{X,Y} [(1-Y)\eta_{\mathcal{J}}(X_{\mathcal{J}}) + Y(1-\eta_{\mathcal{J}}(X_{\mathcal{J}}))] = -\mathbf{E}_X [2\eta_{\mathcal{J}}(X_{\mathcal{J}})(1-\eta_{\mathcal{J}}(X_{\mathcal{J}}))]$ , which is not necessarily optimal for the 0-1 error (see Eq. (7) in their paper). In this work, we go well beyond the simple setting of 0-1 classification, and present a systematic study of Bayes optimal criteria for general performance measures, as seen below.

**Example 3** (Bayes criterion for binary classification with cost-sensitive error). *Let  $\mathcal{Y} = \hat{\mathcal{Y}} = \{\pm 1\}$ . Let  $c \in (0, 1)$  denote the cost of a false positive and  $(1-c)$  the cost of a false negative; the corresponding cost-sensitive loss  $\ell_c : \{\pm 1\} \times \{\pm 1\} \rightarrow \mathbb{R}_+$  is defined as*

$$\ell_c(y, \hat{y}) = \begin{cases} c & \text{if } y = -1, \hat{y} = 1 \\ 1-c & \text{if } y = 1, \hat{y} = -1 \\ 0 & \text{otherwise.} \end{cases}$$

Then

$$C_D^{\text{Bayes}, c}(\mathcal{J}) = -\mathbf{E}_X \left[ \min((1-c)\eta_{\mathcal{J}}(X_{\mathcal{J}}), c(1-\eta_{\mathcal{J}}(X_{\mathcal{J}}))) \right].$$

**Example 4** (Bayes criterion for binary classification with balanced 0-1 error). *Let  $\mathcal{Y} = \hat{\mathcal{Y}} = \{\pm 1\}$ . The balanced loss  $\ell_{\text{bal}} : \{\pm 1\} \times \{\pm 1\} \rightarrow \mathbb{R}_+$  seeks to balance prediction errors on positive and negative examples by weighting them according to their inverse class probabilities, and is frequently used to measure classification performance in class imbalance settings [31]; it depends on the underlying distribution  $D$  via the probability  $p = \mathbf{P}(Y = 1)$ , and*

is defined as

$$\ell_{\text{bal}}(y, \hat{y}) = \begin{cases} \frac{1}{1-p} & \text{if } y = -1, \hat{y} = 1 \\ \frac{1}{p} & \text{if } y = 1, \hat{y} = -1 \\ 0 & \text{otherwise.} \end{cases}$$

Here the Bayes criterion becomes

$$C_D^{\text{Bayes}, \text{bal}}(\mathcal{J}) = -\mathbf{E}_X \left[ \min\left(\frac{\eta_{\mathcal{J}}(X_{\mathcal{J}})}{p}, \frac{1-\eta_{\mathcal{J}}(X_{\mathcal{J}})}{1-p}\right) \right].$$

**Example 5** (Bayes criterion for binary class probability estimation with logarithmic loss). *Let  $\mathcal{Y} = \{\pm 1\}$  and  $\hat{\mathcal{Y}} = [0, 1]$ , with logarithmic loss  $\ell_{\log} : \{\pm 1\} \times [0, 1] \rightarrow \mathbb{R}_+$  defined as*

$$\ell_{\log}(y, \hat{y}) = -\mathbf{1}(y = 1) \ln(\hat{y}) - \mathbf{1}(y = -1) \ln(1 - \hat{y}).$$

Then

$$\begin{aligned} C_D^{\text{Bayes}, \log}(\mathcal{J}) &= -\mathbf{E}_X \left[ -\eta_{\mathcal{J}}(X_{\mathcal{J}}) \ln(\eta_{\mathcal{J}}(X_{\mathcal{J}})) \right. \\ &\quad \left. - (1 - \eta_{\mathcal{J}}(X_{\mathcal{J}})) \ln(1 - \eta_{\mathcal{J}}(X_{\mathcal{J}})) \right] \\ &= -H(Y|X_{\mathcal{J}}) = I(X_{\mathcal{J}}; Y) - H(Y) \\ &= C_D^{\text{MI}}(\mathcal{J}) - H(Y). \end{aligned}$$

*This is equivalent to using the MI criterion! Thus, in the binary setting, the MI criterion effectively selects a feature set that minimizes Bayes log-error, i.e. that allows for a good class probability estimator (in terms of logarithmic loss) in the resulting feature space! (Note that this is not the same as selecting good features for binary classification with 0-1 error or other performance measures; e.g. see Example 1. This is also demonstrated in our experiments in Section 4.)*

**Example 6** (Bayes criterion for regression with squared error). *Let  $\mathcal{Y} = \hat{\mathcal{Y}} = \mathbb{R}$ , with squared loss  $\ell_{\text{sq}} : \mathbb{R} \times \mathbb{R} \rightarrow \mathbb{R}_+$  defined as  $\ell_{\text{sq}}(y, \hat{y}) = (\hat{y} - y)^2$ . Then*

$$C_D^{\text{Bayes}, \text{sq}}(\mathcal{J}) = -\mathbf{E}_X [\text{Var}(Y | X_{\mathcal{J}})].$$

*This is exactly the criterion used in the well-known forward regression feature selection algorithm for sparse linear regression (where one assumes  $\mathbf{E}[Y|X = \mathbf{x}] = \beta^T \mathbf{x}$  for some sparse  $\beta \in \mathbb{R}^n$ ) [32].*

While all examples seen so far have involved performance measures that can be expressed as an expected value of a loss function, we shall next consider examples of learning problems where the performance measure of interest is complex and non-additive.

**Example 7** (Bayes criterion for binary classification/retrieval with  $F_{\beta}$ -measure). *Let  $\mathcal{Y} = \hat{\mathcal{Y}} = \{\pm 1\}$ , and consider a classification or retrieval problem where the goal is to learn a classifier  $h : \mathcal{X} \rightarrow \{\pm 1\}$  with performance measured by the  $F_{\beta}$ -measure (higher values are better):*

$$F_{\beta, D}[h] = \frac{1 + \beta^2}{\frac{\beta^2}{\text{Prec}_D[h]} + \frac{1}{\text{Rec}_D[h]}},$$

---

**Algorithm 1**  $\ell$ -BayesGreedy

---

- 1: **Inputs:**  $S = (\mathbf{x}^1, y^1), \dots, (\mathbf{x}^m, y^m) \in (\mathbb{R}^n \times \mathcal{Y})^m$   
 $k \in [n]$
  - 2: **Initialize:**  $\mathcal{J} \leftarrow \emptyset$
  - 3: **for**  $t = 1 \dots k$  **do**
  - 4:      $j_t \leftarrow \operatorname{argmax}_{j \in [n] \setminus \mathcal{J}} \widehat{C}_S^{\text{Bayes}, \ell}(\mathcal{J} \cup \{j\})$
  - 5:      $\mathcal{J} \leftarrow \mathcal{J} \cup \{j_t\}$
  - 6: **end for**
  - 7: **Output:**  $\mathcal{J}$
- 

where  $\text{Prec}_D[h] = \mathbf{P}(Y = 1 | h(X) = 1)$  and  $\text{Rec}_D[h] = \mathbf{P}(h(X) = 1 | Y = 1)$  are the precision and recall of  $h$ , respectively, and  $\beta > 0$  trades off the relative importance of these two quantities. In this case, the performance measure cannot be expressed as the expected value of a loss function over individual data points. Nevertheless, it is known that the Bayes optimal classifier for the  $F_\beta$ -measure is obtained by thresholding the class probability function  $\eta$  for the given distribution at an optimal point [24, 33]. One can therefore compute the Bayes optimal value of the  $F_\beta$ -measure for a given distribution, and use this as the criterion to be optimized in feature selection:

$$\begin{aligned} C_D^{\text{Bayes}, F_\beta}(\mathcal{J}) &= \sup_{h_{\mathcal{J}}: \mathcal{X}_{\mathcal{J}} \rightarrow \{\pm 1\}} F_{\beta, D_{\mathcal{J}}}[h_{\mathcal{J}}] \\ &= \sup_{t \in [0, 1]} F_{\beta, D_{\mathcal{J}}}[\text{sign} \circ (\eta_{\mathcal{J}} - t)]. \end{aligned}$$

**Example 8** (Bayes criterion for bipartite ranking with AUC). Let  $\mathcal{Y} = \{\pm 1\}$ , and consider a bipartite ranking problem where the goal is to learn a scoring function  $f: \mathcal{X} \rightarrow \mathbb{R}$ , with performance measured by the area under the ROC curve (AUC) (higher values are better):

$$\begin{aligned} \text{AUC}_D[f] &= \mathbf{E}[\mathbf{1}((Y - Y')(f(X) - f(X')) > 0) \\ &\quad + \frac{1}{2} \mathbf{1}(f(X) = f(X')) | Y \neq Y'], \end{aligned}$$

where  $(X, Y), (X', Y')$  are drawn i.i.d. from  $D$ . While here again, the performance measure cannot be expressed as an expectation of loss function, one can indeed compute the Bayes optimal value of the performance measure for a given distribution (e.g. see [34]); we use this as the criterion to be optimized in feature selection:

$$\begin{aligned} C_D^{\text{Bayes}, \text{AUC}}(\mathcal{J}) &= \sup_{f_{\mathcal{J}}: \mathcal{X}_{\mathcal{J}} \rightarrow \mathbb{R}} \text{AUC}_{D_{\mathcal{J}}}[f_{\mathcal{J}}] \\ &= 1 - \frac{\mathbf{E}[\min(\alpha_{\mathcal{J}}(X_{\mathcal{J}}, X'_{\mathcal{J}}), \alpha_{\mathcal{J}}(X'_{\mathcal{J}}, X_{\mathcal{J}}))]}{2p(1-p)}, \end{aligned}$$

where  $\alpha_{\mathcal{J}}(Z, Z') = \eta_{\mathcal{J}}(Z)(1 - \eta_{\mathcal{J}}(Z'))$ .

### 3.2 GREEDY ALGORITHM FOR OPTIMIZING BAYES CRITERION

As noted earlier, in practice, one does not have access to the true distribution  $D$ , and therefore must optimize an approximate version of the Bayes criterion based on the training

sample  $S = ((\mathbf{x}^1, y^1), \dots, (\mathbf{x}^m, y^m))$ . In particular, for a label space  $\mathcal{Y}$ , prediction space  $\widehat{\mathcal{Y}}$ , and loss  $\ell: \mathcal{Y} \times \widehat{\mathcal{Y}} \rightarrow \mathbb{R}_+$ , note that the Bayes  $\ell$ -error w.r.t.  $D$  can be written as

$$\text{er}_D^{\ell, *} = \mathbf{E}_X \left[ \inf_{\widehat{y} \in \widehat{\mathcal{Y}}} \mathbf{E}_{Y|X}[\ell(Y, \widehat{y})] \right].$$

To obtain a sample-based estimate of  $\text{er}_D^{\ell, *}$ , one can replace the outer expectation over  $X$  by an average over the training instances  $\mathbf{x}^i$  in  $S$ , and use an empirical estimate of the conditional distribution of  $Y$  given  $X$  in computing the inner expectation:

$$\widehat{\text{er}}_S^{\ell, *} = \frac{1}{m} \sum_{i=1}^m \inf_{\widehat{y} \in \widehat{\mathcal{Y}}} \widehat{\mathbf{E}}_{Y|X=\mathbf{x}^i}[\ell(Y, \widehat{y})],$$

where  $\widehat{\mathbf{E}}_{Y|X}$  denotes expectation with respect to an approximate conditional distribution  $\widehat{\mathbf{P}}(Y|X)$  estimated from the sample  $S$ . This gives the approximate Bayes criterion

$$\begin{aligned} \widehat{C}_S^{\text{Bayes}, \ell}(\mathcal{J}) &= -\widehat{\text{er}}_{S_{\mathcal{J}}}^{\ell, *} \\ &= -\frac{1}{m} \sum_{i=1}^m \inf_{\widehat{y} \in \widehat{\mathcal{Y}}} \widehat{\mathbf{E}}_{Y|X_{\mathcal{J}}=\mathbf{x}_{\mathcal{J}}^i}[\ell(Y, \widehat{y})], \end{aligned}$$

where again  $\widehat{\mathbf{E}}_{Y|X_{\mathcal{J}}}$  denotes expectation with respect to an approximate conditional distribution  $\widehat{\mathbf{P}}(Y|X_{\mathcal{J}})$  estimated from the sample  $S_{\mathcal{J}}$ . For example, for binary classification with 0-1 error, one gets the approximate criterion:

$$\widehat{C}_S^{\text{Bayes}, 0-1}(\mathcal{J}) = -\frac{1}{m} \sum_{i=1}^m \min(\widehat{\eta}_{\mathcal{J}}(\mathbf{x}_{\mathcal{J}}^i), 1 - \widehat{\eta}_{\mathcal{J}}(\mathbf{x}_{\mathcal{J}}^i)),$$

where  $\widehat{\eta}_{\mathcal{J}}: \mathcal{X}_{\mathcal{J}} \rightarrow [0, 1]$  is a suitable estimate of  $\eta_{\mathcal{J}}$  based on  $S_{\mathcal{J}}$ . An ideal algorithm would then select the best subset of  $k$  features according to the above approximate criterion:

$$\widehat{\mathcal{J}}_S \in \operatorname{argmax}_{\substack{\mathcal{J} \subseteq [n] \\ |\mathcal{J}|=k}} \widehat{C}_S^{\text{Bayes}, \ell}(\mathcal{J}).$$

However, this optimization problem (over  $\binom{n}{k}$  subsets) is typically still hard due to its combinatorial nature. As is often done in other feature selection approaches, one possibility is to use an algorithm that selects features to maximize the above criterion in a greedy fashion. For example, one can use a forward selection algorithm which starts with an empty feature set, and at each iteration, adds the feature with the highest marginal value of the objective  $\widehat{C}_S^{\text{Bayes}, \ell}$  to the current set of features (see Algorithm 1).<sup>3</sup>

**Conditional probability estimation for large  $k$  using  $s$ -variate approximations.** Applying the above algorithm

<sup>3</sup>We note that the proposed greedy method easily extends to settings where the value of  $k$  is not available to us; for example, one can terminate this method based on an appropriate stopping criterion (such as when the difference in feature criterion across two successive iterations falls below a certain value) and use the features chosen up to that point to learn a suitable predictor.

Table 1: Data sets used in our experiments.

| Data set | No. of features | No. of instances | Feature type | $p = \mathbf{P}(Y = 1)$ |
|----------|-----------------|------------------|--------------|-------------------------|
| Mushroom | 116             | 8124             | Binary       | 0.482                   |
| Adult    | 123             | 48824            | Binary       | 0.239                   |
| Splice   | 240             | 3190             | Binary       | 0.519                   |
| Semeion  | 256             | 1593             | Binary       | 0.102                   |
| KDDCup01 | 139351          | 1909             | Binary       | 0.022                   |
| Pcmac    | 3289            | 1943             | Integer      | 0.495                   |
| Basehock | 4862            | 1993             | Integer      | 0.501                   |
| Gisette  | 5000            | 6000             | Integer      | 0.500                   |
| Waveform | 40              | 5000             | Real         | 0.331                   |

as shown requires computing conditional probability estimates  $\hat{\mathbf{P}}(Y|X_{\mathcal{J}})$  for feature sets  $\mathcal{J}$  of size up to  $k$ . For small  $k$ , this is easy to do; for example, for problems with binary labels, one computes:

$$\hat{\eta}_{\mathcal{J}}(\mathbf{z}) = \hat{\mathbf{P}}(Y = 1 | X_{\mathcal{J}} = \mathbf{z}) = \begin{cases} \frac{\sum_{i=1}^m \mathbf{1}(\mathbf{x}_{\mathcal{J}}^i = \mathbf{z}, y^i = 1)}{\sum_{i=1}^m \mathbf{1}(\mathbf{x}_{\mathcal{J}}^i = \mathbf{z})} & \text{if } \sum_{i=1}^m \mathbf{1}(\mathbf{x}_{\mathcal{J}}^i = \mathbf{z}) > 0 \\ \frac{1}{2} & \text{otherwise.} \end{cases}$$

When  $k$  is large, one runs into difficulties in later iterations of the algorithm. Specifically, consider the  $t$ -th iteration, when  $(t - 1) < k$  features  $j_1, \dots, j_{t-1}$  have been added to  $\mathcal{J}$  and the  $t$ -th feature is to be selected. For large  $t$ , it is likely that most configurations of  $\mathbf{x}_{\mathcal{J}}^i$  appear only once in the training sample, and therefore for all potential features  $j_t \in [n] \setminus \mathcal{J}$ , one gets (in a setting with binary labels) that  $\hat{\eta}_{\mathcal{J} \cup \{j_t\}}(\mathbf{x}_{\mathcal{J} \cup \{j_t\}}^i)$  is either 0, 1 or  $\frac{1}{2}$ , thus giving many ties and no useful basis for selecting the next feature. This is an inherent difficulty that arises when estimating high-dimensional multivariate distributions from limited data. A common approach to overcome this problem, often used in the context of optimizing the MI criterion (e.g. see [5]), is to use approximate calculations that require estimating conditional distributions on only smaller subsets of the features; one such approach is a  $s$ -variate approximation (for some small  $s < k$ ), where the given filter criterion on a set of  $k$  features  $\mathcal{J}$  is approximated by the average value of the criterion on all subsets of  $\mathcal{J}$  of size  $s$  [20]:

$$\hat{C}_S^{\text{Bayes}}(\mathcal{J}) \approx \frac{1}{\binom{k}{s}} \sum_{A \subset \mathcal{J}, |A|=s} \hat{C}_S^{\text{Bayes}}(A).$$

With such approximations, one can use algorithms based on both forward selection and backward elimination to greedily maximize the Bayes criterion. In our experiments with large feature subsets, we use the standard bivariate approximation with  $s = 2$ .

## 4 EXPERIMENTS

We now report results of experiments designed to evaluate the proposed Bayes optimal feature selection method in

a variety of settings with different performance measures. These include binary classification with both the standard 0-1 and cost-sensitive losses, binary class probability estimation (CPE) with the logarithmic loss (under which our Bayes criterion reduces to MI criterion), and learning under class imbalance with the balanced 0-1 loss and F-measure. The data sets used in our experiments are shown in Table 1; these include varying numbers of features/examples, feature types, and class probabilities.<sup>4</sup> Each data set was split into train-test sets, with the feature selection methods and learning algorithms applied on the training set, and the learned model evaluated on the test set; the average performance over 5 random train-test splits is then reported. All tunable parameters in the learning algorithms used were chosen using a held-out portion of the training set.<sup>5,6</sup>

**Baselines.** Our main method, which optimizes the Bayes criterion corresponding to the loss or performance measure of interest in a greedy manner (possibly with some approximations in estimating high-dimensional conditional distributions), is termed BayesGreedy. We also include a score-based variant of our method (BayesScore) that scores each feature independently using the Bayes criterion evaluated on the corresponding one-dimensional feature space, and selects the top  $k$  features according to this score. As baselines, we consider a number of standard filter methods popular in practice. These include a method that optimizes the MI criterion in a greedy manner (again with some approximations in estimating high-dimensional conditional distributions), termed MIGreedy [5, 7]; a score-based vari-

<sup>4</sup>We obtained Pcmac and Basehock from the ASU repository (<http://featureselection.asu.edu>), KDDCup01 from the KDD Cup Challenge 2001 (<http://pages.cs.wisc.edu/~kddcup2001/>) and the rest from the UCI ML repository (<http://www.ics.uci.edu/~mllearn/MLRepository.html>). Of these, Semeion and Waveform are multi-class data sets, where one of the class was taken as positive, and the remaining were combined into the negative class.

<sup>5</sup>In the case of the larger Adult data set, 20% of the data was used for training and the remaining for testing. On all other data sets, 70% was used for training. In each case, a held-out 20% of the training set was used for parameter tuning.

<sup>6</sup>For data sets with integer/real valued features, we discretized each feature into three categories based on intervals:  $(-\infty, \mu - \sigma)$ ,  $[\mu - \sigma, \mu + \sigma)$ , and  $[\mu + \sigma, \infty)$ , where  $\mu$  is the mean feature value and  $\sigma$  is the standard deviation.

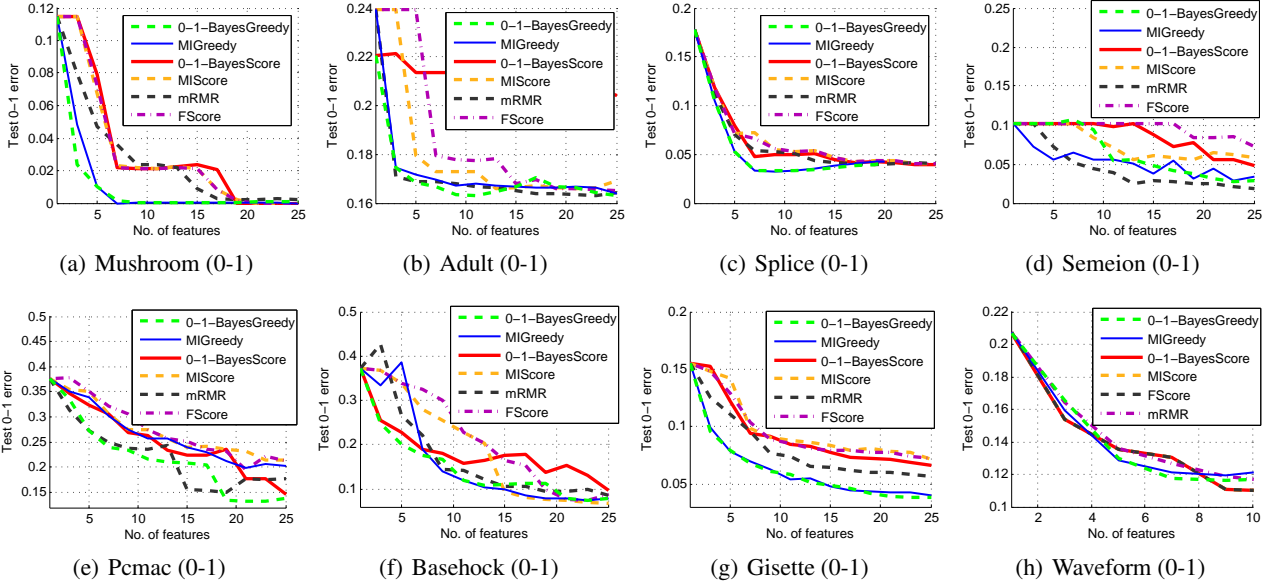

Figure 1: Feature selection for binary 0-1 classification. Plots show test 0-1 error vs. number of features for different feature selection methods, with SVM (RBF kernel) as the classification algorithm.

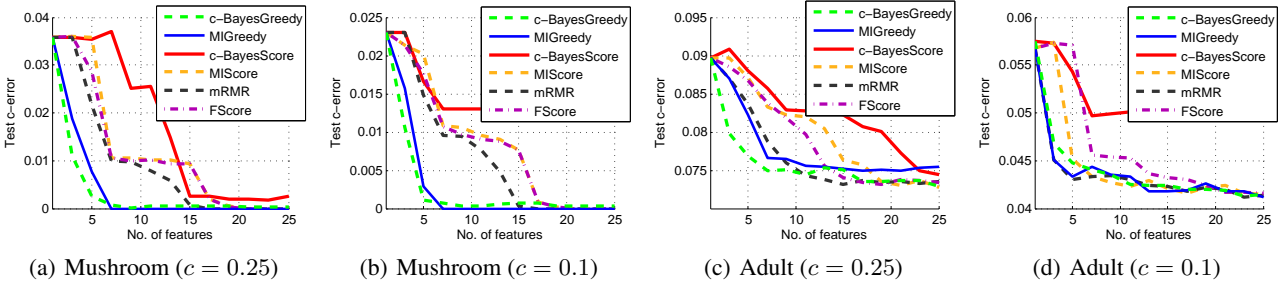

Figure 2: Feature selection for cost-sensitive binary classification with different costs  $c$ . Plots show test cost-sensitive error vs. number of features for various filter methods, with cost-sensitive SVM (RBF kernel) as the classification algorithm.

ant of this method for optimizing the MI criterion (MIScore) [21]; and a score-based method that optimizes another popular feature selection criterion, namely the Fischer score (F-score) [35]. Apart from the above methods, there are other filter methods based on MI that in addition to optimizing for relevant feature subsets, also seek to promote some form of ‘diversity’ among the chosen features. Popular among these is the minimal-redundancy-maximal-relevance (mRMR) method [6], which we include as a representative baseline from this category.

The above baselines are indeed representative of the various filter methods used in practice, with most other methods based on MI being variants of the MIGreedy or mRMR methods. Since the focus of this paper is entirely on filter methods, we do not compare our approach against wrapper or embedded methods, which unlike filter methods are closely tied to the learning algorithm used.

In experiments below, unless otherwise specified, the BayesGreedy and MIGreedy methods shall use exact estimates of class-conditional distributions.

#### 4.1 BINARY CLASSIFICATION (0-1 ERROR AND COST-SENSITIVE ERROR)

The first task that we consider is binary classification with the standard 0-1 error (see Example 2 for the Bayes criterion for this performance measure). We used kernel SVM (with RBF kernel) as the learning algorithm for this task. Figure 1 contains the test 0-1-error for the different feature selection methods as a function of the number of features chosen. As seen, on all data sets except Semeion and for most feature subset sizes, the features chosen by the proposed BayesGreedy method (that explicitly optimizes the 0-1 error) perform comparable to or better than the baseline methods. The poor performance of BayesGreedy on the Semeion data set was due to the inexact/greedy search technique used by the method (when the Bayes criterion was optimized exactly on this data set using an exhaustive search over feature subsets, we did obtain better performance than the MI criterion).

We also consider the task of binary classification with cost-sensitive error (see Example 3 for the Bayes criterion).

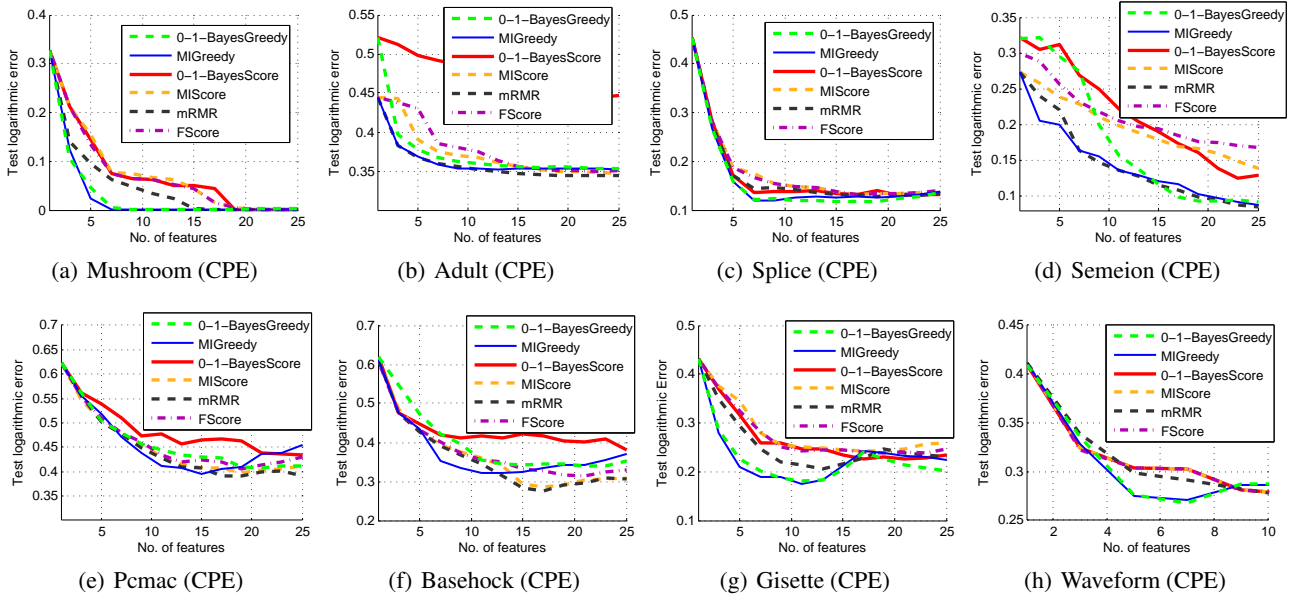

Figure 3: Feature selection for binary CPE. Plots show test logarithmic error vs. number of features for different feature selection methods, with logistic regression (RBF kernel) as the CPE algorithm. Here, MI is the Bayes optimal criterion for the logarithmic error; one can see that MIGreedy performs the best in most cases.

Figure 4: Feature selection for learning under class imbalance. (a), (c) Test balanced 0-1 error vs. number of features, with balanced SVM (RBF kernel) used as the learning algorithm. (b) Test  $F_1$ -measure vs. number of features, with a plug-in method that uses logistic regression (RBF kernel) followed by empirical thresholding as the learning algorithm. Bivariate approximations were used in estimating class-conditionals for KDDCup01. Higher values are better for  $F_1$ -measure.

We used cost-sensitive kernel SVM as the learning algorithm here. Figure 2 contains results on the Adult and Mushroom data sets with different costs. In three of four cases, BayesGreedy yields lower cost-sensitive error than the baselines for smaller feature subset sizes and comparable values for larger feature subset sizes.

On most data sets, the score-based methods do not perform as well as the other methods; this is due to their naive search strategy where the features are scored independently.

#### 4.2 BINARY CLASS PROBABILITY ESTIMATION (LOGARITHMIC ERROR)

The next task that we consider is class probability estimation with the logarithmic error. As mentioned earlier, the Bayes criterion here effectively reduces to the MI criterion (see Example 5). We used regularized kernel logistic regression (with RBF kernel) as the class probability estima-

tion algorithm here. Figure 3 contains plots of the test logarithmic error vs. the number of features chosen for different feature selection methods; we also include for comparison methods that optimize the Bayes criterion for the 0-1 loss. MIGreedy, which optimizes the Bayes criterion for the logarithmic error, performs comparable to or better than the other methods for most feature subset sizes.

#### 4.3 LEARNING UNDER CLASS IMBALANCE (BALANCED 0-1 ERROR AND F-MEASURE)

We now move to the task of binary classification under class imbalance. Commonly used performance measures in this setting include the balanced 0-1-error and  $F_1$ -measure, both of which aim to balance errors on either classes (see Examples 4 and 7 for the Bayes criterion for these measures). We used a balanced version of SVM (where the positive and negative points were weighted with costs  $1/p$  and  $1/(1-p)$  respectively) as the learning algorithm for

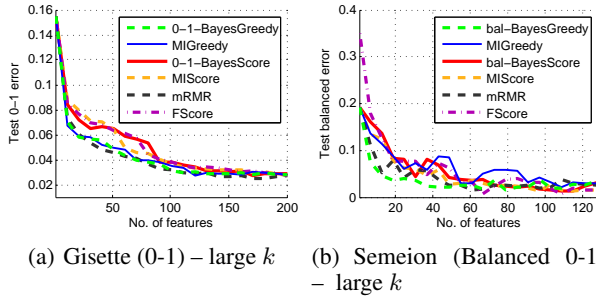

Figure 5: Selecting larger numbers of features. The settings here are similar to previous plots, except that bivariate approximations were used in estimating class-conditionals.

the balanced 0-1-error; and a plug-in method using logistic regression followed by thresholding of the resulting class probability estimate at a sample-based optimal point as the learning algorithm for the  $F_1$ -measure [33, 36, 37]. Figure 4 contains results on the class-imbalanced Semeion ( $p = 0.102$ ) and KDDCup01 ( $p = 0.022$ ) data sets. In the case of Semeion, the BayesGreedy methods perform the best over all. With KDDCup01, where we include results for the balanced 0-1 error (the performance measure used in the KDD Cup 2001 challenge), there is no clear winner; here, BayesScore performs the best for smaller feature subsets, and MIGreedy performs better for larger subsets.

#### 4.4 SELECTING LARGER NUMBER OF FEATURES

We also evaluated the proposed filter methods on large feature subset sizes  $k$ . As noted earlier, an exact implementation of the prescribed greedy algorithm is difficult in this case as estimation of high-dimensional class-conditional distributions from limited data is prone to errors and is also computationally expensive. We therefore resorted to the bivariate approximation technique described in Section 3.2 for estimating the class-conditional distributions; the MIGreedy method also used the same estimation procedure, while the search technique in mRMR inherently used a similar approximation [6]. Figure 5 contains results on the Gisetite (binary classification with 0-1 loss) and Semeion (binary classification with balanced 0-1 loss) data sets. In the case of Semeion, the BayesGreedy method consistently performs as well as (if not better than) the baselines; in the case of Gisetite, BayesGreedy is the second best over all.

#### 4.5 RUN-TIME COMPARISONS

We now present run-time comparisons of the various filter methods for different values of  $k$ . Table 2 contains the run-times (in seconds) for cost-sensitive classification on Adult data, and 0-1 binary classification with large  $k$  on Gisetite data (with approximations used to estimate conditional distributions). All methods here were implemented in MATLAB. As expected, the score-based methods, requiring only a single sort operation, offer the least run-

| Adult ( $c = 0.25$ )       |          |          |          |
|----------------------------|----------|----------|----------|
|                            | $k = 5$  | $k = 10$ | $k = 15$ |
| $c$ -BayesGreedy           | 1.75     | 12.78    | 71.14    |
| MIGreedy                   | 1.95     | 15.63    | 94.06    |
| $c$ -BayesScore            | 0.10     | 0.10     | 0.10     |
| MIScore                    | 0.17     | 0.19     | 0.17     |
| mRMR                       | 1.32     | 5.27     | 11.71    |
| FScore                     | 0.06     | 0.08     | 0.08     |
| Gisetite (0-1) – large $k$ |          |          |          |
|                            | $k = 25$ | $k = 50$ | $k = 75$ |
| 0-1-BayesGreedy            | 954      | 3784     | 8475     |
| MIGreedy                   | 2123     | 8330     | 18475    |
| 0-1-BayesScore             | 2.62     | 2.65     | 2.71     |
| MIScore                    | 2.67     | 2.73     | 2.76     |
| mRMR                       | 1242     | 5046     | 11384    |
| FScore                     | 1.01     | 1.08     | 1.04     |

Table 2: Run-time comparison of various filter methods for different values of  $k$ . All values are in *seconds*. The settings here are same as before. For Gisetite, bivariate approximations were used to estimate conditional distributions.

times; however, as seen earlier, these methods often perform poorly in terms of accuracy. Among the other methods, BayesGreedy is significantly faster than MIGreedy, despite both methods using the same search procedure (this is because the Bayes criteria for the 0-1 and cost-sensitive losses involve simple ‘max’ operations that can be implemented efficiently). On the Adult data, where BayesGreedy computes exact estimates of conditional distributions, it is slower than mRMR; however, when BayesGreedy uses computationally cheaper bivariate approximations to estimate probabilities, it yields lower run-times than mRMR even for larger values of  $k$ , as seen with the Gisetite data.

## 5 CONCLUSION

We have developed a Bayes optimal filter method for feature selection with supervised learning considering general performance measures, and provided instantiations of our method for a variety of learning problems and performance measures. Experiments demonstrate that our approach is competitive with many state-of-the-art methods. While our focus has been on problems with binary labels, our approach easily generalizes to multiclass settings.

A possible direction of work in the future is to investigate approximation guarantees for the greedy algorithm used to optimize a given Bayes optimal criteria. Indeed (under specific assumptions) such guarantees have been established for the MI criterion and the criterion for regression with squared loss, by leveraging tools from submodular optimization [38, 39]. It would be interesting to explore similar results for the other filter criteria developed in this work.

## Abstract

We provide a rigorous definition of the *visual cause* of a behavior that is broadly applicable to the visually driven behavior in humans, animals, neurons, robots and other perceiving systems. Our framework generalizes standard accounts of causal learning to settings in which the causal variables need to be constructed from micro-variables. We prove the Causal Coarsening Theorem, which allows us to gain causal knowledge from observational data with minimal experimental effort. The theorem provides a connection to standard inference techniques in machine learning that identify features of an image that *correlate* with, but may not *cause*, the target behavior. Finally, we propose an active learning scheme to learn a manipulator function that performs optimal manipulations on the image to automatically identify the visual cause of a target behavior. We illustrate our inference and learning algorithms in experiments based on both synthetic and real data.

## 1 INTRODUCTION

Visual perception is an important trigger of human and animal behavior. The visual cause of a behavior can be easy to define, say, when a traffic light turns green, or quite subtle: apparently it is the increased symmetry of features that leads people to judge faces more attractive than others (Grammer and Thornhill, 1994). Significant scientific and economic effort is focused on visual causes in advertising, entertainment, communication, design, medicine, robotics and the study of human and animal cognition. Visual causes profoundly influence our daily activity, yet our understanding of what constitutes a visual cause lacks a theoretical basis. In practice, it is well-known that images are composed of millions of variables (the pixels) but it is functions of the pixels (often called ‘features’) that have meaning, rather than the pixels themselves.

We present a theoretical framework and inference algorithms for visual causes in images. A visual cause is defined (more formally below) as a function (or *feature*) of raw image pixels that has a *causal effect* on the target behavior of a perceiving system of interest. We present three advances:

- We provide a definition of the visual cause of a target behavior as a macro-variable that is constructed from the micro-variables (pixels) that make up the image space. The visual cause is distinguished from other macro-variables in that it contains all the causal information about the target behavior that is available in the image. We place the visual cause within the standard framework of causal graphical models (Spirtes et al., 2000; Pearl, 2009), thereby contributing to an account of how to construct causal variables.
- We prove the Causal Coarsening Theorem (CCT), which shows how observational data can be used to learn the visual cause with minimal experimental effort. It connects the present results to standard classification tasks in machine learning.
- We describe a method to learn the manipulator function, which automatically performs perceptually optimal manipulations on the visual causes.

We illustrate our ideas using synthetic and real-data experiments. Python code that implements our algorithms, as well as reproduces some of the experimental results, is available online at <http://vision.caltech.edu/~kchalupk/code.html>.

We chose to develop the theory within the context of *visual* causes as this setting makes the definitions most intuitive and is itself of significant practical interest. However, the framework and results can be equally well applied to extract causal information from any aggregate of micro-variables on which manipulations are possible. Examples include auditory, olfactory and other sensory stimuli; high-dimensional neural recordings; market data in finance; consumer data in marketing. There, causal feature learning is both of theoretical (“What is the cause?”) and practical (“Can we automatically manipulate it?”) importance.

## 1.1 PREVIOUS WORK

Our framework extends the theory of causal graphical models (Spirtes et al., 2000; Pearl, 2009) to a setting in which the input data consists of raw pixel (or other micro-variable) data. In contrast to the standard setting, in which the macro-variables in the statistical dataset already specify the candidate causal relations, the causal variables in our setting have to be constructed from the micro-variables they supervene on, before any causal relations can be established. We emphasize the difference between our method of causal feature *learning* and methods for causal feature *selection* (Guyon et al., 2007; Pellet and Elisseeff, 2008). The latter choose the best (under some causal criterion) features from a restricted set of plausible macro-variable candidates. In contrast, our framework efficiently searches the whole space of all the possible macro-variables that can be constructed from an image.

Our approach derives its theoretical underpinnings from the theory of computational mechanics (Shalizi and Crutchfield, 2001; Shalizi, 2001), but supports a more explicitly causal interpretation by incorporating the possibility of confounding and interventions. We take the distinction between interventional and observational distributions to be one of the key features of a causal analysis. Since we allow for unmeasured common causes of the features in the image and the target behavior, we have to distinguish between the plain conditional probability distribution of the target behavior ( $T$ ) given the (observed) image ( $I$ ) and the distribution of the target behavior given that the observed image was manipulated (i.e.  $P(T|I)$  vs.  $P(T|do(I))$ ). Hoel et al. (2013), who develop a similar model to investigate the relationship between causal micro- and macro-variables, avoid this distinction by assuming that all their data was generated from what in our setting would be the manipulated distribution  $P(T|do(I))$ . The extant literature on causal learning from image or video data does not generally consider the aggregation from pixel variables into causal macro-variables, but instead starts from annotated or pre-defined features of the image (see e.g. Fire and Zhu (2013a,b)).

## 1.2 CAUSAL FEATURE LEARNING: AN EXAMPLE

Fig. 1 presents a paradigmatic case study in visual causal feature learning, which we will use as a running example. The contents of an image  $I$  are caused by external, non-visual binary hidden variables  $H_1$  and  $H_2$  such that if  $H_1$  is on,  $I$  contains a vertical bar (v-bar<sup>1</sup>) at a random position, and if  $H_2$  is on,  $I$  contains a horizontal bar (h-bar) at a random position. A target behavior  $T \in \{0, 1\}$  is caused by  $H_1$  and  $I$ , such that  $T = 1$  is more likely whenever  $H_1 = 1$  and whenever the image contains an h-bar.

<sup>1</sup>We take a v-bar (h-bar) to consist of a complete column (row) of black pixels.

We deliberately constructed this example such that the visual cause is clearly identifiable: manipulating the presence of an h-bar in the image will influence the distribution of  $T$ . Thus, we can call the following function  $C: \mathcal{I} \rightarrow \{0, 1\}$  the *causal feature* of  $I$  or the *visual cause* of  $T$ :

$$C(I) = \begin{cases} 1 & \text{if } I \text{ contains an h-bar} \\ 0 & \text{otherwise.} \end{cases}$$

The presence of a v-bar, on the other hand, is not a causal feature. Manipulating the presence of a v-bar in the image has no effect on  $H_1$  or  $T$ . Still, the presence of a v-bar is as strongly correlated with the value of  $T$  (via the common cause  $H_1$ ) as the presence of an h-bar is. We will call the following function  $S: \mathcal{I} \rightarrow \{0, 1\}$  the *spurious correlate* of  $T$  in  $I$ :

$$S(I) = \begin{cases} 1 & \text{if } I \text{ contains a v-bar} \\ 0 & \text{otherwise.} \end{cases}$$

Both the presence of h-bars and the presence of v-bars are good individual (and even better joint) predictors of the target variable, but only one of them is a cause. Identifying the visual cause from the image thus requires the ability to distinguish among the correlates of the target variables those that are actually causal, even if the non-causal correlates are (possibly more strongly) correlated with the target.

While the values of  $S$  and  $C$  in our example stand in a bijective correspondence to the values of  $H_1$  and  $H_2$ , respectively, this is only to keep the illustration simple. In general, the visual cause and the spurious correlate can be probabilistic functions of any number of (not necessarily independent) hidden variables, and can share the same hidden causes.

## 2 A THEORY OF VISUAL CAUSAL FEATURES

In our example the identification of the visual cause with the presence of an h-bar is intuitively obvious, as the model is constructed to have an easily describable visual cause. But the example does not provide a theoretical account of what it takes to be a visual cause in the general case when we do not know what the causally relevant pixel configurations are. In this section, we provide a general account of how the visual cause is related to the pixel data.

### 2.1 VISUAL CAUSES AS MACRO-VARIABLES

A visual cause is a high-level random variable that is a function (or feature) of the image, which in turn is defined by the random micro-variables that determine the pixel values. The functional relation between the image and the visual cause is, in general, surjective, though in principle it could be bijective. While we are interested in identifying

Figure 1: Our case study generative model. Two binary hidden (non-visual) variables  $H_1$  and  $H_2$  toss unbiased coins. The content of the image  $I$  depends on these variables as follows. If  $H_1 = H_2 = 0$ ,  $I$  is chosen uniformly at random from all the images containing no v-bars and no h-bars. If  $H_1 = 0$  and  $H_2 = 1$ ,  $I$  is chosen uniformly at random from all images containing at least one h-bar but no v-bars. If  $H_1 = 1$  and  $H_2 = 0$ ,  $I$  is chosen uniformly at random from all the images containing at least one v-bar but no h-bars. Finally, if  $H_1 = H_2 = 1$ ,  $I$  is chosen from images containing at least one v-bar and at least one h-bar. The distribution of the binary behavior  $T$  depends only on the presence of an h-bar in  $I$  and the value of  $H_1$ . In observational studies,  $H_1 = 1$  iff  $I$  contains a v-bar. However, a *manipulation* of any specific image  $I = i$  that introduces a v-bar (without changing  $H_1$ ) will in general not change the probability of  $T$  occurring. Thus,  $T$  does *not* depend causally on the presence of v-bars in  $I$ .

the visual causes of a target behavior, the functional relation between the image pixels and the visual cause should not itself be interpreted as causal. Pixels do not *cause* the features of an image, they *constitute* them, just as the atoms of a table constitute the table (and its features). The difference between the causal and the constitutive relation is that the former requires the possibility of independent manipulation (at least to some extent), whereas by definition one cannot manipulate the visual cause without manipulating the image pixels.

The probability distribution over the visual cause is induced by the probability distribution over the pixels in the image and the functional mapping from the image to the visual cause. But since a visual cause stands in a constitutive relation with the image, we cannot without further explanation describe interventions on the visual cause in terms of the standard *do*-operation (Pearl, 2009). Our goal will be to define a macro-variable  $C$ , which contains all the causal

information available in an image about a given behavior  $T$ , and define its manipulation. To make the problem approachable, we introduce two (natural) assumptions about the causal relation between the image and the behavior: (i) The value of the target behavior  $T$  is determined subsequently to the image in time, and (ii) the variable  $T$  is in no way represented in the image. These assumptions exclude the possibility that  $T$  is a cause of features in the image or that  $T$  can be seen as causing itself.

## 2.2 GENERATIVE MODELS: FROM MICRO- TO MACRO-VARIABLES

Let  $T \in \{0, 1\}$  represent a target behavior.<sup>2</sup> Let  $\mathcal{I}$  be a discrete space of all the images that can influence the target behavior (in our experiments in Section 4,  $\mathcal{I}$  is the space of  $n$ -dimensional black-and-white images). We use the following generative model to describe the relation between the images and the target behavior: An image is generated by a finite set of unobserved discrete variables  $H_1, \dots, H_m$  (we write  $\mathbf{H}$  for short). The target behavior is then determined by the image and possibly a subset of variables  $\mathbf{H}_c \subseteq \mathbf{H}$  that are confounders of the image and the target behavior:

$$\begin{aligned}
 P(T, I) &= \sum_{\mathbf{H}} P(T | I, \mathbf{H}) P(I | \mathbf{H}) P(\mathbf{H}) \\
 &= \sum_{\mathbf{H}} P(T | I, \mathbf{H}_c) P(I | \mathbf{H}) P(\mathbf{H}). \quad (1)
 \end{aligned}$$

Independent noise that may contribute to the target behavior is marginalized and omitted for the sake of simplicity in the above equation. The noise term incorporates any hidden variables which influence the behavior but stand in no causal relation to the image. Such variables are not directly relevant to the problem. Fig. 2 shows this generative model.

Under this model, we can define an *observational partition* of the space of images  $\mathcal{I}$  that groups images into classes that have the same conditional probability  $P(T | I)$ :

**Definition 1** (Observational Partition, Observational Class). *The observational partition  $\Pi_o(T, \mathcal{I})$  of the set  $\mathcal{I}$  w.r.t. behavior  $T$  is the partition induced by the equivalence relation  $\sim$  such that  $i \sim j$  if and only if  $P(T | I = i) = P(T | I = j)$ . We will denote it as  $\Pi_o$  when the context is clear. A cell of an observational partition is called an observational class.*

In standard classification tasks in machine learning, the observational partition is associated with class labels. In our case, two images that belong to the same cell of the observational partition assign equal *predictive* probability to the target behavior. Thus, knowing the observational class

<sup>2</sup>An extension of the framework to non-binary, discrete  $T$  is easy but complicates the notation significantly. An extension to the continuous case is beyond the scope of this article.

Figure 2: A general model of visual causation. In our model each image  $I$  is caused by a number of hidden non-visual variables  $H_i$ , which need not be independent. The image itself is the only observed cause of a target behavior  $T$ . In addition, a (not necessarily proper) subset of the hidden variables can be a cause of the target behavior. These confounders create visual “spurious correlates” of the behavior in  $I$ .

of an image allows us to predict the value of  $T$ . However, the predictive probability assigned to an image does not tell us the *causal* effect of the image on  $T$ . For example, a barometer is widely taken to be an excellent predictor of the weather. But changing the barometer needle does not cause an improvement of the weather. It is not a (visual or otherwise) cause of the weather. In contrast, seeing a particular barometer reading may well be a *visual cause* of whether we pack an umbrella.

Our notion of a visual cause depends on the ability to manipulate the image.

**Definition 2** (Visual Manipulation). A visual manipulation is the operation  $man(I = i)$  that changes (the pixels of) the image to image  $i \in \mathcal{I}$ , while not affecting any other variables (such as  $\mathbf{H}$  or  $T$ ). That is, the manipulated probability distribution of the generative model in Eq. (1) is given by  $P(T | man(I = i)) = \sum_{\mathbf{H}_c} P(T | I = i, \mathbf{H}_c)P(\mathbf{H}_c)$ .

The manipulation changes the values of the image pixels, but does not change the underlying “world”, represented in our model by the  $H_i$  that generated the image. Formally, the manipulation is similar to the *do*-operator for standard causal models. However, we here reserve the *do*-operation for interventions on causal *macro*-variables, such as the visual cause of  $T$ . We discuss the distinction in more detail below.

We can now define the *causal partition* of the image space (with respect to the target behavior  $T$ ) as:

**Definition 3** (Causal Partition, Causal Class). The causal partition  $\Pi_c(T, \mathcal{I})$  of the set  $\mathcal{I}$  w.r.t. behavior  $T$  is the partition induced by the equivalence relation  $\sim$  defined on  $\mathcal{I}$  such that  $i \sim j$  if and only if  $P(T | man(I = i)) = P(T | man(I = j))$  for  $i, j \in \mathcal{I}$ . When the image space and the target behavior are clear from the context, we will indicate the causal partition by  $\Pi_c$ . A cell of a causal partition is

called a causal class.

The underlying idea is that images are considered causally equivalent with respect to  $T$  if they have the same causal effect on  $T$ . Given the causal partition of the image space, we can now define the visual cause of  $T$ :

**Definition 4** (Visual Cause). The visual cause  $C$  of a target behavior  $T$  is a random variable whose value stands in a bijective relation to the causal class of  $I$ .

The visual cause is thus a function over  $\mathcal{I}$ , whose values correspond to the post-manipulation distributions  $C(i) = P(T | man(I = i))$ . We will write  $C(i) = c$  to indicate that the causal class of image  $i \in \mathcal{I}$  is  $c$ , or in other words, that in image  $i$ , the visual cause  $C$  takes value  $c$ . Knowing  $C$  allows us to predict the effects of a visual manipulation  $P(T | man(I = i))$ , as long as we have estimated  $P(T | man(I = i_k^*))$  for one representative  $i_k^*$  of each causal class  $k$ .

### 2.3 THE CAUSAL COARSENING THEOREM

Our main theorem relates the causal and observational partitions for a given  $\mathcal{I}$  and  $T$ . It turns out that in general the causal partition is a coarsening of the observational partition. That is, the causal partition aligns with the observational partition, but the observational partition may subdivide some of the causal classes.

**Theorem 5** (Causal Coarsening). Among all the generative distributions of the form shown in Fig. 2 which induce a given observational partition  $\Pi_o$ , almost all induce a causal partition  $\Pi_c$  that is a coarsening of the  $\Pi_o$ .

Throughout this article, we use “almost all” to mean “all except for a subset of Lebesgue measure zero”. Fig. 3 illustrates the relation between the causal and the observational partition implied by the theorem. We prove the CCT in Supplementary Material A using a technique that extends that of Meek (1995): We show that (1) restricting the space of all the possible  $P(T, H, I)$  to only the distributions compatible with a fixed observational partition puts a linear constraint on the distribution space; (2) requiring that the CCT be false puts a non-trivial polynomial constraint on this subspace, and finally, (3) it follows that the theorem holds for almost all distributions that agree with the given observational partition. The proof strategy indicates a close connection between the CCT and the faithfulness assumption (Spirtes et al., 2000). We note that the measure-zero subset where  $\Pi_c$  does not coarsen  $\Pi_o$  can indeed be non-empty. We provide such counter-examples in Supplementary Material B.

Two points are worth noting here: First, the CCT is interesting inasmuch as the visual causes of a behavior do not contain all the information in the image that predict the behavior. Such information, though not itself a cause of

Figure 3: The Causal Coarsening Theorem. The observational probabilities of  $T$  given  $I$  (gray frame) induce an observational partition on the space of all the images (left, observational partition in gray). The causal probabilities (red frame) induce a causal partition, indicated on the left in red. The CCT allows us to expect that the causal partition is a coarsening of the observational partition. The observational and causal probabilities correspond to the generative model shown in Fig. 1.

the behavior, can be informative about the state of other non-visual causes of the target behavior. Second, the CCT allows us to take any classification problem in which the data is divided into observational classes, and assume that the causal labels do not change within each observational class. This will help us develop efficient causal inference algorithms in Section 3.

## 2.4 VISUAL CAUSES IN A CAUSAL MODEL CONSISTING OF MACRO-VARIABLES

We can now simplify our generative model by omitting all the information in  $I$  unrelated to behavior  $T$ . Assume that the observational partition  $\Pi_o^T$  refines the causal partition  $\Pi_c^T$ . Each of the causal classes  $c_1, \dots, c_K$  delineates a region in the image space  $\mathcal{I}$  such that all the images belonging to that region induce the same  $P(T \mid \text{man}(I))$ . Each of those regions—say, the  $k$ -th one—can be further partitioned into sub-regions  $s_1^k, \dots, s_{M_k}^k$  such that all the images in the  $m$ -th sub-region of the  $k$ -th causal region induce the same observational probability  $P(T \mid I)$ . By assumption, the observational partition has a finite number of classes, and we can arbitrarily order the observational classes within each causal class. Once such an ordering is fixed, we can assign an integer  $m \in \{1, 2, \dots, M_k\}$  to each image  $i$  belonging to the  $k$ -th causal class such that  $i$  belongs to the  $m$ -th observational class among the  $M_k$  observational classes contained in  $c_k$ . By construction, this integer explains all the variation of the observational class within a given causal class. This suggests the following definition:

**Definition 6 (Spurious Correlate).** *The spurious correlate  $S$  is a discrete random variable whose value differentiates between the observational classes contained in any causal*

Figure 4: A macro-variable model of visual causation. Using our theory of visual causation we can aggregate the information present in visual micro-variables (image pixels) into the visual cause  $C$  and spurious correlate  $S$ . According to Theorem 7,  $C$  and  $S$  contain all the information about  $T$  available in  $I$ .

class.

The spurious correlate is a well-defined function on  $\mathcal{I}$ , whose value ranges between 1 and  $\max_k M_k$ . Like  $C$ , the spurious correlate  $S$  is a macro-variable constructed from the pixels that make up the image.  $C$  and  $S$  together contain all and only the visual information in  $I$  relevant to  $T$ , but only  $C$  contains the causal information:

**Theorem 7 (Complete Macro-variable Description).** *The following two statements hold for  $C$  and  $S$  as defined above:*

1.  $P(T \mid I) = P(T \mid C, S)$ .
2. Any other variable  $X$  such that  $P(T \mid I) = P(T \mid X)$  has Shannon entropy  $H(X) \geq H(C, S)$ .

We prove the theorem in Supplementary Material C. It guarantees that  $C$  and  $S$  constitute the smallest-entropy macro-variables that encompass all the information about the relationship between  $T$  and  $I$ . Fig. 4 shows the relationship between  $C, S$  and  $T$ , the image space  $\mathcal{I}$  and the observational and causal partitions schematically.  $C$  is now a cause of  $T$ ,  $S$  correlates with  $T$  due to the unobserved common causes  $\mathbf{H}_C$ , and any information irrelevant to  $T$  is pushed into the independent noise variables (commonly not shown in graphical representations of structural equation models).<sup>3</sup>

The macro-variable model lends itself to the standard treatment of causal graphical models described in Pearl

<sup>3</sup>We note that  $C$  may retain predictive information about  $T$  that is not causal, i.e. it is not the case that all spurious correlations can be accounted for in  $S$ . See Supplementary Material D for an example.

(2009). We can define interventions on the causal variables  $\{C, S, T\}$  using the standard *do*-operation. The *do*-operator only sets the value of the intervened variable to the desired value, making it independent of its causes, but it does not (directly) affect the other variables in the system or the relationships between them (see the *modularity assumption* in Pearl (2009)). However, unlike the standard case where causal variables are separated in location (e.g. *smoking* and *lung cancer*), the causal variables in an image may involve the same pixels:  $C$  may be the average brightness of the image, whereas  $S$  may indicate the presence or absence of particular shapes in the image. An intervention on a causal variable using the *do*-operator thus requires that the underlying manipulation of the image respects the state of the other causal variables:

**Definition 8** (Causal Intervention on Macro-variables). *Given the set of macro-variables  $\{C, S\}$  that take on values  $\{c, s\}$  for an image  $i \in \mathcal{I}$ , an intervention  $do(C = c')$  on the macro-variable  $C$  is given by the manipulation of the image  $man(I = i')$  such that  $C(i') = c'$  and  $S(i') = s$ . The intervention  $do(S = s')$  is defined analogously as the change of the underlying image that keeps the value of  $C$  constant.*

In some cases it can be impossible to manipulate  $C$  to a desired value without changing  $S$ . We do not take this to be a problem special to our case. In fact, in the standard macro-variable setting of causal analysis we would expect interventions to be much more restricted by physical constraints than we are with our interventions in the image space.

### 3 CAUSAL FEATURE LEARNING: INFERENCE ALGORITHMS

Given the theoretical specification of the concepts of interest in the previous section, we can now develop algorithms to learn  $C$ , the visual cause of a behavior. In addition, knowledge of  $C$  will allow us to specify a *manipulator function*: a function that, given any image, can return a maximally similar image with the desired causal effect.

**Definition 9** (Manipulator Function). *Let  $C$  be the causal variable of  $T$  and  $d$  a metric on  $\mathcal{I}$ . The manipulator function of  $C$  is a function  $M_C: \mathcal{I} \times \mathcal{C} \rightarrow \mathcal{I}$  such that  $M_C(i, k) = \arg \min_{i \in C^{-1}(k)} d(i, \hat{i})$  for any  $i \in \mathcal{I}, k \in \mathcal{C}$ . In case  $d(i, \cdot)$  has multiple minima, we group them together into one equivalence class and leave the choice of the representative to the manipulator function.*

The manipulator searches for an image closest to  $I$  among all the images with the desired causal effect  $k$ . The meaning of “closest” depends on the metric  $d$  and is discussed further in Section 3.2 below. Note that the manipulator function can find candidates for the image manipulation underlying the desired causal manipulation  $do(C = c)$ , but it does not check whether other variables in the system (in

particular, the spurious correlate) remain in fact unchanged. Using the closest possible image with the desired causal effect is a heuristic approach to fulfilling that requirement.

There are several reasons why we might want such a manipulator function:

- If our goal is to perform causal manipulations on images, the manipulator function offers an automated solution.
- A manipulator that uses a given  $C$  and produces images with the desired causal effect provides strong evidence that  $C$  is indeed the visual cause of the behavior.
- Using the manipulator function we can enrich our dataset with new datapoints, in hope of achieving better generalization on both the causal and predictive learning tasks.

The problem of visual causal feature learning can now be posed as follows: Given an image space  $\mathcal{I}$  and a metric  $d$ , learn  $C$ —the visual cause of  $T$ —and the manipulator  $M_C$ .

#### 3.1 CAUSAL EFFECT PREDICTION

A standard machine learning approach to learning the relation between  $I$  and  $T$  would be to take an *observational dataset*  $\mathcal{D}_{obs} = \{(i_k, P(T | i_k))\}_{k=1, \dots, N}$  and learn a predictor  $f$  whose training performance guarantees a low test error (so that  $f(i^*) \approx P(T | i^*)$  for a test image  $i^*$ ). In causal feature learning, low test error on observational data is insufficient; it is entirely possible that  $\mathcal{D}$  contains spurious information useful in predicting test labels which is nevertheless not causal. That is, the prediction may be highly accurate for observational data, but completely inaccurate for a prediction of the effect of a manipulation of the image (recall the barometer example). However, we can use the CCT to obtain a causal dataset from the observational data, and then train a predictor on that dataset. Algorithm 1 uses this strategy to learn a function  $C$  that, presented with any image  $i \in \mathcal{I}$ , returns  $C(i) \approx P(T | man(I = i))$ . We use a fixed neural network architecture to learn  $C$ , but any differentiable hypothesis class could be substituted instead. Differentiability of  $C$  is necessary in Section 3.2 in order to learn the manipulator function.

In Step 1 the algorithm picks a representative member of each observational class. The CCT tells us that the causal partition coarsens the observational one. That is, in principle (ignoring sampling issues) it is sufficient to estimate  $\hat{C}_m = P(T | man(I = i_{k_m}))$  for just one image in an observational class  $m$  in order to know that  $P(T | man(I = i)) = \hat{C}_m$  for any other  $i$  in the same observational class. The choice of the experimental method of estimating the causal class in Step 2 is left to the user and depends on the behaving agent and the behavior in question. If, for example,  $T$  represents whether the spiking rate of a recorded neuron is above a fixed threshold,

---

**Algorithm 1: Causal Predictor Training**

---

**input** :  $\mathcal{D}_{obs} = \{(i_1, p_1 = p(T | i_1)), \dots, (i_N, p_N = p(T | i_N))\}$  – observational data  
 $\mathcal{P} = \{P_1, \dots, P_M\}$  – the set of observational classes (so that  $\forall k, p_k \in \mathcal{P}, 1 \leq k \leq N$ )  
 $\text{Train}$  – a neural net training algorithm

**output**:  $C: \mathcal{I} \rightarrow [0, 1]$  – the causal variable

- 1 Pick  $\{i_{k_1}, \dots, i_{k_M}\} \subset \{i_1, \dots, i_N\}$  s.t.  $p_{k_m} = P_m$ ;
- 2 Estimate  $\hat{C}_m \leftarrow P(T | \text{man}(I = i_{k_m}))$  for each  $m$ ;
- 3 For all  $k$  let  $\hat{C}(i_k) \leftarrow \hat{C}_m$  if  $p_k = P_m$ ;
- 4  $\mathcal{D}_{csl} \leftarrow \{(i_1, \hat{C}(i_1)), \dots, (i_N, \hat{C}(i_N))\}$ ;
- 5  $C \leftarrow \text{Train}(\mathcal{D}_{csl})$ ;

---

estimating  $P(T | \text{man}(I = i))$  could consist of recording the neuron’s response to  $i$  in a laboratory setting multiple times, and then calculating the probability of spiking from the finite sample. The causal dataset created in Step 4 consists of the observational inputs and their causal classes. The causal dataset is acquired through  $\mathcal{O}(N)$  experiments, where  $N$  is the number of observational classes. The final step of the algorithm trains a neural network that predicts the causal labels on unseen images. The choice of the method of training is again left to the user.

### 3.2 CAUSAL FEATURE MANIPULATION

Once we have learned  $C$  we can use the causal neural network to create synthetic examples of images as similar as possible to the originals, but with a different causal label. The meaning of “as similar as possible” depends on the image metric  $d$  (see Definition 9). The choice of  $d$  is task-specific and crucial to the quality of the manipulations. In our experiments, we use a metric induced by an  $L_2$  norm. Alternatives include other  $L_p$ -induced metrics, distances in implicit feature spaces induced by image kernels (Harchaoui and Bach, 2007; Grauman and Darrell, 2007; Bosch et al., 2007; Vishwanathan, 2010) and distances in learned representation spaces (Bengio et al., 2013).

Algorithm 2 proposes one way to learn the manipulator function using a simple manipulation procedure that approximates the requirements of Definition 9 up to local minima. The algorithm, inspired by the active learning techniques of uncertainty sampling (Lewis and Gale, 1994) and density weighing (Settles and Craven, 2008), starts off by training a causal neural network in Step 2. If only observational data is available, this can be achieved using Algorithm 1. Next, it randomly chooses a set of images to be manipulated, and their target post-manipulation causal labels. The loop that starts in Step 6 then takes each of those images and searches for the image that, among the images with the same desired causal class, is closest to the original image. Note that the causal class boundaries are defined by the current causal neural net  $C$ . Since  $C$  is in general a

---

**Algorithm 2: Manipulator Function Learning**

---

**input** :  $d: \mathcal{I} \times \mathcal{I} \rightarrow \mathbb{R}_+$  – a metric on the image space  
 $\mathcal{D}_{csl} = \{(i_1, c_1), \dots, (i_N, c_N)\}$  – causal data  
 $\mathcal{C} = \{C_1, \dots, C_M\}$  – the set of causal classes (so that  $\forall i, c_i \in \mathcal{C}$ )  
 $\text{Train}$  – a neural net training algorithm  
 $n\text{Iters}$  – number of experiment iterations  
 $Q$  – number of queries per iteration  
 $\alpha$  – manipulation tuning parameter  
 $A: \mathcal{I} \rightarrow \mathcal{C}$  – an oracle for  $P(T | do(I))$

**output**:  $M_C: \mathcal{I} \times \mathcal{C} \rightarrow \mathcal{I}$  – the manipulator function

- 1 **for**  $l \leftarrow 1$  **to**  $n\text{Iters}$  **do**
- 2      $C \leftarrow \text{Train}(\mathcal{D}_{csl})$ ;
- 3     Choose manipulation starting points  $\{i_{l,1}, \dots, i_{l,Q}\}$  at random from  $\mathcal{D}_{csl}$ ;
- 4     Choose manipulation targets  $\{\hat{c}_{l,1}, \dots, \hat{c}_{l,Q}\}$  such that  $\hat{c}_{l,k} \neq c_{l,k}$ ;
- 5     **for**  $k \leftarrow 1$  **to**  $Q$  **do**
- 6          $\hat{i}_{l,k} \leftarrow \operatorname{argmin}_{j \in \mathcal{I}} (1 - \alpha)|C(j) - \hat{c}_{l,k}| + \alpha d(j, i_{l,k})$ ;
- 7     **end**
- 8      $\mathcal{D}_{csl} \leftarrow \mathcal{D}_{csl} \cup \{(i_{l,1}, A(\hat{i}_{l,1})), \dots, (i_{l,Q}, A(\hat{i}_{l,Q}))\}$ ;
- 9 **end**

---

highly nonlinear function and it can be hard to find its inverse sets, we use an approximate solution. The algorithm thus finds the minimum of a weighted sum of  $|C(j) - \hat{c}_{l,k}|$  (the difference of the output image  $j$ ’s label and the desired label  $\hat{c}_{l,k}$ ) and  $d(i_{l,k}, j)$  (the distance of the output image  $j$  from the original image  $i_{l,k}$ ).

At each iteration, the algorithm performs  $Q$  manipulations and the same number of causal queries to the agent, which result in new datapoints  $(\hat{i}_{l,1}, A(\hat{i}_{l,1})), \dots, (\hat{i}_{l,Q}, A(\hat{i}_{l,Q}))$ . It is natural to claim that the manipulator performs well if  $A(\hat{i}_{l,k}) \approx \hat{c}_{l,k}$  for many  $k$ , which means the target causal labels agree with the true causal labels. We thus define the *manipulation error* of the  $l$ th iteration  $M\text{Err}_l$  as

$$M\text{Err}_l = \frac{1}{Q} \sum_{k=1}^Q |A(\hat{i}_{l,k}) - \hat{c}_{l,k}|. \quad (2)$$

While it is important that our manipulations are accurate, we also want them to be minimal. Another measure of interest is thus the *average manipulation distance*

$$M\text{Dist}_l = \frac{1}{Q} \sum_{k=1}^Q d(I_{l,k}, \hat{i}_{l,k}). \quad (3)$$

A natural variant of Algorithm 2 is to set  $n\text{Iters}$  to a large

integer and break the loop when one or both of these performance criteria reaches a desired value.

## 4 EXPERIMENTS

In order to illustrate the concepts presented in this article we perform two causal feature learning experiments. The first experiment, called GRATING, uses observational and causal data generated by the model from Section 1.2. The GRATING experiment confirms that our system can learn the ground truth cause and ignore the spurious correlates of a behavior. The second experiment, MNIST, uses images of hand-written digits (LeCun et al., 1998) to exemplify the use of the manipulator function on slightly more realistic data: in this example, we transform an image into a maximally similar image with another class label.

We chose problems that are simple from the computer vision point of view. Our goal is to develop the theory of visual causal feature learning and show that it has feasible algorithmic solutions; we are at this point not engineering advanced computer vision systems.

### 4.1 THE GRATING EXPERIMENT

In this experiment we generate data using the model of Fig. 1, with two minor differences:  $H_1$  and  $H_2$  only induce one v-bar or h-bar in the image and we restrict our observational dataset to images with only about 3% of the pixels filled with random noise (see Fig. 5). Both restrictions increase the clarity of presentation. We use Algorithms 1 and 2 (with minor modifications imposed by the binary nature of the images) to learn the visual cause of behavior  $T$ .

Figure 5 (top) shows the progress of the training process. The first step (not shown in the figure) uses the CCT to learn the causal labels on the observational data. We then train a simple neural network (a fully connected network with one hidden layer of 100 units) on this data. The same network is used on Iteration 1 to create new manipulated exemplars. We then follow Algorithm 2 to train the manipulator iteratively. Fig. 5 (bottom) illustrates the difference between the manipulator on Iteration 1 (which fails almost 40% of the time) and Iteration 20, where the error is about 6%. Each column shows example manipulations of a particular kind. Columns with green labels indicate successful manipulations of which there are two kinds: switching the causal variable on ( $0 \Rightarrow 1$ , “adding the h-bar”), or switching it off ( $1 \Rightarrow 0$ , “removing the h-bar”). Red-labeled columns show cases in which the manipulator failed to influence the cause: That is, each red column shows an original image and its manipulated version which the manipulator believes should cause a change in  $T$ , but which does not induce such change. The red/green horizontal bars show the percentage of success/error for each manipulation direction. Fig. 5 (bottom, a) shows that after training on the

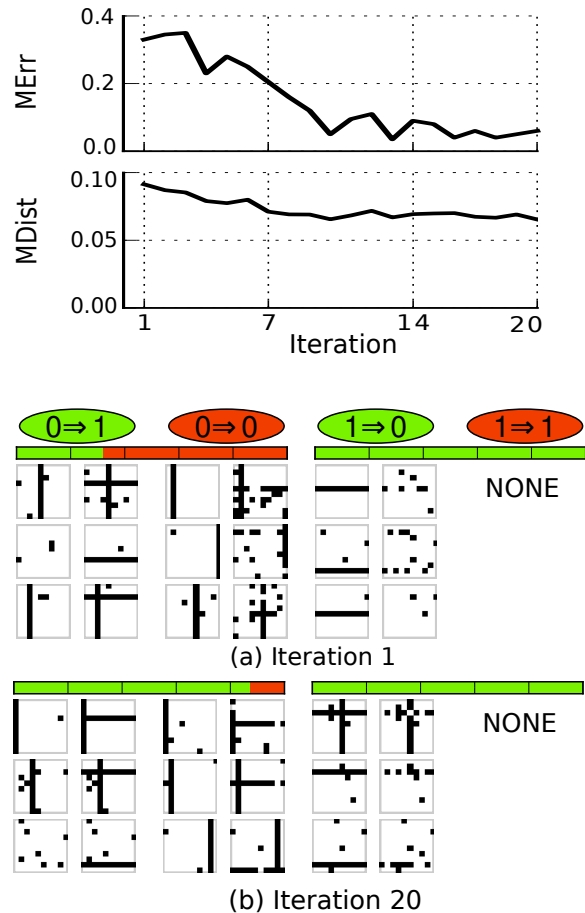

Figure 5: Manipulator learning for GRATING. **Top.** The plots show the progress of our manipulator function learning algorithm over twenty iterations of experiments for the GRATING problem. The manipulation error decreases quickly with progressing iterations, whereas the manipulation distance stays close to constant. **Bottom.** Original and manipulated GRATING images. See text for the details.

causally-coarsened observational dataset, the manipulator fails about 40% of the time. In Fig. 5 (b), after twenty manipulator learning iterations, only six manipulations out of a hundred are unsuccessful. Furthermore, the causally irrelevant image pixels are also much better preserved than at iteration 1. The fully-trained manipulator correctly learned to manipulate the presence of the h-bar to cause changes in  $T$ , and ignores the v-bar that is strongly correlated with the behavior but does not cause it.

### 4.2 THE MNIST ON MTURK EXPERIMENT

In this experiment we start with the MNIST dataset of handwritten digits. In our terminology, this – as well as any standard vision dataset – is already causal data: the labels are assigned in an experimental setting, not “in nature”.

Consider the following binary human behavior:  $T = 1$  if a human observer answers affirmatively to the question

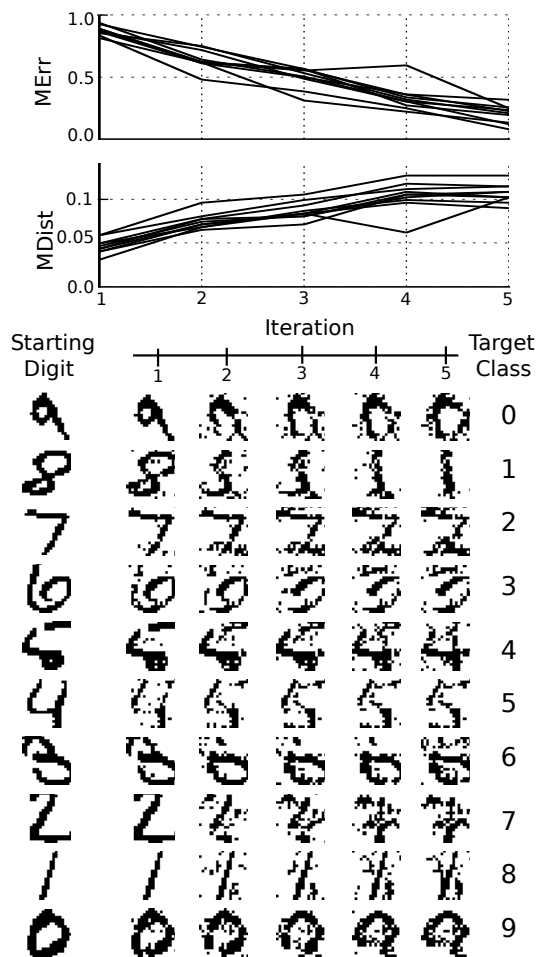

Figure 6: Manipulator Learning for MNIST ON MTURK. **Top.** In contrast to the GRATING experiment, here the manipulation distance grows as the manipulation error decreases. This is because a successful manipulator needs to change significant parts of each image (such as continuous strokes). **Bottom.** Visualization of manipulator training on randomly selected (not cherry-picked) MNIST digits. See text for the details.

“Does this image contain the digit ‘7’?”, while  $T = 0$  if the observer judges that the image does not contain the digit ‘7’. For simplicity we will assume that for any image either  $P(T = 1 | man(I)) = 0$  or  $P(T = 1 | man(I)) = 1$ . Our task is to learn the manipulator function that will take any image and modify it minimally such that it will become a ‘7’ if it was not before, or will stop resembling a ‘7’ if it did originally.

We conduct the manipulator training separately for all the ten MNIST digits using human annotators on Amazon Mechanical Turk. The exact training procedure is described in Supplementary Material E. Fig. 6 (top) shows training progress. As in Fig. 5, the manipulation error decreases with training. Fig. 6 (bottom) visualizes the manipulator training progress. In the first row we see a randomly chosen MNIST “9” being manipulated to resemble a “0”, pushed

through successive “0-vs-all” manipulators trained at iterations 0, 1, ..., 5 (iteration 1 shows what the neural net takes to be the closest manipulation to change the “9” to a “0” purely on the basis of the non-manipulated data). Further rows perform similar experiments for the other digits. The plots show how successive manipulators progressively remove the original digits’ features and add target class features to the image.

## 5 DISCUSSION

We provide a link between causal reasoning and neural network models that have recently enjoyed tremendous success in the fields of machine learning and computer vision (LeCun et al., 1998; Russakovsky et al., 2014). Despite very encouraging results in image classification (Krizhevsky et al., 2012), object detection (Dollar et al., 2012) and fine-grained classification (Branson et al., 2014; Zhang et al., 2014), some researchers have found that visual neural networks can be easily fooled using adversarial examples (Szegedy et al., 2014; Goodfellow et al., 2014). The learning procedure for our manipulator function could be viewed as an attempt to train a classifier that is robust against such examples. The procedure uses causal reasoning to improve on the boundaries of a standard, correlational classifier (Fig. 5 and 6 show the improvement). However, the ultimate purpose of a causal manipulator network is to extract truly causal features from data and automatically perform causal manipulations based on those features.

A second contribution concerns the field of causal discovery. Modern causal discovery algorithms presuppose that the set of causal variables is well-defined and meaningful. What exactly this presupposition entails is unclear, but there are clear counter-examples:  $x$  and  $2x$  cannot be two distinct causal variables. There are also well understood problems when causal variables are aggregates of other variables (Chu et al., 2003; Spirtes and Scheines, 2004). We provide an account of how causal macro-variables can supervene on micro-variables.

This article is an attempt to clarify how one may construct a set of well-defined causal macro-variables that function as basic relata in a causal graphical model. This step strikes us as essential if causal methodology is to be successful in areas where we do not have clearly delineated candidate causes or where causes supervene on micro-variables, such as in climate science and neuroscience, economics and—in our specific case—vision.

## Abstract

Determinantal point processes (DPPs) offer a powerful approach to modeling diversity in many applications where the goal is to select a diverse subset from a ground set of items. We study the problem of learning the parameters (i.e., the kernel matrix) of a DPP from labeled training data. In this paper, we develop a novel parameter estimation technique particularly tailored for DPPs based on the principle of large margin separation. In contrast to the state-of-the-art method of maximum likelihood estimation of the DPP parameters, our large-margin loss function explicitly models errors in selecting the target subsets, and it can be customized to trade off different types of errors (precision vs. recall). Extensive empirical studies validate our contributions, including applications on challenging document and video summarization, where flexibility in balancing different errors while training the summarization models is indispensable.

## 1 INTRODUCTION

Imagine we are to design a search engine to retrieve web images that match user queries. In response to the search term JAGUAR, what should we retrieve—the images of the animal jaguar or the images of the automobile jaguar?

This frequently cited example illustrates the need to incorporate the notion of *diversity*. In many tasks, we want to select a subset of items from a “ground set”. While the ground set might contain many similar items, our goal is *not* to discover all of the same ones, but rather to find a subset of diverse items that ensure coverage (the exact definition of coverage is task-specific). In the example of retrieving images for JAGUAR, we achieve diversity by including both types of images.

---

\*Equal contribution

Recently, the determinantal point process (DPP) has emerged as a promising technique for modeling diversity [Kulesza and Taskar, 2012]. A DPP defines a probability distribution over the power set of a ground set. Intuitively, subsets of higher diversity are assigned larger probabilities, and thus are more likely to be selected than those with lower diversity. Since its original application to quantum physics, DPP has found many applications in modeling random trees and graphs [Burton and Pemantle, 1993], document summarization [Kulesza and Taskar, 2011b], search and ranking in information retrieval [Kulesza and Taskar, 2011a], and clustering [Kang, 2013]. Various extensions have also been studied, including k-DPP [Kulesza and Taskar, 2011a], structured DPP [Kulesza and Taskar, 2011c], Markov DPP [Affandi et al., 2012], and DPP on continuous spaces [Affandi et al., 2013].

The probability distribution of a DPP depends crucially on its kernel—a square and symmetric, positive semidefinite matrix whose elements specify how similar every pair of items in the ground set are. This kernel matrix is often unknown and needs to be estimated from training data.

This is a very challenging problem for several reasons. First, the number of the parameters, i.e., the number of elements in the kernel matrix, is quadratic in the number of items in the ground set. For many tasks (for instance, image search), the ground set can be very large. Thus it is impractical to directly specify every element of the matrix, and a suitable reparameterization of the matrix is necessary. Secondly, the number of training samples is often limited in many practical applications. One such example is the task of document summarization, where our aim is to select a succinct subset of sentences from a long document. There, acquiring accurate annotations from human experts is costly and difficult. Thirdly, for many tasks, we need to evaluate the performance of the learned DPP not only by its accuracy in predicting whether an item should be selected, but also by other measures like precision and recall. For instance, failing to select key sentences for summarizing documents might be regarded as being more catastrophic than injecting sentences with repetitive information into the

summary.

Existing methods of parameter estimation for DPPs are inadequate to address these challenges. For example, maximum likelihood estimation (MLE) typically requires a large number of training samples in order to estimate the underlying model correctly. This also limits the number of the parameters it can estimate reliably, restricting its use to DPPs whose kernels can be parameterized with few degrees of freedom. It also does not offer fine control over precision and recall.

We propose a two-pronged approach for learning a DPP from labeled data. First, we improve modeling flexibility by reparameterizing the DPP’s kernel matrix with multiple base kernels. This representation could easily incorporate domain knowledge and requires learning fewer parameters (instead of the whole kernel matrix). Then, we optimize the parameters such that the probability of the correct subset is larger than other erroneous subsets by a large margin. This margin is task-specific and can be customized to reflect the desired performance measure—for example, to monitor precision and recall. As such, our approach defines objective functions that closely track selection errors and work well with few training samples. While the principle of large margin separation has been widely used in classification [Vapnik, 1998] and structured prediction [Taskar et al., 2005], formulating DPP learning with the large margin principle is novel. Our empirical studies show that the proposed method attains superior performance on two challenging tasks of practical interest: document and video summarization.

The rest of the paper is organized as follows. We provide background on the DPP in section 2, followed by our approach in section 3. We discuss related work in section 4 and report our empirical studies in section 5. We conclude in section 6.

## 2 BACKGROUND: DETERMINANTAL POINT PROCESSES

We first review background on the determinantal point process (DPP) [Macchi, 1975] and the standard maximum likelihood estimation technique for learning DPP parameters from data. More details can be found in the excellent tutorial [Kulesza and Taskar, 2012].

Given a ground set of  $M$  items,  $\mathcal{Y} = \{1, 2, \dots, M\}$ , a DPP defines a probabilistic measure over the power set, i.e., all possible subsets (including the empty set) of  $\mathcal{Y}$ . Concretely, let  $\mathbf{L}$  denote a symmetric and positive semidefinite matrix in  $\mathbb{R}^{M \times M}$ . The probability of selecting a subset  $\mathbf{y} \subseteq \mathcal{Y}$  is given by

$$P(\mathbf{y}; \mathbf{L}) = \det(\mathbf{L} + \mathbf{I})^{-1} \det(\mathbf{L}_{\mathbf{y}}), \quad (1)$$

where  $\mathbf{L}_{\mathbf{y}}$  denotes the submatrix of  $\mathbf{L}$ , with rows and

columns selected by the indices in  $\mathbf{y}$ .  $\mathbf{I}$  is the identity matrix with the proper size. We define  $\det(\mathbf{L}_{\emptyset}) = 1$ . The above way of defining a DPP is called an L-ensemble. An equivalent way of defining a DPP is to use a kernel matrix to define the marginal probability of selecting a random subset:

$$P_{\mathbf{y}} = \sum_{\mathbf{y}' \subseteq \mathcal{Y}} P(\mathbf{y}'; \mathbf{L}) \mathbb{I}[\mathbf{y} \subseteq \mathbf{y}'] = \det(\mathbf{K}_{\mathbf{y}}), \quad (2)$$

where we sum over all subsets  $\mathbf{y}'$  that contain  $\mathbf{y}$  ( $\mathbb{I}[\cdot]$  is an indicator function). The matrix  $\mathbf{K}$  is another positive semidefinite matrix, computable from the  $\mathbf{L}$  matrix

$$\mathbf{K} = \mathbf{L}(\mathbf{L} + \mathbf{I})^{-1}, \quad (3)$$

and  $\mathbf{K}_{\mathbf{y}}$  is the submatrix of  $\mathbf{K}$  indexed by  $\mathbf{y}$ . Despite the exponential number of summands in eq. (2), the marginalization is analytically tractable and computable in polynomial time.

### 2.1 MODELING DIVERSITY

One particularly useful property of the DPP is its ability to model *pairwise repulsion*. Consider the marginal probability of having two items  $i$  and  $j$  simultaneously in a subset:

$$\begin{aligned} P_{\{i,j\}} &= \det \begin{vmatrix} K_{ii} & K_{ij} \\ K_{ji} & K_{jj} \end{vmatrix} = K_{ii}K_{jj} - K_{ij}^2 \\ &\leq K_{ii}K_{jj} = P_{\{i\}}P_{\{j\}} \leq \min(P_{\{i\}}, P_{\{j\}}). \end{aligned} \quad (4)$$

Thus, unless  $K_{ij} = 0$ , the probability of observing  $i$  and  $j$  jointly is always less than observing either  $i$  or  $j$  separately. Namely, having  $i$  in a subset repulsively excludes  $j$  and vice versa. Another extreme case is when  $i$  and  $j$  are the same; then  $K_{ii} = K_{jj} = K_{ij}$ , which leads to  $P_{\{i,j\}} = 0$ . Namely, we should never allow them together in any subset.

Consequently, a subset with a large (marginal) probability cannot have too many items that are similar to each other (i.e., with high values of  $K_{ij}$ ). In other words, the probability provides a gauge of the diversity of the subset. The most diverse subset, which balances all the pairwise repulsions, is the subset that attains the highest probability

$$\mathbf{y}^{\text{MAP}} = \arg \max_{\mathbf{y}} P(\mathbf{y}; \mathbf{L}). \quad (5)$$

Note that this MAP inference is computed with respect to the L-ensemble (instead of  $\mathbf{K}$ ) as we are interested in the mode, not the marginal probability of having the subset. Unfortunately, the MAP inference is NP-hard [Ko et al., 1995]. Various approximation algorithms have been investigated [Gillenwater et al., 2012, Kulesza and Taskar, 2012].

## 2.2 MAXIMUM LIKELIHOOD ESTIMATION

Suppose we are given a training set  $\{(\mathcal{Y}_n, \mathbf{y}_n)\}$ , where each ground set  $\mathcal{Y}_n$  is annotated with its most diverse subset  $\mathbf{y}_n$ . How can we discover the underlying parameters  $\mathbf{L}$  or  $\mathbf{K}$ ? Note that different ground sets need not have overlap. Thus, directly specifying kernel values for every pair of items is unlikely to be scalable. Instead, we will need to assume that either  $\mathbf{L}$  or  $\mathbf{K}$  for each ground set is represented by a shared set of parameters  $\theta$ .

For items  $i$  and  $j$  in  $\mathcal{Y}_n$ , suppose their kernel values  $K_{n_{ij}}$  can be computed as a function of  $\mathbf{x}_{n_i}$ ,  $\mathbf{x}_{n_j}$  and  $\theta$ , where  $\mathbf{x}_{n_i}$  and  $\mathbf{x}_{n_j}$  are features characterizing those items. Our learning objective is to optimize  $\theta$  such that  $\mathbf{y}_n$  is the most diverse subset in  $\mathcal{Y}_n$ , or attains the highest probability. This gives rise to the following maximum likelihood estimate (MLE) [Kulesza and Taskar, 2011b],

$$\theta^{\text{MLE}} = \arg \max_{\theta} \sum_n \log P(\mathbf{y}_n; \mathbf{L}_n(\mathcal{Y}_n; \theta)), \quad (6)$$

where  $\mathbf{L}_n(\mathcal{Y}_n; \theta)$  converts features in  $\mathcal{Y}_n$  to the  $\mathbf{L}$  matrix for the ground set  $\mathcal{Y}_n$ . MLE has been a standard approach for estimating DPP parameters. However, as we will discuss in section 3.2, it has important limitations.

Next, we introduce our method for learning the parameters. We first present our multiple kernel based representation of the  $\mathbf{L}$  matrix and then the large-margin based estimation.

## 3 OUR APPROACH

Our approach consists of two components that are developed in parallel, yet work in concert: (1) the use of multiple kernel functions to represent the DPP; (2) applying the principle of large margin separation to optimize the parameters. The former reduces the number of parameters to learn and thus is especially advantageous when the number of training samples is limited. The latter strengthens the advantage by optimizing objective functions that closely track subset selection errors.

### 3.1 MULTIPLE KERNEL REPRESENTATION

Learning the  $\mathbf{L}$  or  $\mathbf{K}$  matrix for a DPP is an instance of learning kernel functions, as those matrices are positive semidefinite matrices, interpretable as kernel functions being evaluated on the items in the ground set. Thus, our goal is essentially to learn the right kernel function to measure similarity.

However, for many applications, similarity is just one of the criteria for selecting items. For instance, in the previous example of image retrieval, the retrieved images not only need to be diverse (thus different) but also need to have strong relevance to the query term. Similarly, in document summarization, the selected sentences not only need to be

succinct and not redundant, but also need to represent the contents of the document [Lin and Bilmes, 2010].

Kulesza and Taskar [2011b] propose to balance these two potentially conflicting forces with a decomposable  $\mathbf{L}$  matrix:

$$\begin{aligned} L_{ij} &= q_i q_j S_{ij} = q_i q_j \phi_i^T \phi_j, \\ q_i &= q(\mathbf{x}_i) = \exp(\theta^T \mathbf{x}_i), \quad \forall i, j \in \mathcal{Y}, \end{aligned} \quad (7)$$

where  $q_i$  is referred to as the *quality* factor, modeling how representative or relevant the selected items are. It depends on item  $i$ 's feature vector  $\mathbf{x}_i$ , which encodes  $i$ 's contextual information and its *representativeness* of other items. For example, in document summarization, possible features are the sentence lengths, positions of the sentences in the text, or others.  $S_{ij}$ , on the other hand, measures how *similar* two sentences are, computed from a different set of features,  $\phi_i$  and  $\phi_j$ , such as bag-of-words descriptors that represent each item's individual characteristics.

However, prior work [Kulesza and Taskar, 2011b] does not investigate whether this specific definition of similarity could be made optimal and adapted to the data, thus limiting the modeling power of the DPP largely to infer the quality  $q_i$ . Our empirical studies show that this limitation can be severe, especially when the modeling choice is erroneous (cf. section 5.2).

In this paper, we retain the aspect of quality modeling but improve the modeling of similarity  $S_{ij}$  in two ways. First, we use nonlinear kernel functions such as the Gaussian RBF kernel to determine similarity. Secondly, and more importantly, we combine several base kernels:

$$S_{ij} = \sum_k \alpha_k \exp\{-\|\phi_i - \phi_j\|_2^2 / \sigma_k^2\} + \beta \phi_i^T \phi_j, \quad (8)$$

where  $k$  indexes the base kernels and  $\sigma_k$  is a scaling factor. The combination coefficients are constrained such that  $\sum_k \alpha_k + \beta = 1$ . They are optimized on the annotated data, either via maximum likelihood estimation or via our novel parameter estimation technique, to be described next.

### 3.2 LARGE-MARGIN ESTIMATION OF DPP

Maximum likelihood estimation does not closely track discriminative errors [Ng and Jordan, 2002, Vapnik, 1998, Jebara, 2004]. While improving the likelihood of the ground-truth subset  $\mathbf{y}_n$ , MLE could also improve the likelihoods of other competing subsets. Consequentially, a model learned with MLE could have modes that are very different subsets yet are very close to each other in their probability values. Having highly confusable modes is especially problematic for DPP's NP-hard MAP inference—the difference between such modes can fall within the approximation errors of approximate inference algorithms such that the true MAP cannot be easily extracted.

### 3.2.1 Multiplicative Large Margin Constraints

To address these deficiencies, our large-margin based approach aims to maintain or increase the margin between the correct subset and alternative, incorrect ones. Specifically, we formulate the following large margin constraints

$$\begin{aligned} \log P(\mathbf{y}_n; \mathbf{L}_n) &\geq \max_{\mathbf{y} \subseteq \mathcal{Y}_n} \log \ell(\mathbf{y}_n, \mathbf{y}) P(\mathbf{y}; \mathbf{L}_n) \\ &= \max_{\mathbf{y} \subseteq \mathcal{Y}_n} \log \ell(\mathbf{y}_n, \mathbf{y}) + \log P(\mathbf{y}; \mathbf{L}_n), \end{aligned} \quad (9)$$

where  $\ell(\mathbf{y}_n, \mathbf{y})$  is a loss function measuring the discrepancy between the correct subset and an alternative  $\mathbf{y}$ . We assume  $\ell(\mathbf{y}_n, \mathbf{y}_n) = 0$ .

Intuitively, the more different  $\mathbf{y}$  is from  $\mathbf{y}_n$ , the larger the gap we want to maintain between the two probabilities. This way, the incorrect one has less chance to be identified as the most diverse one. Note that while similar intuitions have been explored in multi-way classification and structured prediction, the margin here is *multiplicative* instead of additive—this is by design, as it leads to a tractable optimization over the exponential number of constraints, as we will explain later.

### 3.2.2 Design of the Loss Function

A natural choice for the loss function is the Hamming distance between  $\mathbf{y}_n$  and  $\mathbf{y}$ , counting the number of disagreements between two subsets:

$$\ell_H(\mathbf{y}_n, \mathbf{y}) = \sum_{i \in \mathbf{y}} \mathbb{I}[i \notin \mathbf{y}_n] + \sum_{i \notin \mathbf{y}} \mathbb{I}[i \in \mathbf{y}_n]. \quad (10)$$

In this loss function, failing to select the right item costs the same as adding an unnecessary item. In many tasks, however, this symmetry does not hold. For example, in summarizing a document, omitting a key sentence has more severe consequences than adding a (trivial) sentence.

To balance these two types of errors, we introduce the generalized Hamming loss function,

$$\ell_\omega(\mathbf{y}_n, \mathbf{y}) = \sum_{i \in \mathbf{y}} \mathbb{I}[i \notin \mathbf{y}_n] + \omega \sum_{i \notin \mathbf{y}} \mathbb{I}[i \in \mathbf{y}_n]. \quad (11)$$

When  $\omega$  is greater than 1, the learning biases towards higher *recall* to select as many items in  $\mathbf{y}_n$  as possible. When  $\omega$  is significantly less than 1, the learning biases towards high *precision* to avoid incorrect items as much as possible. Our empirical studies demonstrate such flexibility and its advantages in two real-world summarization tasks.

### 3.2.3 Numerical Optimization

To overcome the challenge of dealing with an exponential number of constraints in eq. (9), we reformulate it as a tractable optimization problem. We first upper-bound

the hard-max operation with Jensen’s inequality (i.e., softmax):

$$\begin{aligned} \log P(\mathbf{y}_n; \mathbf{L}_n) &\geq \log \sum_{\mathbf{y} \subseteq \mathcal{Y}} e^{\log \ell_\omega(\mathbf{y}_n, \mathbf{y}) P(\mathbf{y}; \mathbf{L}_n)} \\ &= \text{softmax}_{\mathbf{y} \subseteq \mathcal{Y}_n} \log \ell_\omega(\mathbf{y}_n, \mathbf{y}) + \log P(\mathbf{y}; \mathbf{L}_n). \end{aligned} \quad (12)$$

With the loss function  $\ell_\omega(\mathbf{y}_n, \mathbf{y})$ , the right-hand-side is computable in polynomial time,

$$\begin{aligned} &\text{softmax}_{\mathbf{y} \subseteq \mathcal{Y}_n} \log \ell_\omega(\mathbf{y}_n, \mathbf{y}) + \log P(\mathbf{y}; \mathbf{L}_n) \\ &= \log \left( \sum_{i \notin \mathbf{y}_n} K_{n_{ii}} + \omega \sum_{i \in \mathbf{y}_n} (1 - K_{n_{ii}}) \right), \end{aligned} \quad (13)$$

where  $K_{n_{ii}}$  is the  $i$ -th element on the diagonal of  $\mathbf{K}_n$ , the marginal kernel matrix corresponding to  $\mathbf{L}_n$ . The detailed derivation of this result is in the supplementary material. Note that  $\mathbf{K}_n$  can be computed efficiently from  $\mathbf{L}_n$  through the identity eq. (3).

The softmax can be seen as a summary of all undesirable subsets (the correct subset  $\mathbf{y}_n$  does not contribute to the weighted sum as  $\ell_\omega(\mathbf{y}_n, \mathbf{y}_n) = 0$ ). Our optimization balances this term with the likelihood of the target with the hinge loss function  $[z]_+ = \max(0, z)$ ,

$$\begin{aligned} \min \sum_n &\left[ -\log P(\mathbf{y}_n; \mathbf{L}_n) \right. \\ &\left. + \lambda \log \left( \sum_{i \notin \mathbf{y}_n} K_{n_{ii}} + \omega \sum_{i \in \mathbf{y}_n} (1 - K_{n_{ii}}) \right) \right]_+, \end{aligned} \quad (14)$$

where  $\lambda \geq 0$  is a tradeoff coefficient, to be tuned on validation datasets. Note that this objective function subsumes maximum likelihood estimation where  $\lambda = 0$ . We optimize the objective function with subgradient descent. Details are in the supplementary material.

## 4 RELATED WORK

The DPP arises from random matrix theory and quantum physics [Macchi, 1975, Kulesza and Taskar, 2012]. In machine learning, researchers have proposed different variations to improve its modeling capacity. Kulesza and Taskar [2011a] introduced k-DPP to restrict the sets to have a constant size  $k$ . Affandi et al. [2012] proposed a Markov DPP which offers diversity at adjacent time stamps. A structured DPP was presented in [Kulesza and Taskar, 2011c] to model trees and graphs. The MAP inference of DPP is generally NP-hard [Ko et al., 1995]. Gillenwater et al. [2012] developed an 1/4-approximation algorithm. In practice, greedy inference gives rise to decent results [Kulesza and Taskar, 2011b] though it lacks theoretical guarantees.

Another popular alternative is to resort to fast sampling algorithms [Kang, 2013, Kulesza and Taskar, 2012].

In spite of much research activity surrounding DPPs, there is very little work exploring how to effectively learn the model parameters. MLE is the most popular estimator. Compared to MLE, our approach is more robust to the number of training data or mis-specified models, and offers greater flexibility by incorporating customizable error functions. A recent Bayesian approach works with the posterior over the parameters [Affandi et al., 2014]. In contrast to that work, we develop a large-margin training approach for DPPs and directly minimize the set selection errors. The large margin principle has been widely used in classification [Vapnik, 1998] and structured prediction [Taskar et al., 2005, Tsochantaridis et al., 2004, Taskar et al., 2004, Sha and Saul, 2006], but its application to DPP is original. In order to make it tractable for DPPs, we use multiplicative rather than additive margin constraints.

## 5 EXPERIMENTS

We validate our large-margin approach to learn DPP parameters (DPP<sup>LME</sup>) with extensive empirical studies on both synthetic data and two real-world summarization tasks with documents and videos. While DPP also has applications beyond summarization, this is a particularly good testbed to illustrate diverse subset selection: a compact summary ought to include high quality items that, taken together, offer good coverage of the source content.

### 5.1 SETUP

#### 5.1.1 Evaluation Metrics

We evaluate the quality of the selected subset  $\mathbf{y}^{\text{MAP}}$  against the ground-truth  $\mathbf{y}^*$  using the F-score, which is the harmonic mean of precision and recall:

$$\text{F-score} = \frac{2 \text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}},$$

$$\text{Precision} = \frac{|\mathbf{y}^{\text{MAP}} \cap \mathbf{y}^*|}{|\mathbf{y}^{\text{MAP}}|}, \quad \text{Recall} = \frac{|\mathbf{y}^{\text{MAP}} \cap \mathbf{y}^*|}{|\mathbf{y}^*|}. \quad (15)$$

All three quantities are between 0 and 1, and higher values are better.

#### 5.1.2 MAP Inference

We conduct the MAP inference of DPP by brute-force search on the synthetic data, and turn to the so called minimum Bayes risk (MBR) decoding [Goel and Byrne, 2000, Kulesza and Taskar, 2012] for larger ground sets on real data.

The MBR inference samples subsets  $\mathcal{S} = \{\mathbf{y}_1, \dots, \mathbf{y}_T\}$  from the learned DPP and outputs the one  $\hat{\mathbf{y}}$  which achieves

the highest consensus with the others, where the consensus can be measured by different evaluation metrics depending on applications. We use the F-score in our case. Particularly,

$$\hat{\mathbf{y}} \leftarrow \arg \max_{\mathbf{y}_{t'} \in \mathcal{S}} \frac{1}{T} \sum_{t=1}^T \text{F-SCORE}(\mathbf{y}_{t'}, \mathbf{y}_t). \quad (16)$$

Note that the MBR inference has actually introduced some degrees of flexibility to DPP (and to other probabilistic models). It allows users to infer the desired output according to different evaluation metrics. As a result, the selected subset is not necessarily the “true” diverse subset, but is biased towards the users’ specific interests.

## 5.2 SYNTHETIC DATASET

### 5.2.1 Data

Our ground set has 10 items,  $\mathcal{Y} = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_{10}\}$ . For each item, we sample a 5-dimensional feature vector from a spherical Gaussian:  $\mathbf{x}_i \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$ . To generate the  $\mathbf{L}$  matrix for the DPP, we follow the model in eq. (7); for the parameter vector  $\boldsymbol{\theta}$  we sample from a spherical Gaussian,  $\boldsymbol{\theta} \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$ , and for the similarity we simply let  $\phi_i = \mathbf{x}_i$  and compute  $S_{ij} = \phi_i^T \phi_j$ .

We identify the most diverse subset  $\mathbf{y}^*$  (eq. (5)) via exhaustive search of all subsets, which is possible given the small ground set. The resulting  $\mathbf{y}^*$  has 5 items on average. We then add noise by randomly (with probability 0.1) adding or dropping an item to or from  $\mathbf{y}^*$ . We repeat the process of sampling another pair of the ground set and its most diverse set. We do so 200 times and use 100 pairs for holdout and 100 for testing. We repeat the process to yield training sets of various sizes.

### 5.2.2 Learning

We compare our large-margin approach using the Hamming loss (eq. (10)) to the standard MLE method for learning DPP parameters.<sup>1</sup> All hyperparameters are tuned by cross-validation. After learning, we apply MAP inference to the testing ground sets.

### 5.2.3 Results

The DPP is parameterized by two things:  $\boldsymbol{\theta}$  for the quality of the items, and  $S_{ij}$  for the similarity among them. Since the ground-truth parameters are known to us, we conduct experiments to isolate the impact of learning either one.

Fig. 1(a) contrasts the two methods when learning  $\boldsymbol{\theta}$  only, assuming all  $S_{ij}$  are known and the ground-truths

<sup>1</sup>Adding a zero-mean Gaussian prior over  $\boldsymbol{\theta}$  while learning with MLE, as in [Kulesza and Taskar, 2011b], did not yield improvement.

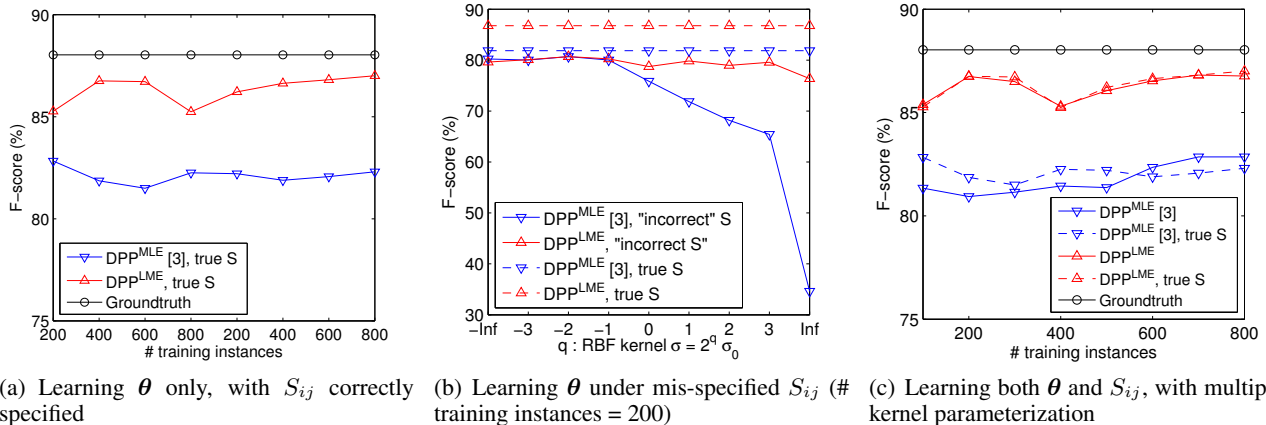

Figure 1: On synthetic datasets, our method DPP<sup>LME</sup> significantly outperforms the state-of-the-art parameter estimation technique DPP<sup>MLE</sup> [Kulesza and Taskar, 2011b] in various learning settings. See text for details. Best viewed in color.

are used. Our DPP<sup>LME</sup> method significantly outperforms DPP<sup>MLE</sup>. When the number of training samples is increased, the performance of our method generally improves and gets very close to the oracle’s performance, for which the true values of *both*  $S_{ij}$  and  $\theta$  are used.

Fig. 1(b) examines the two methods in the setting of model mis-specification, where the  $S_{ij}$  values deliberately deviate from the true values. Specifically, we set them to  $\exp(-\|\mathbf{x}_i - \mathbf{x}_j\|_2^2 / \sigma^2)$  where the bandwidth  $\sigma$  varies from small to large, while the true values are  $\mathbf{x}_i^T \mathbf{x}_j$ . All methods generally suffer. However, our method is fairly robust to the mis-specification while DPP<sup>MLE</sup> quickly deteriorates. Our advantage is likely due to our method’s focus on learning to reduce subset selection errors, whereas MLE focuses on learning the right probabilistic model (even if it is already mis-specified).

Fig. 1(c) compares the two methods when both  $\theta$  and  $S_{ij}$  need to be learned from the data. We apply our multiple kernel parameterization technique to model  $S_{ij}$ , as in eq. (8), except  $\beta$  is set to be zero to avoid including the ground-truth. We see that our parameterization overcomes the problems of model mis-specification in Fig. 1(b), demonstrating its effectiveness in approximating unknown similarities. In fact, both learning methods match the performance of the corresponding methods with ground-truth similarity values, respectively. Nonetheless, our large-margin estimation still outperforms MLE significantly.

In summary, our results on synthetic data are very encouraging. Our multiple kernel parameterization avoids the pitfall of model mis-specification, and the large-margin estimation outperforms MLE due to its ability to track selection errors more closely.

### 5.3 DOCUMENT SUMMARIZATION

Next we apply DPP to the task of extractive multi-document summarization [Dang, 2005, Kulesza and

Taskar, 2011b, Lin and Bilmes, 2010]. In this task, the input is a document cluster consisting of several documents on a single topic. The desired output is a subset of the sentences in the cluster that serve as a summary for the entire cluster. Naturally, we want the sentences in this subset to be both representative and diverse.

#### 5.3.1 Experimental Setting

We use the text data from Document Understanding Conference (DUC) 2003 and 2004 [Dang, 2005] as the training and testing sets, respectively. There are 60 document clusters in DUC 2003 and 50 in DUC 2004, each collected over a short time period on a single topic. A cluster includes 10 news articles and on average 250 sentences. Four human reference summaries are provided along with each cluster. Following prior work, we generate the oracle/ground-truth summary by identifying a subset of the original sentences that best agree with the human reference summaries [Kulesza and Taskar, 2011b]. On average, the oracle summary consists of 5 sentences. As is standard practice, we use the oracles only during training. During testing, the algorithm output is evaluated against each of the four human reference summaries separately, and we report the average accuracy [Dang, 2005, Kulesza and Taskar, 2011b, Lin and Bilmes, 2010].

We use the widely-used evaluation package ROUGE [Lin, 2004], which scores document summaries based on  $n$ -gram overlap statistics. We use ROUGE 1.5.5 along with WordNet 2.0, and report the F-score (F), Precision (P), and Recall (R) of both unigram and bigram matchings, denoted by ROUGE-1X and ROUGE-2X respectively ( $X \in \{F, P, R\}$ ). Additionally, we limit the maximum length of each summary to be 665 characters to be consistent with existing work [Dang, 2005]. This yields 5 sentences on average for subsets generated by our algorithm.

To allow the fairest comparison to existing DPP work for

Table 1: Accuracy on document summarization. Our methods outperform others with statistical significance.

| Method  | ROUGE-1F          | ROUGE-1P          | ROUGE-1R          | ROUGE-2F         | ROUGE-2P         | ROUGE-2R         |
|---|-------------------|-------------------|-------------------|------------------|------------------|------------------|
| PEER 35 [Dang, 2005]                                | 37.54             | 37.69             | 37.45             | 8.37             | –                | –                |

this task, we use the same features designated in [Kulesza and Taskar, 2011b]. To model quality, the features are the sentence length, position in the original document, mean cluster similarity, LexRank [Erkan and Radev, 2004], and personal pronouns. To model the similarity, the features are the standard normalized term frequency-inverse document frequency (tf-idf) vectors.

### 5.3.2 Learning

We consider two ways of modeling similarities. The first one is to use the cosine similarity (COS) between feature vectors, as in [Kulesza and Taskar, 2011b]. The second is our multiple kernel based similarity (MKR, eq. (8)). For MKR, the bandwidths are  $\sigma = 2^q$ ,  $q = -6, -5, \dots, 6$ , and the combination coefficients are learned on the data. We implement the method in [Kulesza and Taskar, 2011b] as a baseline (DPP<sup>MLE</sup>+COS). We also test an enhanced variant of that method by replacing its cosine similarity with our multiple kernel based similarity (DPP<sup>MLE</sup>+MKR).

### 5.3.3 Results

Table 1 compares several DPP-based methods, as well as the top three results (PEER 35, 104, 65) from the DUC 2004 competition, which are not DPP-based (“–” indicates results not available). Since the DPP MAP inference is NP-hard, we use a sampling technique to extract the most diverse subset [Kulesza and Taskar, 2012]. We run inference 10 times and report the mean accuracy and standard error.

The state-of-the-art MLE-trained DPP model (DPP<sup>MLE</sup>+COS) [Kulesza and Taskar, 2011b] achieves about the same performance as the best PEER results of DUC 2004. We obtain a noticeable improvement by applying our large-margin estimation (DPP<sup>LME</sup>+COS). By applying multiple kernels to model similarity, we obtain significant improvements (above the standard errors) for both parameter estimation techniques. In particular, our complete method, DPP<sup>LME</sup>+MKR, attains the best performance across all the evaluation metrics.

## 5.4 VIDEO SUMMARIZATION

Finally, we demonstrate the broad applicability of our method by applying it to video summarization. In this case, the goal is to select a set of representative and diverse

frames from a video sequence.

### 5.4.1 Experimental Setting

The dataset consists of 50 videos from the Open Video Project (OVP)<sup>2</sup>. They are 30fps, 352×240 pixels, vary from 1 to 4 minutes, and are distributed across several genres including documentary, educational, historical, etc. We use the provided ground truth key frame summaries [de Avila et al., 2011], where each video is labeled by five annotators independently. We perform 5-fold validation and report the average result. We apply several preprocessing steps to remove frames that are trivially redundant (due to high temporal correlation) or of low visual quality. We use a similar procedure as in the document summarization task to generate the oracle/ground-truth subsets. On average, the ground-truth has 9 frames (in contrast, our method yields subsets from 5 to 20 frames). We use the public evaluation package VSUMM to evaluate the system-generated summary frames and again compute Precision, Recall and F-score [de Avila et al., 2011]. More details are in the supplementary material.

### 5.4.2 Features

We extract from each frame a color histogram and SIFT-based Fisher vector [Lowe, 2004, Perronnin and Dance, 2007] to model pairwise frame similarity  $S_{ij}$ . The two features are combined via our multiple kernel representation. To model the quality of each frame, we extract both intra-frame and inter-frame representativeness features. They are computed on the saliency maps [Rahtu et al., 2010, Hou et al., 2012] and include the mean, standard deviation, median, and quantiles of the maps as well as the the visual similarities between a frame and its neighbors. We z-score them within each video sequence.

### 5.4.3 Results

Table 2 compares several methods for selecting key frames: an unsupervised clustering method VSUMM [de Avila et al., 2011] (we implemented its two variants, offering a degree of tradeoff between precision and recall, and finely tuned the parameters), DPP<sup>MLE</sup> with a multiple kernel parameterization of  $S_{ij}$ , and our margin-based approach. For

| F-score   | 70.25                   | 68.20                   | 72.94±0.08              | 71.25±0.09                     | <b>73.46±0.07</b> | 72.39±0.10        |
| Precision | 70.57                   | 73.14                   | 68.40±0.08              | <b>74.00±0.09</b>              | 69.68±0.08        | 67.19±0.11        |
| Recall    | 75.77                   | 69.14                   | 82.51±0.11              | 72.71±0.11                     | 81.39±0.09        | <b>83.24±0.09</b> |

our method, we illustrate its flexibility to target different operating points, by varying the tradeoff constant  $\omega$  in the generalized Hamming distance loss function eq. (11). Recall that higher values of  $\omega$  will promote higher recall, while lower promote higher precision.

The results clearly demonstrate the advantage of our approach, particularly in how it offers finer control of the tradeoff between precision and recall. By adjusting  $\omega$ , our method performs the best in each of the three metrics and outperforms the baselines by a statistically significant margin measured in the standard errors. Controlling the tradeoff is quite valuable in this application; for example, high precision may be preferable to a user summarizing a video he himself captured (he knows what appeared in the video, and wants a noise-free summary), whereas high recall may be preferable to a user summarizing a video taken by a third party (he has not seen the original video, and prefers some noise to dropped frames).

More details are illustrated in Fig. 2, in which by varying  $\omega$  from  $2^{-6}$  to  $2^8$  we obtain 8 pairs of (precision, recall) values. We apply uniform interpolation among them and draw the precision-recall curve. One can see that DPP<sup>MLE</sup> is able to control the characteristics of the DPP generated summaries, biasing them to either high precision or high recall and without sacrificing the other too much. Though MLE or VSUMM does not supply such modeling flexibility, we also include them in the figure for reference.

We also present qualitative results on video summarization in Fig. 3. For this particular video, DPP<sup>MLE</sup>, DPP<sup>MLE</sup> with  $\omega = 1$ , and DPP<sup>MLE</sup> with  $\omega = 64$  all give rise to high recalls. Their output summaries are pretty lengthy, and may be boring to some users who just want to grasp something interesting to watch. By turning down the weight to  $\omega = 1/64$ , our DPP<sup>MLE</sup> dramatically improves the precision to 76% (in contrast to the 48% of DPP<sup>MLE</sup>).

### 5.5 COMPUTATIONAL COMPLEXITY

The computational complexities of MLE and our large-margin approach are the same,  $\mathcal{O}(N \times D^3)$ , for computing the objective functions. Here  $N$  is the number of training instances, and  $D$  is the size of the largest ground set. Our softmax trick allows us to handle tractably an exponentially large number of constraints. Using gradient descent in parameter learning, the computational complexity in each iteration is thus also  $\mathcal{O}(N \times D^3)$  for both methods. MLE is slightly faster (20% measured in wall-clock time).

Figure 2: Balancing precision and recall. Through our large-margin DPPs (DPP<sup>MLE</sup>), we can balance precision and recall by varying  $\omega$  in the generalized Hamming distance. In contrast, neither MLE nor VSUMM (the two variants in [de Avila et al., 2011]) are plotted together) is readily able to support such flexibility.

## 6 CONCLUSION

The determinantal point process (DPP) offers a powerful and probabilistically grounded approach for selecting diverse subsets. We proposed a novel technique for learning DPPs from annotated data. In contrast to the status quo of maximum likelihood estimation, our method is more flexible in modeling pairwise similarity and avoids the pitfall of model mis-specification. Empirical results demonstrate its advantages on both synthetic datasets and challenging real-world summarization applications.

## Abstract

Ridge regression is one of the most popular and effective regularized regression methods, and one case of particular interest is that the number of features  $p$  is much larger than the number of samples  $n$ , i.e.  $p \gg n$ . In this case, the standard optimization algorithm for ridge regression computes the optimal solution  $\mathbf{x}^*$  in  $O(n^2p + n^3)$  time. In this paper, we propose a fast *relative-error* approximation algorithm for ridge regression. More specifically, our algorithm outputs a solution  $\tilde{\mathbf{x}}$  satisfying  $\|\tilde{\mathbf{x}} - \mathbf{x}^*\|_2 \leq \epsilon \|\mathbf{x}^*\|_2$  with high probability and runs in  $\tilde{O}(\text{nnz}(\mathbf{A}) + n^3/\epsilon^2)$  time, where  $\text{nnz}(\mathbf{A})$  is the number of non-zero entries of matrix  $\mathbf{A}$ .

To the best of our knowledge, this is the first algorithm for ridge regression that runs in  $o(n^2p)$  time with provable relative-error approximation bound on the output vector. In addition, we analyze the risk inflation bound of our algorithm and apply our techniques to two generalizations of ridge regression, including multiple response ridge regression and a non-linear ridge regression problem. Finally, we show empirical results on both synthetic and real datasets.

## 1 INTRODUCTION

Ridge regression is one of the most popular and effective regularized regression methods, and one case of particular interest is that the number of features  $p$  is much larger than the number of samples  $n$ , i.e.  $p \gg n$ . The definition of ridge regression problem is as follows. Given an  $n \times p$  sample-by-feature design matrix  $\mathbf{A}$  together with an  $n$ -dimensional target vector  $\mathbf{b}$ , and a parameter  $\lambda > 0$ , the goal of ridge regression is to find a  $p$ -dimensional vector

$\mathbf{x}^*$  such that

$$\mathbf{x}^* = \arg \min_{\mathbf{x} \in \mathbb{R}^p} \|\mathbf{A}\mathbf{x} - \mathbf{b}\|_2^2 + \lambda \|\mathbf{x}\|_2^2. \quad (1)$$

Saunders et al. [29] showed that that the unique minimizer of Eq. (1) can be computed as follows

$$\mathbf{x}^* = \mathbf{A}^T(\mathbf{A}\mathbf{A}^T + \lambda\mathbf{I}_n)^{-1}\mathbf{b}. \quad (2)$$

Using Eq. (2), the time complexity of computing  $\mathbf{x}^*$  is  $O(n^2p + n^3)$ , which is  $O(n^2p)$  when  $p \gg n$ . This approach is widely applied in practice for the  $p > n$  cases. However, for large dataset with high dimensional features, i.e.  $p \gg n \gg 1$ , this approach can be prohibitively slow.

**Our contributions.** In this paper, we present the first algorithm for ridge regression that runs in  $o(n^2p)$  time with a provable relative-error approximation bound on the output vector. Specifically, our proposed algorithm outputs a vector  $\tilde{\mathbf{x}}$  such that  $\|\tilde{\mathbf{x}} - \mathbf{x}^*\|_2 \leq \epsilon \|\mathbf{x}^*\|_2$  with high probability without any assumptions on input  $\mathbf{A}$  and  $\mathbf{b}$ . We show that our proposed algorithm runs in  $O(\text{nnz}(\mathbf{A}) + n^2r \log(\frac{r}{\epsilon})/\epsilon^2)$  time, where  $\text{nnz}(\mathbf{A})$  is the number of non-zero entries of  $\mathbf{A}$  and  $r$  is the rank of  $\mathbf{A}$ . Since  $\text{nnz}(\mathbf{A}) \leq np \ll n^2p$  and  $r \leq n$ , our algorithm is substantially faster than the existing approach, which uses  $O(n^2p + n^3)$  for  $p \gg n$  instances, even if  $\mathbf{A}$  is full rank (in this case, our algorithm runs in  $O(\text{nnz}(\mathbf{A}) + n^3 \log(\frac{n}{\epsilon})/\epsilon^2)$  time).

For supplements to our main result, we also prove a risk inflation bound of our algorithm under standard statistical assumptions. In addition, we apply our techniques to several generalizations of ridge regression. In particular, we extend our algorithm to multiple ridge regression problem, where there are multiple target vectors. Similar to our result for standard ridge regression, we also prove a relative-error bound on the output. Moreover, building upon the recent results [3], we extend our techniques and design a fast relative-error approximation algorithm for a non-linear ridge regression problem.

We evaluate our algorithm on both synthetic and real datasets. The experimental results support our theoretical

analysis and demonstrate that the proposed algorithm can achieve considerable speed gains and produce highly accurate outputs.

### 1.1 Related work

**Oblivious subspace embedding (OSE).** Sarlós [28] pioneered the use of OSEs for accelerating approximation algorithms for numerical linear algebra problems, including matrix multiplication, linear regression and low rank approximation. His algorithms were later improved by several work [12, 24] using different OSEs such as sparse embedding. More recent work showed that OSEs can be used to speed up other problems as well, including  $k$ -means clustering [10], approximating leverage scores [23], canonical correlation analysis [2], support vector machine [25], SVD-truncated linear regression [9], and non-linear regression [3]. In this line of research, approximation algorithms of linear regression [28, 12, 24, 27] are the most relevant to ours. However, all of these work focused on  $n \gg p$  instances and the fastest algorithm [24] among them runs in  $O(\text{nnz}(\mathbf{A}) + p^3 \log(p)/\epsilon^2)$  time, which is inefficient in  $p \gg n$  cases. Moreover, they used the sketched matrix  $\mathbf{SA}$  which reduces the sample size  $n$  while we use  $\mathbf{AS}^T$  which reduces feature dimension  $p$ . This distinction leads to a very different design and analysis of algorithms.

**Ridge regression.** The bottlenecks of solving ridge regression are constructing and inverting the kernel matrix  $\mathbf{AA}^T$ . In the mean time, fast kernel approximation algorithms for large datasets have been a research focus for many years. Many approximation schemes are highly successful such as low rank approximation [33], Nyström methods [7, 15, 19, 34], sampling [20, 1], incomplete Cholesky factorization [5, 16] and specialized techniques for certain classes of kernels [26, 21]. We notice that many of these proposals focused on speeding up the  $n \gg p$  cases but did not necessarily improve the  $p \gg n$  cases. More importantly, from these work, it is not clear how the error of kernel approximation impacts on the accuracy of the approximation result of ridge regression. This problem was recently studied in several work [13, 4, 35] under different settings. However, none of these work provided a relative-error approximation guarantee on the output vector.

The work most closely related to our results is [22]. They proposed an approximation algorithm for ridge regression by accelerating the computation of kernel matrix  $\mathbf{AA}^T$  using subsampled randomized Hadamard transformation (SRHT). Their algorithm runs in  $O(np \log(n)/\epsilon^2 + n^3)$  time, which is  $o(n^2p)$  time. However, their algorithm does not have a provable guarantee on the error of the output vector. In addition, the risk inflation bound they proved might not hold since their proof is based on a problematic claim. We have included a detailed argument and counterexample for their proof in our supplementary material (see Section E).

## 2 PRELIMINARIES

### 2.1 NOTATION

Let  $[k]$  denote the set of integers  $\{1, 2, \dots, k\}$ . Given a matrix  $\mathbf{M} \in \mathbb{R}^{n \times p}$  of rank  $r$ . For  $i \in [n]$ , let  $\mathbf{M}_{(i)}$  denote the  $i$ -th row of  $\mathbf{M}$  as a row vector. Let  $\text{nnz}(\mathbf{M})$  denote the number of non-zero entries of  $\mathbf{M}$ . Let  $\|\mathbf{M}\|_F$  denote the Frobenius norm of  $\mathbf{M}$  and let  $\|\mathbf{M}\|_2$  denote the spectral norm of  $\mathbf{M}$ . Let  $\sigma_i(\mathbf{M})$  denote the  $i$ -th largest singular value of  $\mathbf{M}$  and let  $\sigma_{\max}(\mathbf{M})$  and  $\sigma_{\min}(\mathbf{M})$  denote the largest and smallest singular values of  $\mathbf{M}$ . The thin SVD of  $\mathbf{M}$  is  $\mathbf{M} = \mathbf{U}_M \mathbf{\Sigma}_M \mathbf{V}_M^T$ , where  $\mathbf{U}_M \in \mathbb{R}^{n \times r}$ ,  $\mathbf{\Sigma}_M \in \mathbb{R}^{r \times r}$  and  $\mathbf{V}_M \in \mathbb{R}^{p \times r}$ .

The Moore-Penrose pseudoinverse of  $\mathbf{M}$  is a  $p \times n$  matrix defined by  $\mathbf{M}^\dagger = \mathbf{V}_M \mathbf{\Sigma}_M^{-1} \mathbf{U}_M^T$ , which can be computed in  $O(n^2p)$  time when  $p > n$ . Finally, let  $\mathbf{I}_n$  denote the  $n \times n$  identity matrix and let  $\mathbf{0}_n$  denote the  $n \times n$  zero matrix.

### 2.2 OBLIVIOUS SUBSPACE EMBEDDING

We start by reviewing the definition of oblivious subspace embedding (OSE).

**Definition 1.** *Given any  $r > 0$ ,  $\delta \in (0, 1)$  and  $\epsilon \in (0, 1)$ , we call a  $t \times p$  random matrix  $\mathbf{S}$  an  $(r, \delta, \epsilon)$ -OSE, if, for any rank  $r$  matrix  $\mathbf{M} \in \mathbb{R}^{p \times m}$ , the following holds simultaneously for all  $\mathbf{z} \in \mathbb{R}^m$ ,*

$$(1 - \epsilon) \|\mathbf{Mz}\|_2 \leq \|\mathbf{SMz}\|_2 \leq (1 + \epsilon) \|\mathbf{Mz}\|_2,$$

with probability at least  $1 - \delta$ .

In fact, many random matrices, which are widely used in machine learning, have been shown to be OSEs, e.g. Gaussian matrices [14] and random sign matrices [28]. However, many of these matrices are dense. For a dense OSE  $\mathbf{S} \in \mathbb{R}^{t \times p}$ , computing sketched matrix  $\mathbf{SM}$  given  $\mathbf{M} \in \mathbb{R}^{p \times m}$  requires time  $O(t \cdot \text{nnz}(\mathbf{M}))$ . To speed up the computation of the sketched matrix  $\mathbf{SM}$ , several work sought  $\mathbf{S}$  supporting fast matrix-vector multiplication [12, 32, 24]. We refer interested readers to [8] for an overview of the development of fast OSEs.

In this paper, we use a combination of two types of fast OSEs: *sparse embedding* and *subsampled randomized Hadamard transformation* (SRHT). In the following, we review their definitions and key properties.

**Sparse embedding.** A sparse embedding matrix  $\mathbf{\Phi}_{\text{sparse}}$  is a very sparse matrix such that there is only one non-zero element per column.  $\mathbf{\Phi}_{\text{sparse}} \in \mathbb{R}^{t \times p}$  can be constructed as follows. Let  $h : [p] \rightarrow [t]$  be a random mapping such that for each  $i \in [p]$ ,  $h(i)$  is uniformly distributed over  $[t]$ . Let  $\mathbf{\Phi} \in \{0, 1\}^{t \times p}$  be a binary matrix with  $\mathbf{\Phi}_{h(i), i} = 1$  for each  $i \in [p]$  and all remaining entries 0. Let  $\mathbf{D}$  be an  $p \times p$  random diagonal matrix where each diagonal entry is independent chosen  $+1$  or  $-1$  with equal probability. Finally,

the sparse embedding matrix  $\Phi_{\text{sparse}}$  is the product of  $\mathbf{D}$  and  $\Phi$ , i.e.  $\Phi_{\text{sparse}} = \Phi\mathbf{D}$ . It is easy to see that computing  $\Phi_{\text{sparse}}\mathbf{M}$  takes  $O(\text{nnz}(\mathbf{M}))$  time due to the sparsity of  $\Phi_{\text{sparse}}$ .

Recently, Clarkson and Woodruff [12] showed that  $\Phi_{\text{sparse}}$  is an  $(r, \delta, \epsilon)$ -OSE if  $t \geq O(r^2/\epsilon^4)$ . Later, the bound on  $t$  was improved to  $t \geq O(r^2/\epsilon^2)$  by Nelson and Nguyen [24]. Their result is restated in the following.

**Theorem 1.** [24, Theorem 3] *Given  $\epsilon \in (0, 1)$ ,  $\delta \in (0, 1)$  and  $r > 0$ , if  $t \geq \delta^{-1}(r^2 + r)/(2\epsilon - \epsilon^2)^2$ , then sparse embedding matrix  $\Phi_{\text{sparse}} \in \mathbb{R}^{t \times p}$  is an  $(r, \delta, \epsilon)$ -OSE.*

**SRHT.** An SRHT matrix  $\Phi_{\text{srht}}$  is a highly structured matrix which allows fast, FFT-style matrix-vector multiplication. The definition of SRHT matrix  $\Phi_{\text{srht}} \in \mathbb{R}^{t \times p}$  is as follows. Without loss of generality, suppose that  $p$  is a power of 2 (otherwise we can pad a sufficient number of zeros). Then,  $\Phi_{\text{srht}}$  is given by

$$\Phi_{\text{srht}} = \sqrt{\frac{p}{t}} \mathbf{R}\mathbf{H}\mathbf{D},$$

where  $\mathbf{D} \in \mathbb{R}^{p \times p}$  is a random diagonal matrix whose entries are  $+1$  or  $-1$  with equal probability;  $\mathbf{R} \in \mathbb{R}^{t \times p}$  are  $t$  rows from the  $p \times p$  identity matrix, where the rows are chosen uniformly at random without replacement; and  $\mathbf{H} \in \mathbb{R}^{p \times p}$  is a normalized Walsh-Hadamard matrix, which is defined as

$$\mathbf{H}_k = \begin{bmatrix} \mathbf{H}_{k/2} & \mathbf{H}_{k/2} \\ \mathbf{H}_{k/2} & -\mathbf{H}_{k/2} \end{bmatrix} \text{ with } \mathbf{H}_2 = \begin{bmatrix} +1 & +1 \\ +1 & -1 \end{bmatrix},$$

and  $\mathbf{H} = p^{-\frac{1}{2}} \mathbf{H}_p \in \mathbb{R}^{p \times p}$ .

Using FFT-style algorithms, the product  $\Phi_{\text{srht}}\mathbf{M}$  can be computed in  $O(np \log(p))$  time [32]. Tropp [32] showed that  $\Phi_{\text{srht}}$  is an OSE if  $t \geq O([\sqrt{r} + \sqrt{\log(p)}]^2 \log(r)/\epsilon)$ , or  $t \geq O(r \log(r)/\epsilon)$  when  $r > \log(p)$ . His result is restated in the next theorem.

**Theorem 2.** [32, Lemma 4.1] *Given  $\epsilon \in (0, 1)$ ,  $\delta \in (0, 1)$  and  $r > 0$ , if  $t \geq 6\epsilon^{-1}[\sqrt{r} + \sqrt{8 \log(3p/\delta)}]^2 \log(3r/\delta)$ , then SRHT matrix  $\Phi_{\text{srht}} \in \mathbb{R}^{t \times p}$  is an  $(r, \delta, \epsilon)$ -OSE.*

### 2.3 COMBINATION OF SPARSE EMBEDDING AND SRHT

Sparse embedding matrix is an extremely fast OSE since computing  $\Phi_{\text{sparse}}\mathbf{M}$  takes only  $O(\text{nnz}(\mathbf{M}))$  time, which equals to the complexity of reading  $\mathbf{M}$ . Meanwhile SRHT produces a sketch with  $t = O(r \log(r)/\epsilon)$  rows which is smaller than sparse embedding, which requires  $t = O(r^2/\epsilon^2)$ . In this paper, we use the combination of SRHT and sparse embedding that enjoys the benefits from both of them. Specifically, we consider the product  $\mathbf{S} = \Phi_{\text{srht}}\Phi_{\text{sparse}}$ , where  $\Phi_{\text{srht}}$  is a  $t \times t'$  SRHT matrix and  $\Phi_{\text{sparse}}$  is a  $t' \times p$  sparse embedding matrix. The next theorem shows that, if  $t = O([\sqrt{r} + \sqrt{\log(p)}]^2 \log(r)/\epsilon)$  and  $t' = O(r^2/\epsilon^2)$ , the product  $\mathbf{S}$  is an OSE.

**Theorem 3.** *Given  $\epsilon \in (0, 1)$ ,  $\delta \in (0, 1)$  and  $r > 0$ , select integers  $t' \geq 2\delta^{-1}(r^2 + r)/(2\epsilon/3 - \epsilon^2/9)^2$  and  $t \geq 18\epsilon^{-1}[\sqrt{r} + \sqrt{8 \log(6p/\delta)}]^2 \log(6r/\delta)$ . Let  $\Phi_{\text{sparse}}$  be a  $t' \times p$  sparse embedding matrix and let  $\Phi_{\text{srht}}$  be a  $t \times t'$  SRHT matrix. Then the product  $\mathbf{S} = \Phi_{\text{srht}}\Phi_{\text{sparse}}$  is an  $(r, \delta, \epsilon)$ -OSE.*

Hence, when  $r \geq O(\log(p))$ , the product  $\mathbf{S}$  has  $t = O(r \log(r)/\epsilon)$  rows, which is smaller than only using sparse embedding matrix, and computing a sketched matrix  $\mathbf{S}\mathbf{M}$  given  $\mathbf{M} \in \mathbb{R}^{p \times m}$  takes  $O(\text{nnz}(\mathbf{M}) + mr^2 \log(r)/\epsilon^2)$  time. The proof of Theorem 3 is deferred to the supplementary material.

## 3 ALGORITHMS AND MAIN RESULTS

In this section, we present our approximation algorithm for ridge regression (Algorithm 1). Then, we state our main result on the approximation guarantee of our algorithm (Theorem 4). In Section 3.1, we outline the proofs of our main result.

**Algorithm.** Algorithm 1 takes inputs of the design matrix  $\mathbf{A} \in \mathbb{R}^{n \times p}$ , target vector  $\mathbf{b} \in \mathbb{R}^n$ , regularization parameter  $\lambda > 0$  and integer parameters  $t'$  and  $t$ . The first part of Algorithm 1 is to compute the sketched matrix  $\mathbf{A}\mathbf{S}^T$ , where  $\mathbf{S} \in \mathbb{R}^{t \times p}$  is chosen to be the product of sparse embedding matrix  $\Phi_{\text{sparse}} \in \mathbb{R}^{t' \times p}$  and SRHT matrix  $\Phi_{\text{srht}} \in \mathbb{R}^{t \times t'}$ , i.e.  $\mathbf{S} = \Phi_{\text{srht}}\Phi_{\text{sparse}}$ . As the first step, the algorithm constructs the sparse embedding matrix  $\Phi_{\text{sparse}}$  and the SRHT matrix  $\Phi_{\text{srht}}$ . After that, the algorithm applies  $\Phi_{\text{sparse}}$  and  $\Phi_{\text{srht}}$  to each row  $\mathbf{A}_{(i)}$  and obtains the sketched row  $(\mathbf{A}\mathbf{S}^T)_{(i)} = (\mathbf{A}_{(i)}\Phi_{\text{sparse}}^T)\Phi_{\text{srht}}^T$  for all  $i \in [n]$ . This step can be done in one pass through the rows of  $\mathbf{A}$  in arbitrary order. The algorithm then combines the sketched rows  $\{(\mathbf{A}\mathbf{S}^T)_{(i)}\}_{i \in [n]}$  to form the sketched matrix  $\mathbf{A}\mathbf{S}^T$ .

Next, the algorithm uses the sketched matrix  $\mathbf{A}\mathbf{S}^T$  to compute the approximate solution  $\tilde{\mathbf{x}}$  of ridge regression Eq. (1). In this step, we use the following key estimation of  $\tilde{\mathbf{x}}$ ,

$$\tilde{\mathbf{x}} = \mathbf{A}^T(\mathbf{A}\mathbf{S}^T)^\dagger{}^T(\lambda(\mathbf{A}\mathbf{S}^T)^\dagger{}^T + \mathbf{A}\mathbf{S}^T)^\dagger{} \mathbf{b}. \quad (3)$$

This step requires access to  $\mathbf{A}\mathbf{S}^T$ , which is computed in the previous step, and a second pass through  $\mathbf{A}$  (for pre-multiplying  $\mathbf{A}^T$ ). We summarize the above procedure of computing  $\mathbf{A}\mathbf{S}^T$  and  $\tilde{\mathbf{x}}$  in Algorithm 1.

**Main result.** Our main result is the following theorem which states that, with high probability, the output  $\tilde{\mathbf{x}}$  obtained in Algorithm 1 is a relative-error approximation to the optimal solution  $\mathbf{x}^*$  of ridge regression.

**Theorem 4.** *Suppose that we are given a design matrix  $\mathbf{A} \in \mathbb{R}^{n \times p}$  of rank  $r$ , a target vector  $\mathbf{b} \in \mathbb{R}^n$ , a regularization parameter  $\lambda > 0$ , accuracy parameters  $\epsilon \in (0, 1)$  and  $\delta \in (0, 1)$ . Select integers  $t', t$  such that  $t' \geq 2\delta^{-1}(r^2 + r)/(\epsilon/6 - \epsilon^2/144)^2$  and  $t \geq 72\epsilon^{-1}[\sqrt{r} + \sqrt{8 \log(6p/\delta)}]^2 \log(6r/\delta)$ . Run Algorithm 1 with inputs*

---

**Algorithm 1** Fast relative-error approximation algorithm of ridge regression

---

**Input:** design matrix  $\mathbf{A} \in \mathbb{R}^{n \times p}$  ( $n$  samples with  $p$  features), target vector  $\mathbf{b} \in \mathbb{R}^n$ , regularization parameter  $\lambda > 0$ , integer parameters  $t'$  and  $t$ .

**Output:** approximate solution  $\tilde{\mathbf{x}} \in \mathbb{R}^p$  to ridge regression problem Eq. (1).

- 1: Construct sparse embedding matrix  $\Phi_{\text{sparse}} \in \mathbb{R}^{t' \times p}$ .
  - 2: Construct SRHT matrix  $\Phi_{\text{srht}} \in \mathbb{R}^{t \times t'}$ .
  - 3: **for** each row  $\mathbf{A}_{(i)}$  of  $\mathbf{A}$  in arbitrary order **do**
  - 4:     Compute  $(\mathbf{A}\mathbf{S}^T)_{(i)} \leftarrow (\mathbf{A}_{(i)} \Phi_{\text{sparse}}^T) \Phi_{\text{srht}}^T$
  - 5: **end for**
  - 6: Construct  $\mathbf{A}\mathbf{S}^T$  by concatenating row vectors  $\{(\mathbf{A}\mathbf{S}^T)_{(i)}\}_{i \in [n]}$ .
  - 7: Compute the pseudoinverse  $(\mathbf{A}\mathbf{S}^T)^\dagger$
  - 8: Set  $\tilde{\mathbf{x}} \leftarrow \mathbf{A}^T (\mathbf{A}\mathbf{S}^T)^\dagger^T (\lambda (\mathbf{A}\mathbf{S}^T)^\dagger^T + \mathbf{A}\mathbf{S}^T)^\dagger \mathbf{b}$
  - 9: **return**  $\tilde{\mathbf{x}}$
- 

$\mathbf{A}$ ,  $\mathbf{b}$ ,  $\lambda$ ,  $t'$ ,  $t$  and let  $\tilde{\mathbf{x}}$  denote the output of the algorithm. Then, with probability at least  $1 - \delta$ , we have

$$\|\tilde{\mathbf{x}} - \mathbf{x}^*\|_2 \leq \epsilon \|\mathbf{x}^*\|_2, \quad (4)$$

where  $\mathbf{x}^*$  is the optimal solution of ridge regression in Eq. (1).

In addition, if  $t' = O(r^2/\epsilon^2)$  and  $t = O(r \log(r)/\epsilon)$ , the time complexity of Algorithm 1 is

$$O\left(\text{nnz}(\mathbf{A}) + nr^2 \log\left(\frac{r}{\epsilon}\right) / \epsilon^2 + n^2 r \log(r) / \epsilon\right).$$

**Running times.** Set  $t' = O(r^2/\epsilon^2)$  and  $t = O(r \log(r)/\epsilon)$  according to Theorem 4. Then, the time complexity of each step of Algorithm 1 can be analyzed as follows. Constructing sparse embedding matrix  $\Phi_{\text{sparse}}$  and SRHT matrix  $\Phi_{\text{srht}}$  uses  $O(p)$  time. Right-multiplying the sparse embedding matrix  $\mathbf{A}\Phi_{\text{sparse}}^T$  takes  $O(\text{nnz}(\mathbf{A}))$  time. Computing SRHT  $(\mathbf{A}\Phi_{\text{sparse}}^T)\Phi_{\text{srht}}^T$  uses  $O(nt' \log(t')) = O(nr^2 \log(\frac{r}{\epsilon})/\epsilon^2)$  time. The pseudoinverse of  $\mathbf{A}\mathbf{S}^T$  and  $\lambda(\mathbf{A}\mathbf{S}^T)^\dagger^T + \mathbf{A}\mathbf{S}^T$  can be computed in  $O(n^2 t) = O(n^2 r \log(r)/\epsilon)$  time. Computing the product  $(\mathbf{A}\mathbf{S}^T)^\dagger^T (\lambda(\mathbf{A}\mathbf{S}^T)^\dagger^T + \mathbf{A}\mathbf{S}^T)^\dagger \mathbf{b}$  also takes  $O(n^2 t) = O(n^2 r \log(r)/\epsilon)$  time. Finally, left-multiplying  $\mathbf{A}^T$  uses  $O(\text{nnz}(\mathbf{A}))$  time. So, the total running time is the sum of all these operations, which is  $O(\text{nnz}(\mathbf{A}) + nr^2 \log(\frac{r}{\epsilon})/\epsilon^2 + n^2 r \log(r)/\epsilon)$ .

**Remarks.** In practice, one may not have prior knowledge on the rank  $r$  of  $\mathbf{A}$ . By Theorem 4, it is safe to assume that  $r = n$ , which is the largest possible value of  $r$ , and hence set  $t' = O(n^2/\epsilon^2)$  and  $t = O(n \log(n)/\epsilon)$ . In this case, the running time of Algorithm 1 is  $O(\text{nnz}(\mathbf{A}) + n^3 \log(\frac{n}{\epsilon})/\epsilon^2)$ . This is still an  $o(n^2 p)$  algorithm and is substantially faster than the standard  $O(n^2 p + n^3)$  solver for  $p \gg n$  instances.

In addition, the estimation method of  $\tilde{\mathbf{x}}$  as in Eq. (3) holds for general OSEs  $\mathbf{S}$ , not necessarily limiting to the one used

in Algorithm 1, i.e.  $\mathbf{S} = \Phi_{\text{srht}} \Phi_{\text{sparse}}$ . This fact is formalized in the following lemma.

**Lemma 1.** Given  $\mathbf{A} \in \mathbb{R}^{n \times p}$  of rank  $r$ ,  $\mathbf{b} \in \mathbb{R}^n$ ,  $\lambda > 0$ . Suppose that  $\mathbf{S} \in \mathbb{R}^{t \times p}$  is an  $(r, \delta, \epsilon/4)$ -OSE for  $\epsilon \in (0, 1)$  and  $\delta \in (0, 1)$ . Then, with probability at least  $1 - \delta$ , the approximation solution  $\tilde{\mathbf{x}}$  obtained by Eq. (3) satisfies

$$\|\tilde{\mathbf{x}} - \mathbf{x}^*\|_2 \leq \epsilon \|\mathbf{x}^*\|_2,$$

where  $\mathbf{x}^*$  is the optimal solution to ridge regression Eq. (1).

Our choice of OSE  $\mathbf{S} = \Phi_{\text{srht}} \Phi_{\text{sparse}}$  in Algorithm 1 guarantees that the sketched matrix  $\mathbf{A}\mathbf{S}^T$  can be computed efficiently while has a small number of columns. By Lemma 1, one may use other OSEs as well, for example, SRHT  $\mathbf{S} = \Phi_{\text{srht}}$ . This would lead to a total time complexity of  $O(np \log(p) + n^2 r \log(r)/\epsilon)$ , which is slower than our choice in Algorithm 1 if  $\mathbf{A}$  is a sparse matrix.

### 3.1 PROOF

From this point on, we denote the thin SVD of matrix  $\mathbf{A} \in \mathbb{R}^{n \times p}$  with rank  $r$  by  $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^T$ , with  $\mathbf{U} \in \mathbb{R}^{n \times r}$ ,  $\mathbf{\Sigma} \in \mathbb{R}^{r \times r}$  and  $\mathbf{V} \in \mathbb{R}^{p \times r}$ . We denote the full SVD of  $\mathbf{S}\mathbf{V}$  by  $\mathbf{S}\mathbf{V} = \mathbf{U}_\phi \mathbf{\Sigma}_\phi \mathbf{V}_\phi^T$ , with  $\mathbf{U}_\phi \in \mathbb{R}^{t \times r}$ ,  $\mathbf{\Sigma}_\phi \in \mathbb{R}^{r \times r}$  and  $\mathbf{V}_\phi \in \mathbb{R}^{r \times r}$ . Notice that  $\mathbf{V}_\phi$  is an  $r \times r$  unitary matrix and therefore  $\mathbf{V}_\phi \mathbf{V}_\phi^T = \mathbf{I}_r$ . We will frequently use the following property of the pseudoinverse of matrix product.

**Fact 1.** For any matrix  $\mathbf{A} \in \mathbb{R}^{m \times n}$  and  $\mathbf{B} \in \mathbb{R}^{n \times p}$ , we have  $(\mathbf{A}\mathbf{B})^\dagger = \mathbf{B}^\dagger \mathbf{A}^\dagger$ , if at least one of the following holds.

1.  $\mathbf{A}$  has orthonormal columns.
2.  $\mathbf{B}$  has orthonormal rows.
3.  $\mathbf{A}$  has full column rank and  $\mathbf{B}$  has full row rank.

By Fact 1, we immediately obtain the following lemma.

**Lemma 2.** Suppose that  $\mathbf{S}\mathbf{V}$  is full rank, then the pseudoinverse of  $\mathbf{A}\mathbf{S}^T$  is given by

$$(\mathbf{A}\mathbf{S}^T)^\dagger = (\mathbf{S}\mathbf{V})^\dagger \mathbf{\Sigma}^{-1} \mathbf{U}^T.$$

The first step of our proof is to represent  $\mathbf{x}^*$  and  $\tilde{\mathbf{x}}$  in a form that is easier to work with.

**Lemma 3.** Let the optimal solution of ridge regression  $\mathbf{x}^*$  be defined as in Eq. (2). We have

$$\mathbf{x}^* = \mathbf{V}\mathbf{G}^{-1} \mathbf{U}^T \mathbf{b},$$

where  $\mathbf{G} = \lambda \mathbf{\Sigma}^{-1} + \mathbf{\Sigma}$ .

*Proof.* Consider the full SVD of  $\mathbf{A}$  as  $\mathbf{A} = \mathbf{U}_+ \mathbf{\Sigma}_+ \mathbf{V}_+^T$ , with  $\mathbf{U}_+ \in \mathbb{R}^{n \times n}$ ,  $\mathbf{\Sigma}_+ \in \mathbb{R}^{n \times n}$  and  $\mathbf{V}_+ \in \mathbb{R}^{p \times n}$ . By the relationship between thin SVD and full SVD, we can see that  $\mathbf{U}_+ = [\mathbf{U}, \mathbf{U}_-]$ ,  $\mathbf{\Sigma}_+ = \begin{bmatrix} \mathbf{\Sigma} & \\ & \mathbf{0}_{n-r} \end{bmatrix}$  and  $\mathbf{V}_+ = [\mathbf{V}, \mathbf{V}_-]$ , with  $\mathbf{U}_- \in \mathbb{R}^{n \times (n-r)}$  and  $\mathbf{V}_- \in \mathbb{R}^{p \times (n-r)}$  being column orthonormal matrices.

Now, by definition of  $\mathbf{x}^*$ , we have

$$\begin{aligned}
\mathbf{x}^* &= \mathbf{A}^T(\mathbf{A}\mathbf{A}^T + \lambda\mathbf{I})^{-1}\mathbf{b} \\
&= \mathbf{V}_+\Sigma_+\mathbf{U}_+^T(\mathbf{U}_+\Sigma_+^2\mathbf{U}_+^T + \lambda\mathbf{U}_+\mathbf{U}_+^T)^{-1}\mathbf{b} \\
&= \mathbf{V}_+\Sigma_+(\Sigma_+^2 + \lambda\mathbf{I})^{-1}\mathbf{U}_+^T\mathbf{b} \\
&= \mathbf{V}_+\begin{bmatrix} \Sigma & \\ & \mathbf{0}_{n-r} \end{bmatrix} \begin{bmatrix} (\Sigma^2 + \lambda\mathbf{I}_r)^{-1} & \\ & \lambda^{-1}\mathbf{I}_{n-r} \end{bmatrix} \mathbf{U}_+^T\mathbf{b} \\
&= \mathbf{V}_+\begin{bmatrix} (\Sigma + \lambda\Sigma^{-1})^{-1} & \\ & \mathbf{0}_{n-r} \end{bmatrix} \mathbf{U}_+^T\mathbf{b} \\
&= \mathbf{V}(\Sigma + \lambda\Sigma^{-1})^{-1}\mathbf{U}^T\mathbf{b}.
\end{aligned}$$

□

**Lemma 4.** Define matrix  $\tilde{\mathbf{G}} = \lambda\Sigma^{-1} + \Sigma(\mathbf{S}\mathbf{V})^T(\mathbf{S}\mathbf{V})$ . Let  $\tilde{\mathbf{x}}$  be defined as in Eq. (3). Suppose that  $\mathbf{S}\mathbf{V}$  is full rank. Then, we have that  $\tilde{\mathbf{G}}$  is full rank and that

$$\tilde{\mathbf{x}} = \mathbf{V}\tilde{\mathbf{G}}^{-1}\mathbf{U}^T\mathbf{b}.$$

*Proof.* By the construction of  $\tilde{\mathbf{x}}$ , we have

$$\begin{aligned}
\tilde{\mathbf{x}} &= \mathbf{A}^T((\mathbf{A}\mathbf{S}^T)^\dagger)^T \left( \lambda((\mathbf{A}\mathbf{S}^T)^\dagger)^T + \mathbf{A}\mathbf{S}^T \right)^\dagger \mathbf{b} \\
&= \mathbf{V}\Sigma\mathbf{U}^T\mathbf{U}\Sigma^{-1}(\mathbf{S}\mathbf{V})^\dagger (\lambda\mathbf{U}\Sigma^{-1}(\mathbf{S}\mathbf{V})^\dagger + \mathbf{U}\Sigma(\mathbf{S}\mathbf{V})^T)^\dagger \mathbf{b} \\
&= \mathbf{V}(\mathbf{S}\mathbf{V})^\dagger (\lambda\mathbf{U}\Sigma^{-1}(\mathbf{S}\mathbf{V})^\dagger + \mathbf{U}\Sigma(\mathbf{S}\mathbf{V})^T)^\dagger \mathbf{b} \\
&= \mathbf{V}\mathbf{V}_\phi\Sigma_\phi^{-1}\mathbf{U}_\phi^T \left( \lambda\mathbf{U}\Sigma^{-1}\mathbf{V}_\phi\Sigma_\phi^{-1}\mathbf{U}_\phi^T + \mathbf{U}\Sigma\mathbf{V}_\phi\Sigma_\phi\mathbf{U}_\phi^T \right)^\dagger \mathbf{b} \\
&= \mathbf{V}\mathbf{V}_\phi\Sigma_\phi^{-1}\mathbf{U}_\phi^T\mathbf{U}_\phi \left( \lambda\Sigma^{-1}\mathbf{V}_\phi\Sigma_\phi^{-1} + \Sigma\mathbf{V}_\phi\Sigma_\phi \right)^\dagger \mathbf{U}^T\mathbf{b} \\
&= \mathbf{V}\mathbf{V}_\phi\Sigma_\phi^{-1} \left( \lambda\Sigma^{-1}\mathbf{V}_\phi\Sigma_\phi^{-1} + \Sigma\mathbf{V}_\phi\Sigma_\phi \right)^\dagger \mathbf{U}^T\mathbf{b}, \quad (5)
\end{aligned}$$

where we have repeatedly used Fact 1 and Lemma 2.

Define  $\mathbf{T}_1 = \lambda\Sigma^{-1}\mathbf{V}_\phi\Sigma_\phi^{-1} + \Sigma\mathbf{V}_\phi\Sigma_\phi$ . Next, we show that  $\text{rank}(\mathbf{T}_1) = r$ . To see this, we define  $\mathbf{T}_2 = \lambda\mathbf{I} + \Sigma\mathbf{V}_\phi\Sigma_\phi^2\mathbf{V}_\phi^T\Sigma$  and notice that  $\mathbf{T}_2 = \mathbf{T}_1(\Sigma_\phi\mathbf{V}_\phi^T\Sigma)$ . Since  $\lambda > 0$ , it is clear that  $\mathbf{T}_2$  is a positive definite matrix and therefore  $\text{rank}(\mathbf{T}_2) = r$ .

Now notice that  $\text{rank}(\Sigma_\phi\mathbf{V}_\phi^T\Sigma) = \text{rank}(\Sigma_\phi) = r$ . Hence, we have

$$\text{rank}(\mathbf{T}_1) = \text{rank}(\mathbf{T}_1(\Sigma_\phi\mathbf{V}_\phi^T\Sigma)) = \text{rank}(\mathbf{T}_2) = r.$$

Then, using Fact 1 on  $\Sigma_\phi^\dagger$  and  $\mathbf{T}_1^\dagger$ , we have

$$\begin{aligned}
(5) &= \mathbf{V}\mathbf{V}_\phi \left( \lambda\Sigma^{-1}\mathbf{V}_\phi + \Sigma\mathbf{V}_\phi\Sigma_\phi^2 \right)^\dagger \mathbf{U}^T\mathbf{b} \\
&= \mathbf{V} \left( \lambda\Sigma^{-1} + \Sigma\mathbf{V}_\phi\Sigma_\phi^2\mathbf{V}_\phi^T \right)^\dagger \mathbf{U}^T\mathbf{b} \\
&= \mathbf{V}\tilde{\mathbf{G}}^\dagger\mathbf{U}^T\mathbf{b},
\end{aligned}$$

where we have used Fact 1 again and that  $\mathbf{S}\mathbf{V} = \mathbf{U}_\phi\Sigma_\phi\mathbf{V}_\phi^T$ . Finally, the rank of  $\tilde{\mathbf{G}}$  is given by

$$\text{rank}(\tilde{\mathbf{G}}) = \text{rank}(\mathbf{T}_1\Sigma_\phi\mathbf{V}_\phi^T) = \text{rank}(\mathbf{T}_1) = r.$$

Hence the pseudoinverse of  $\tilde{\mathbf{G}}$  equals to its inverse, i.e.  $\tilde{\mathbf{G}}^\dagger = \tilde{\mathbf{G}}^{-1}$ , and this concludes our proof of the lemma. □

From Lemma 3 and Lemma 4, we see that  $\tilde{\mathbf{x}}$  admits a representation that is very similar to  $\mathbf{x}^*$ . It is clear that the key difference between  $\tilde{\mathbf{x}}$  and  $\mathbf{x}^*$  comes from that of  $\tilde{\mathbf{G}}$  and  $\mathbf{G}$ .

The next lemma (Lemma 5) is our key technical lemma, which shows that  $\tilde{\mathbf{G}}$  is closely related to  $\mathbf{G}$  in the sense that  $\mathbf{G}^{-1}$  is an approximate matrix inversion of  $\tilde{\mathbf{G}}$ .

**Lemma 5.** Given  $\epsilon \in (0, 1/4)$  and  $\delta \in (0, 1)$ . Let  $\mathbf{S}$  be an  $(r, \delta, \epsilon)$ -OSE. Let  $\tilde{\mathbf{G}} = \lambda\Sigma^{-1} + \Sigma(\mathbf{S}\mathbf{V})^T(\mathbf{S}\mathbf{V})$  and  $\mathbf{G} = \lambda\Sigma^{-1} + \Sigma$ . Notice that  $\mathbf{G}$  is invertible and define  $\mathbf{R} = \mathbf{G}^{-1}\tilde{\mathbf{G}} - \mathbf{I}$ . Then, with probability at least  $1 - \delta$ , we have (a)  $\mathbf{S}\mathbf{V}$  is a full rank matrix, (b)  $\|\mathbf{R}\|_2 \leq 2\epsilon + \epsilon^2$ , and (c)

$$\|(\mathbf{I} + \mathbf{R})^{-1}\mathbf{R}\|_2 \leq \frac{2\epsilon + \epsilon^2}{1 - (2\epsilon + \epsilon^2)}.$$

To prove Lemma 5, we need two ingredients from linear algebra and the theory of OSEs. First, we use the following property on the stability of singular values.

**Lemma 6.** [31, Section 1.3.22 (iv)] Let  $\mathbf{C} \in \mathbb{R}^{m \times n}$  and  $\mathbf{D} \in \mathbb{R}^{m \times n}$  be two matrices of the same size. Then, for all  $i \in [\min\{m, n\}]$ ,

$$|\sigma_i(\mathbf{C} + \mathbf{D}) - \sigma_i(\mathbf{C})| \leq \|\mathbf{D}\|_2.$$

Lemma 6 can be regarded as a generalization of Weyl's inequality to singular values of non-Hermitian matrices. We refer readers to [see 31, Section 1.3] for a proof.

The second ingredient we needed is the following characterization of OSEs.

**Theorem 5.** Let  $\mathbf{V} \in \mathbb{R}^{p \times r}$  be a column orthonormal matrix. Let  $\mathbf{S} \in \mathbb{R}^{t \times p}$  be an  $(r, \delta, \epsilon)$ -OSE. Then, with probability  $1 - \delta$  over the choices of  $\mathbf{S}$ , we have that (a)  $\mathbf{S}\mathbf{V}$  is a full rank matrix and (b) for all  $i \in [r]$ , the  $i$ -th largest singular value of  $\mathbf{S}\mathbf{V}$  is bounded by

$$|1 - \sigma_i(\mathbf{S}\mathbf{V})| \leq \epsilon. \quad (6)$$

The proof of Lemma 6 and Theorem 5 is deferred to the supplementary material. Using them, we are now ready to prove Lemma 5.

*Proof of Lemma 5.* Since  $\mathbf{S}$  is an  $(r, \delta, \epsilon)$ -OSE. By Theorem 5, we have that, with probability  $1 - \delta$ ,  $\mathbf{S}\mathbf{V}$  is a full rank matrix and all singular values of  $\mathbf{S}\mathbf{V}$  are bounded in  $[1 - \epsilon, 1 + \epsilon]$ . In the rest of the proof, we assume this holds. And this already proves part (a) of the lemma.

We start with bounding  $\|\mathbf{R}\|_2$ . By the definition of  $\mathbf{R}$ , we have

$$\|\mathbf{R}\|_2 = \left\| \mathbf{G}^{-1}(\tilde{\mathbf{G}} - \mathbf{G}) \right\|_2$$

$$\begin{aligned}
&= \|(\lambda\boldsymbol{\Sigma}^{-1} + \boldsymbol{\Sigma})^{-1}\boldsymbol{\Sigma}((\mathbf{S}\mathbf{V})^T(\mathbf{S}\mathbf{V}) - \mathbf{I})\|_2 \\
&\leq \|(\lambda\boldsymbol{\Sigma}^{-1} + \boldsymbol{\Sigma})^{-1}\boldsymbol{\Sigma}\|_2 \|\mathbf{V}_\phi \boldsymbol{\Sigma}_\phi^2 \mathbf{V}_\phi^T - \mathbf{I}\|_2 \\
&= \|(\lambda\boldsymbol{\Sigma}^{-1} + \boldsymbol{\Sigma})^{-1}\boldsymbol{\Sigma}\|_2 \|\mathbf{V}_\phi \boldsymbol{\Sigma}_\phi^2 \mathbf{V}_\phi^T - \mathbf{V}_\phi \mathbf{V}_\phi^T\|_2 \\
&= \|(\lambda\boldsymbol{\Sigma}^{-1} + \boldsymbol{\Sigma})^{-1}\boldsymbol{\Sigma}\|_2 \|\boldsymbol{\Sigma}_\phi^2 - \mathbf{I}\|_2 \\
&\leq \max_i \frac{\sigma_i}{\lambda\sigma_i^{-1} + \sigma_i} ((1 + \epsilon)^2 - 1) \\
&\leq 2\epsilon + \epsilon^2, \tag{7}
\end{aligned}$$

where we have used the fact that  $\mathbf{V}_\phi$  is a unitary matrix and dropped terms that do not change spectral norm.

Now, we apply Lemma 6 by setting  $\mathbf{C} = \mathbf{I}$  and  $\mathbf{D} = \mathbf{R}$ . Then, for all  $i \in [r]$ , we have

$$\sigma_i(\mathbf{I} + \mathbf{R}) \geq 1 - \|\mathbf{R}\|_2 \geq 1 - (2\epsilon + \epsilon^2). \tag{8}$$

Hence, we have

$$\begin{aligned}
\|(\mathbf{I} + \mathbf{R})^{-1}\mathbf{R}\|_2 &\leq \|(\mathbf{I} + \mathbf{R})^{-1}\|_2 \|\mathbf{R}\|_2 \\
&\leq (\sigma_{\min}(\mathbf{I} + \mathbf{R}))^{-1} \|\mathbf{R}\|_2 \\
&\leq \frac{2\epsilon + \epsilon^2}{1 - (2\epsilon + \epsilon^2)}.
\end{aligned}$$

□

We are now ready to prove our main results: Lemma 1 and Theorem 4.

*Proof of Lemma 1.* Let  $\epsilon' = \epsilon/4$  and recall the definition  $\tilde{\mathbf{R}} = \mathbf{G}^{-1}\tilde{\mathbf{G}} - \mathbf{I}$ . Since  $\mathbf{S}$  is an  $(r, \delta, \epsilon')$ -OSE. By Lemma 5, with probability  $1 - \delta$ , we have that  $\mathbf{S}\mathbf{V}$  is a full rank matrix and that  $\|(\mathbf{I} + \mathbf{R})^{-1}\mathbf{R}\|_2 \leq \frac{2\epsilon' + \epsilon'^2}{1 - (2\epsilon' + \epsilon'^2)}$ . In the rest of the proof, we assume that this event happens.

Since  $\mathbf{S}\mathbf{V}$  is a full rank matrix. Applying Lemma 3 and Lemma 4, we have

$$\begin{aligned}
\|\tilde{\mathbf{x}} - \mathbf{x}^*\|_2 &= \|\mathbf{V}(\tilde{\mathbf{G}}^{-1} - \mathbf{G}^{-1})\mathbf{U}^T\mathbf{b}\|_2 \\
&= \|(\tilde{\mathbf{G}}^{-1} - \mathbf{G}^{-1})\mathbf{U}^T\mathbf{b}\|_2, \tag{9}
\end{aligned}$$

where we have dropped the unitary term  $\mathbf{V}$  which does not change  $l_2$  norm.

Next, we write  $\tilde{\mathbf{G}} = \mathbf{G}(\mathbf{I} + \mathbf{R})$ . This means that  $\tilde{\mathbf{G}}^{-1} = (\mathbf{I} + \mathbf{R})^{-1}\mathbf{G}^{-1}$ . Therefore,

$$\begin{aligned}
(9) &= \|((\mathbf{I} + \mathbf{R})^{-1} - \mathbf{I})\mathbf{G}^{-1}\mathbf{U}^T\mathbf{b}\|_2 \\
&= \|-(\mathbf{I} + \mathbf{R})^{-1}\mathbf{R}\mathbf{G}^{-1}\mathbf{U}^T\mathbf{b}\|_2 \tag{10} \\
&\leq \|(\mathbf{I} + \mathbf{R})^{-1}\mathbf{R}\|_2 \|\mathbf{G}^{-1}\mathbf{U}^T\mathbf{b}\|_2 \\
&= \|(\mathbf{I} + \mathbf{R})^{-1}\mathbf{R}\|_2 \|\mathbf{x}^*\|_2
\end{aligned}$$

$$\begin{aligned}
&\leq \frac{2\epsilon' + \epsilon'^2}{1 - (2\epsilon' + \epsilon'^2)} \|\mathbf{x}^*\|_2 \tag{11} \\
&\leq 4\epsilon' \|\mathbf{x}^*\|_2 = \epsilon \|\mathbf{x}^*\|_2,
\end{aligned}$$

where Eq. (10) follows from matrix inversion lemma, i.e.  $\mathbf{C}^{-1} - \mathbf{D}^{-1} = -\mathbf{C}^{-1}(\mathbf{C} - \mathbf{D})\mathbf{D}^{-1}$  for any squared matrices  $\mathbf{C}$  and  $\mathbf{D}$  of the same size, and Eq. (11) follows from the assumption on  $\|(\mathbf{I} + \mathbf{R})^{-1}\mathbf{R}\|_2$ . □

*Proof of Theorem 4.* It is easy to see that the solution  $\tilde{\mathbf{x}}$  returned by Algorithm 1 is given by Eq. (3) with  $\mathbf{S} = \boldsymbol{\Phi}_{\text{srt}}\boldsymbol{\Phi}_{\text{sparse}}$ . Therefore, the bound on  $\|\tilde{\mathbf{x}} - \mathbf{x}\|_2$  follows immediately from Lemma 1 and Theorem 3 which shows that  $\mathbf{S} = \boldsymbol{\Phi}_{\text{srt}}\boldsymbol{\Phi}_{\text{sparse}}$  is an  $(r, \delta, \epsilon/4)$ -OSE. And the running time analysis of Algorithm 1 is given in Section 3. □

## 4 RISK INFLATION BOUND

In this section, we study the risk inflation of the approximate solution  $\tilde{\mathbf{x}}$  returned by Algorithm 1 with respect to the optimal solution  $\mathbf{x}^*$  of ridge regression. We begin with review the definition of risk of ridge regression. To properly define the risk, we need to that  $\mathbf{A}$  and  $\mathbf{b}$  have the linear relationship as follows

$$\mathbf{b} = \mathbf{A}\mathbf{x}_0 + \mathbf{e}, \tag{12}$$

where  $\mathbf{x}_0 \in \mathbb{R}^p$  is an unknown vector which is assumed to be the “true” parameter and  $\mathbf{e} \in \mathbb{R}^n$  is independent noise in each coordinate, with  $\mathbf{E}[e_i] = 0$  and  $\mathbf{Var}[e_i] = \sigma^2$ . Under this assumption, the risk of any vector  $\hat{\mathbf{b}} \in \mathbb{R}^n$  is given by

$$\text{risk}(\hat{\mathbf{b}}) \triangleq \frac{1}{n} \mathbf{E} \left[ \|\hat{\mathbf{b}} - \mathbf{A}\mathbf{x}_0\|_2^2 \right],$$

where the expectation is taken over the randomness of noise [4].

The following theorem shows that, compared with the optimal solution  $\mathbf{x}^*$ , the approximate solution  $\tilde{\mathbf{x}}$  returned by Algorithm 1 increases the risk by a small additive factor.

**Theorem 6.** *Given  $\mathbf{A} \in \mathbb{R}^{n \times p}$  of rank  $r$ ,  $\mathbf{b} \in \mathbb{R}^n$ ,  $\lambda > 0$ ,  $\epsilon \in (0, 1)$  and  $\lambda \in (0, 1)$ . Assume that  $\mathbf{A}$  and  $\mathbf{b}$  have the linear relationship as in Eq. (12). Let  $\tilde{\mathbf{x}}$  denote the output of Algorithm 1 with inputs  $\mathbf{A}$ ,  $\mathbf{b}$ ,  $\lambda$ ,  $t' = \lceil 2\delta^{-1}(r^2 + r)/(\epsilon/6 - \epsilon^2/144)^2 \rceil$  and  $t = \lceil 72\epsilon^{-1}[\sqrt{r} + \sqrt{8\log(6p/\delta)}]^2 \log(6r/\delta) \rceil$ . Let  $\mathbf{x}^*$  denote the optimal solution of ridge regression. Then, with probability at least  $1 - \delta$ ,*

$$\text{risk}(\tilde{\mathbf{b}}) \leq \text{risk}(\mathbf{b}^*) + \frac{3\epsilon}{n} \|\mathbf{A}\|_2^2 \left( \|\mathbf{x}_0\|_2^2 + \sigma^2 \rho^2 \right), \tag{13}$$

where we define  $\tilde{\mathbf{b}} = \mathbf{A}\tilde{\mathbf{x}}$  and  $\mathbf{b}^* = \mathbf{A}\mathbf{x}^*$ ; we also define  $\rho^2 = \sum_{i \in [r]} \left( \frac{\sigma_i}{\sigma_i^2 + \lambda} \right)^2$  and  $\sigma_i$  is the  $i$ -th largest singular value of  $\mathbf{A}$ .

## 5 EXTENSIONS

In this section, we present two extensions to our algorithm. First, we consider the multiple response ridge regression

problem, and obtain an efficient approximation algorithm with relative-error guarantee similar with Algorithm 1. Second, combining with the recent results of Avron et al. [3], we present a fast relative-error approximation algorithm of a special nonlinear ridge regression problem called structured ridge regression.

## 5.1 MULTIPLE RESPONSE RIDGE REGRESSION

In this part, we generalize our techniques to solve multiple response ridge regression [11]. The multiple response ridge regression problem is defined as follows. Given a design matrix  $\mathbf{A} \in \mathbb{R}^{n \times p}$ ,  $m$  target vectors (responses)  $\mathbf{B} \in \mathbb{R}^{p \times m}$  and a regression parameter  $\lambda > 0$ , the multiple response regression problem is to find an  $n \times m$  matrix  $\mathbf{X}^*$  such that

$$\mathbf{X}^* = \arg \min_{\mathbf{X} \in \mathbb{R}^{n \times m}} \|\mathbf{A}\mathbf{X} - \mathbf{B}\|_F^2 + \lambda \|\mathbf{X}\|_F^2. \quad (14)$$

The optimal solution of Eq. (14) is given by

$$\mathbf{X}^* = \mathbf{A}^T (\lambda \mathbf{I}_n + \mathbf{A}\mathbf{A}^T)^{-1} \mathbf{B}. \quad (15)$$

It is clear that Eq. (15) takes  $O(n^2p + n^3 + nm)$  time to compute, which is expensive if  $p \gg n \gg 1$ .

Next, we generalize our techniques to solve multiple response regression problem. The first step is to compute the sketched matrix  $\mathbf{A}\mathbf{S}^T$ , where  $\mathbf{S} = \Phi_{\text{srht}} \Phi_{\text{sparse}}$ . Notice that this step is identical to that of Algorithm 1, which uses one pass through  $\mathbf{A}$ . Then, we use the following generalized version of Eq. (3) to compute the approximate solution  $\tilde{\mathbf{X}}$ ,

$$\tilde{\mathbf{X}} = \mathbf{A}^T (\mathbf{A}\mathbf{S}^T)^\dagger (\lambda (\mathbf{A}\mathbf{S}^T)^\dagger + \mathbf{A}\mathbf{S}^T)^\dagger \mathbf{B}, \quad (16)$$

which uses a second pass through  $\mathbf{A}$ . We show that the approximate solution  $\tilde{\mathbf{X}}$  given by Eq. (16) is a relative-error approximation of  $\mathbf{X}^*$  in the following theorem.

**Theorem 7.** *Given  $\mathbf{A} \in \mathbb{R}^{n \times p}$  of rank  $r$ ,  $\mathbf{B} \in \mathbb{R}^{n \times m}$ ,  $\lambda > 0$ , parameter  $\epsilon \in (0, 1)$  and  $\delta \in (0, 1)$ . Select integers  $t', t$  such that  $t' \geq 2\delta^{-1}(r^2 + r)/(\epsilon/6 - \epsilon^2/144)^2$  and  $t \geq 72\epsilon^{-1}[\sqrt{r} + \sqrt{8 \log(6p/\delta)}]^2 \log(6r/\delta)$ . Let  $\mathbf{S} = \Phi_{\text{srht}} \Phi_{\text{sparse}}$ , where  $\Phi_{\text{sparse}} \in \mathbb{R}^{t' \times p}$  is a sparse embedding matrix and  $\Phi_{\text{srht}} \in \mathbb{R}^{t \times t'}$  is an SRHT matrix. Then, with probability at least  $1 - \delta$ , we have*

$$\left\| \tilde{\mathbf{X}} - \mathbf{X}^* \right\|_F \leq \epsilon \|\mathbf{X}^*\|_F,$$

where  $\tilde{\mathbf{X}}$  is given by Eq. (16) and  $\mathbf{X}^*$  is the optimal solution to multiple response ridge regression Eq. (14). In addition, the total time complexity of computing  $\mathbf{A}\mathbf{S}^T$  and  $\tilde{\mathbf{X}}$  is  $O(\text{nnz}(\mathbf{A}) + nr^2 \log(\frac{r}{\epsilon})/\epsilon^2 + n^2r \log(r)/\epsilon + nm)$ .

## 5.2 STRUCTURED RIDGE REGRESSION

In this part, we consider a non-linear ridge regression problem, called *structured ridge regression*, which is closely related to kernel ridge regression with polynomial kernels.

Structured ridge regression uses a non-linear kernel expansion function  $\varphi_q$ , which is studied recently by Avron et al. [3] under the context of (non-regularized) structured regression. The kernel expansion function  $\varphi_q$  maps a  $p$ -dimensional vector  $\mathbf{a}$  to a  $pq$ -dimensional vector  $\varphi_q(\mathbf{a}) = \{a_i^{j-1}\}_{(i,j) \in [p] \times [q]}$  for  $q > 1$ . The definition of  $\varphi_q$  corresponds to the kernel function  $k_{\varphi_q}(\mathbf{a}, \mathbf{b}) = \varphi_q(\mathbf{a})^T \varphi_q(\mathbf{b}) = \sum_{(i,j) \in [p] \times [q]} (a_i b_j)^{j-1}$ , for any  $p$ -dimensional  $\mathbf{a}$  and  $\mathbf{b}$ . Clearly,  $k_{\varphi_q}$  is related to polynomial kernels, which is defined as  $k_q(\mathbf{a}, \mathbf{b}) = (\mathbf{a}^T \mathbf{b})^q = \left( \sum_{i \in [p]} a_i b_i \right)^q$ . For more detailed discussion and the connections of  $\varphi_q$  to other kernels, we refer interested readers to [3].

In the following, we define structured ridge regression, which can be seen an  $l_2$  regularized version of structured regression proposed by Avron et al. [3],

$$\mathbf{x}^* = \arg \min_{\mathbf{x} \in \mathbb{R}^{pq}} \|\varphi_q(\mathbf{A})\mathbf{x} - \mathbf{b}\|_2^2 + \lambda \|\mathbf{x}\|_2^2, \quad (17)$$

where  $\varphi_q(\mathbf{A})$  is an  $n \times pq$  matrix consisting of  $n$  expanded samples, i.e. its  $i$ -th row vector is  $\varphi_q(\mathbf{A})_{(i)} = \varphi_q(\mathbf{A}_{(i)})$  for all  $i \in [n]$ . Clearly, Eq (17) is a non-linear ridge regression problem. For this problem, the dual space approach gives that  $\mathbf{x}^* = \varphi_q(\mathbf{A})^T (\mathbf{K} + \lambda \mathbf{I}_n)^{-1} \mathbf{b}$ , where  $\mathbf{K} = \varphi_q(\mathbf{A}) \varphi_q(\mathbf{A})^T$ . It is clear that computing  $\mathbf{x}^*$  using this approach takes  $O(n^2pq + n^3)$  time.

We extend our techniques to accelerate the computation of structured ridge regression for  $p \gg n$  instances by using the following property of  $\varphi_q$ . Avron et al. [3] showed that there exists a fast multiplication algorithm which computes the product  $\varphi_q(\mathbf{A}) \Phi_{\text{sparse}}^T$  in  $O((\text{nnz}(\mathbf{A}) + nqt') \log^2(q))$  time by exploiting the structure of  $\varphi_q(\mathbf{A})$ . Therefore, we only need to modify Algorithm 1 to use the fast multiplication algorithm for computing the sketched matrix  $(\varphi_q(\mathbf{A}) \Phi_{\text{sparse}}^T) \Phi_{\text{srht}}^T$ ; then run the modified algorithm with input  $\varphi_q(\mathbf{A})$  and  $\mathbf{b}$ . We show that this procedure gives a relative-error approximation algorithm for structured ridge regression that runs in  $O(\text{nnz}(\mathbf{A}) \log^2(q) + n^3q \log^2(q)/\epsilon^2 + n^3 \log(\frac{n}{\epsilon})/\epsilon^2)$  time, which is faster than the dual space approach when  $p \gg n$ . For constant  $q$ , this is also asymptotically faster than solving kernel ridge regression with polynomial kernel in dual space, whose computational complexity is  $O(n^2p + n^3)$ . We defer the detailed description of the approximation algorithm and its related analysis to the supplementary material (see Section D).

## 6 EXPERIMENTS

**Baselines.** We compare the performance of our algorithm SKETCHING (Algorithm 1) to three baselines. The first baseline is the STANDARD algorithm, which computes the optimal solution using the dual space approach in Eq. (2). The other two baselines use popular randomized dimen-

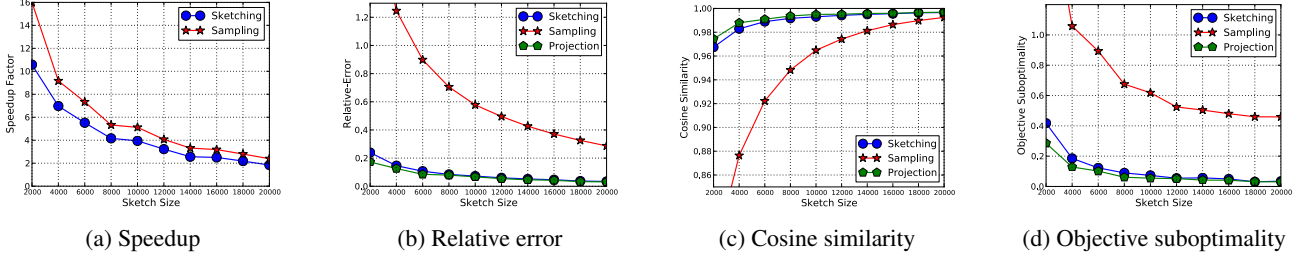

Figure 1: Quality-of-approximation and running times on synthetic dataset

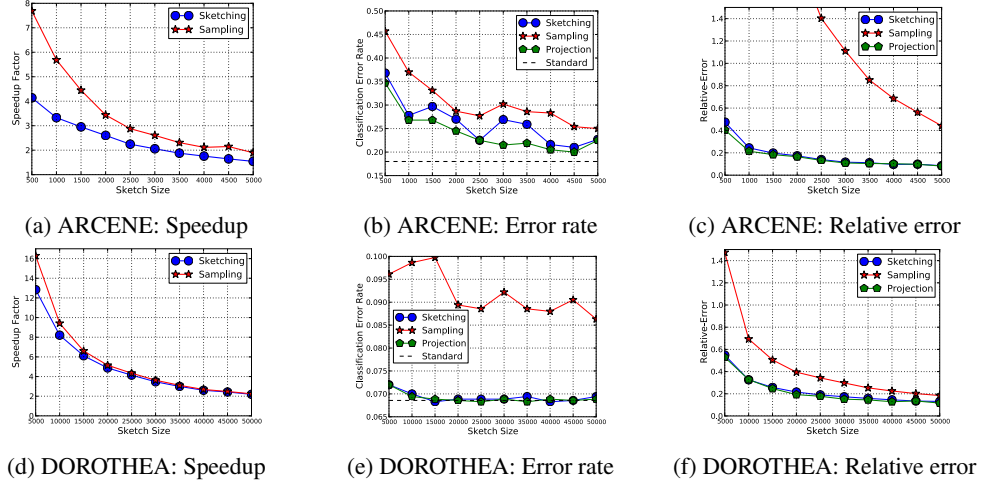

Figure 2: Classification accuracy and running times on realworld datasets

sionality reduction methods, including sampling and random projection. The SAMPLING algorithm simply samples a subset of  $t$  columns of  $\mathbf{A}$  uniformly at random. The PROJECTION algorithm post-multiplies  $\mathbf{A}$  by a random sign matrix  $\Phi_{\text{sign}}^T \in \mathbb{R}^{p \times t}$ , with each entry of  $\Phi_{\text{sign}}$  having value chosen from  $\{\pm 1/\sqrt{t}\}$  uniformly at random. Then, sketched matrices with  $t$  columns obtained by SAMPLING and PROJECTION are plugged in Eq. (3) to compute an approximate solution  $\tilde{\mathbf{x}}$  of ridge regression. Finally, notice that  $\Phi_{\text{sign}}$  is also an OSE for sufficiently large  $t$  [28] and therefore, by Lemma 1, the PROJECTION algorithm produces a relative-error approximation as well. However, for dense  $\mathbf{A}$ , computing  $\mathbf{A}\Phi_{\text{sign}}^T$  alone takes  $O(tnp)$  time, which is even slower than the STANDARD algorithm when  $t > n$ . Hence, we do not compare its running time to other competing algorithms.

**Implementation.** Our implementation of Algorithm 1 is slightly different from its description in two places. First, Algorithm 1, and its analysis, uses the Walsh-Hadamard transformation (as a step of SRHT), while our implementation uses discrete Hartley transformation (DHT) [30]. DHT has a highly optimized implementation provided in FFTW package [17]. In addition, it is possible to show that DHT or other Fourier-type transformations have a guarantee similar to Walsh-Hadamard transformation [2, 32]. Second, we set

$t' = 2t$ , i.e. the sketch size of sparse embedding is two times larger than that of SRHT. Empirically, this setting offers a good trade-off between accuracy and speed. All competing algorithms are implemented using C++ and the experiments are conducted on a standard workstation using a single core.

## 6.1 SYNTHETIC DATASET

**Setup.** We generate the  $n \times p$  design matrix  $\mathbf{A}$  using the following method, such that each row (sample) of  $\mathbf{A}$  contains an  $s$ -dimensional signal and  $p$ -dimensional noises. Specifically, we define  $\mathbf{A} = \mathbf{M}\mathbf{\Sigma}\mathbf{V}^T + \alpha\mathbf{E}$ . Here,  $\mathbf{M}$  is an  $n \times s$  matrix which represents the signals, and each entry  $M_{ij} \sim \mathcal{N}(0, 1)$  is an i.i.d Gaussian random variable.  $\mathbf{\Sigma}$  is an  $s \times s$  diagonal matrix and the diagonal entries are given by  $\Sigma_{ii} = 1 - (i - 1)/p$  for each  $i \in [s]$ .  $\mathbf{V}$  is a  $p \times n$  column orthonormal matrix which contains a random  $s$ -dimensional subspace of  $\mathbb{R}^p$ . Notice that  $\mathbf{M}\mathbf{\Sigma}\mathbf{V}^T$  is a rank  $s$  matrix with linearly decreasing singular values.  $\mathbf{E}$  is an  $n \times p$  matrix which contributes the additive Gaussian noise  $E_{ij} \sim \mathcal{N}(0, 1)$ .  $\alpha > 0$  is a parameter chosen to balance the energy of signals  $\mathbf{M}\mathbf{\Sigma}\mathbf{V}^T$  and the energy of noises  $\mathbf{E}$ . In this experiment, we choose  $\alpha = 0.05$  which brings  $\|\mathbf{M}\mathbf{\Sigma}\mathbf{V}^T\|_F \approx \alpha \|\mathbf{E}\|_F$ . Then, we generate the target vector  $\mathbf{x} \in \mathbb{R}^p$  with  $x_i \sim \mathcal{N}(0, 1)$ . Finally, the target vector

$\mathbf{b} \in \mathbb{R}^n$  is given by  $\mathbf{b} = \mathbf{A}\mathbf{x} + \gamma\mathbf{e}$ , where  $e_i \sim \mathcal{N}(0, 1)$  and  $\gamma = 5$ .

**Metrics.** We measure the performance of our algorithm and baselines both in terms of accuracy and speedup factor. More specifically, let  $\mathbf{x}^*$  denote the optimal solution produced by the standard algorithm and let  $\tilde{\mathbf{x}}$  denote the output vector returned by an approximation algorithm. To evaluate the accuracy of approximation, we compute three metrics: *relative error*:  $\frac{\|\tilde{\mathbf{x}} - \mathbf{x}^*\|_2}{\|\mathbf{x}^*\|_2}$ ; *cosine similarity*:  $\frac{\tilde{\mathbf{x}}^T \mathbf{x}^*}{\|\tilde{\mathbf{x}}\|_2 \|\mathbf{x}^*\|_2}$ ; *objective suboptimality*:  $\frac{f(\tilde{\mathbf{x}})}{f(\mathbf{x}^*)} - 1$ , with  $f(\mathbf{x}) \triangleq \|\mathbf{A}\mathbf{x} - \mathbf{b}\|_2^2 + \lambda \|\mathbf{x}\|_2^2$ . In addition, the speedup factor is given by the ratio between the time used by STANDARD algorithm and that of a competing algorithm.

**Results.** In the experiment, we set  $n = 500$ ,  $p = 50000$  and  $s = 50$ . We run the competing algorithms with 10 different choices of  $t$  within range  $[2000, 20000]$ . The results are shown in Figure 1. Figure 1(a) reports the speed up of approximation algorithms with respect to the STANDARD algorithm. We see that our algorithm SKETCHING is slightly slower than the SAMPLING algorithm, but both of them speed up considerably with respect to the STANDARD algorithm. Figure 1(b), (c) and (d) plot the accuracy metrics of the competing algorithms. We see that indeed the accuracy of approximation improves as the sketch size  $t$  increases. In addition, both of our SKETCHING algorithm and the PROJECTION algorithm output a significantly more accurate solution than the SAMPLING algorithm. Notably, when the sketch size  $t \approx 10000$ , our algorithm SKETCHING has a relative-error smaller than 10%, cosine similarity larger than 99% and objective suboptimality less than 10%; meanwhile speeds up the computation about 4 times.

## 6.2 REALWORLD DATASETS

**Setup.** We also test the proposed algorithm on two binary classification datasets: ARCENE and DOROTHEA [18]. Both datasets are publicly available from the UCI repository [6]. ARCENE contains 200 samples (100 for training and 100 for testing) with 10000 real valued features. DOROTHEA consists of 1150 samples (800 for training and 350 for testing) with 100000 binary valued features. We apply ridge regression on both classification tasks by setting the responses to be +1 for positive examples and -1 for negative examples. We run ridge regression algorithms on the training data to compute the feature weights and measure the classification error rate on the testing data. For each dataset, we test 10 different choices of sketch size  $t$  and record the classification error rates and speed up factors of competing algorithms.

**Results.** The experiment results are shown in Figure 2. From the results, we observe that the classification error decreases as the sketch size  $t$  increases. It is also clear that, using the same sketch size  $t$ , SKETCHING and PRO-

JECTION produce more accurate predictions than SAMPLING. On the other hand, SKETCHING and SAMPLING algorithms are considerably faster than the STANDARD algorithm. From the results, we see that our algorithm SKETCHING substantially speeds up the computation, while attains a very small increase in error rate. For ARCENE dataset, when  $t \approx 3000$ , SKETCHING accelerates the computation by 2.1 times while increases the error rate by 4.5%; and, for DOROTHEA dataset, when  $t \approx 20000$ , the speedup of SKETCHING is about 4.1 times and the error rate is almost the same to the STANDARD algorithm. In addition, we continue to observe that the relative-error decreases as  $t$  increases. The SKETCHING algorithm and the PROJECTION algorithm outperform the SAMPLING algorithm in terms of accuracy on both datasets. We remark that, for moderately large  $t$ , the SKETCHING algorithm achieves a relative-error that is smaller than 20% on both datasets.

## 7 CONCLUSIONS

We presented an efficient relative-error approximation algorithm for ridge regression for  $p \gg n$  cases. Our algorithm runs in  $\tilde{O}(\text{nnz}(A) + n^3/\epsilon^2)$  time, which is substantially faster than the existing  $O(n^2p + n^3)$  algorithm for large  $p$  instances. In addition, we analyzed the risk inflation of our algorithm and extended our techniques to design fast relative-error approximation algorithms for multiple response ridge regression and structured ridge regression. We reported experimental results of our algorithm on both synthetic and real datasets, which supported our analysis and demonstrated good practical performance.

## Abstract

We introduce Selective Greedy Equivalence Search (SGES), a restricted version of Greedy Equivalence Search (GES). SGES retains the asymptotic correctness of GES but, unlike GES, has polynomial performance guarantees. In particular, we show that when data are sampled independently from a distribution that is perfect with respect to a DAG  $\mathcal{G}$  defined over the observable variables then, in the limit of large data, SGES will identify the equivalence class of  $\mathcal{G}$  after a number of score evaluations that is (1) polynomial in the number of nodes and (2) exponential in various complexity measures including maximum-number-of-parents, maximum-clique-size, and a new measure called *v-width* that is at least as small as—and potentially much smaller than—the other two. More generally, we show that for any hereditary and equivalence-invariant property  $\Pi$  known to hold in  $\mathcal{G}$ , we retain the large-sample optimality guarantees of GES even if we ignore any GES deletion operator during the backward phase that results in a state for which  $\Pi$  does not hold in the common-descendants subgraph.

## 1 INTRODUCTION

Greedy Equivalence Search (GES) is a score-based search algorithm that searches over equivalence classes of Bayesian-network structures. The algorithm is appealing because (1) for finite data, it explicitly (and greedily) tries to maximize the score of interest, and (2) as the data grows large, it is guaranteed—under suitable distributional assumptions—to return the generative structure. Although empirical results show that the algorithm is efficient in real-world domains, the number of search states that GES needs to evaluate in the worst case can be exponential in the number of domain variables.

In this paper, we show that if we assume the generative distribution is perfect with respect to some DAG  $\mathcal{G}$  defined over the observable variables, and if  $\mathcal{G}$  is known to be constrained by one of various graph-theoretic measures of complexity, then we can disregard all but a polynomial number of the backward search operators considered by GES while retaining the large-sample guarantees of the algorithm; we call this new variant of GES *selective greedy equivalence search* or *SGES*. Our complexity results are a consequence of a new understanding of the backward phase of GES, in which edges (either directed or undirected) are greedily deleted from the current state until a local minimum is reached. We show that for any *hereditary* and *equivalence-invariant* property known to hold in generative model  $\mathcal{G}$ , we can remove from consideration any edge-deletion operator between  $X$  and  $Y$  for which the property does not hold in the resulting induced subgraph over  $X$ ,  $Y$ , and their common descendants. As an example, if we know that each node has at most  $k$  parents, we can remove from consideration any deletion operator that results in a common child with more than  $k$  parents.

By casting limited *v-width* and two other complexity measures—maximum-clique size and maximum-parent-set size—as graph properties, we show how to enumerate directly over a polynomial number of edge-deletion operators at each step, and we show that we need only a polynomial number of calls to the scoring function to complete the algorithm.

The main contributions of this paper are theoretical. Our definition of the new SGES algorithm deliberately leaves unspecified the details of how to implement its forward phase; we prove our results for SGES given *any* implementation of this phase that completes with a polynomial number of calls to the scoring function. A naive implementation is to immediately return a complete (i.e., no independence) graph using *no* calls to the scoring function, but this choice is unlikely to be reasonable in practice, particularly in discrete domains where the sample complexity of this initial model will likely be a problem. Whereas we believe it an important direction, our paper does not explore practical al-

ternatives for the forward phase that have polynomial-time guarantees.

Our paper is organized as follows. In Section 2, we describe related work. In Section 3, we provide notation and background material. In Section 4, we present our new SGES algorithm, we show that it is optimal in the large-sample limit, and we provide complexity bounds when given an equivalence-invariant and hereditary property that holds on the generative structure. In Section 5, we present a simple synthetic experiment that demonstrates the value of restricting the backward operators in SGES. We conclude with a discussion of our results in Section 6.

## 2 RELATED WORK

It is useful to distinguish between approaches to learning the structure of graphical models as *constraint based*, *score based* or *hybrid*. Constraint-based approaches typically use (conditional) independence tests to eliminate potential models, whereas score-based approaches typically use a penalized likelihood or a marginal likelihood to evaluate alternative model structures; hybrid methods combine these two approaches. Because score-based approaches are driven by a global likelihood, they are less susceptible than constraint-based approaches to incorrect categorical decisions about independences.

There are polynomial-time algorithms for learning the best model in which each node has at most one parent. In particular, the Chow-Liu algorithm (Chow and Liu, 1968) used with any equivalence-invariant score will identify the highest-scoring tree-like model in polynomial time; for scores that are not equivalence invariant, we can use the polynomial-time maximum-branching algorithm of Edmonds (1967) instead. Gaspers et al. (2012) show how to learn *k-branchings* in polynomial time; these models are polytrees that differ from a branching by a constant  $k$  number of edge deletions.

Without additional assumptions, most results for learning non-tree-like models are negative. Meek (2001) shows that finding the maximum-likelihood path is NP-hard, despite this being a special case of a tree-like model. Dasgupta (1999) shows that finding the maximum-likelihood polytree (a graph in which each pair of nodes is connected by at most one path) is NP-hard, even with bounded in-degree for every node. For general directed acyclic graphs, Chickering (1996) shows that finding the highest marginal-likelihood structure is NP-hard, even when each node has at most two parents. Chickering et al. (2004) extend this same result to the large-sample case.

Researchers often assume that the “generative” distribution of the training data is *perfect* with respect to some model class in order to reduce the complexity of learning algorithms. Geiger et al. (1990) provide a polynomial-time

constraint-based algorithm for recovering a polytree under the assumption that the generative distribution is perfect with respect to a polytree; an analogous score-based result follows from this paper. The constraint-based PC algorithm of Sprites et al. (1993) can identify the equivalence class of Bayesian networks in polynomial time if the generative structure is a DAG model over the observable variables in which each node has a bounded degree; this paper provides a similar result for a score-based algorithm. Kalish and Buhlmann (2007) show that for Gaussian distributions, the PC algorithm can identify the right structure even when the number of nodes in the domain is larger than the sample size. Chickering (2002) uses the same DAG-perfectness-over-observables assumption to show that the greedy GES algorithm is optimal in the large-sample limit, although the branching factor of GES is worst-case exponential; the main result of this paper shows how to limit this branching factor without losing the large-sample guarantee. Chickering and Meek (2002) show that GES identifies a “minimal” model in the large-sample limit under a less restrictive set of assumptions.

Hybrid methods for learning DAG models use a constraint-based algorithm to prune out a large portion of the search space, and then use a score-based algorithm to select among the remaining (Friedman et al., 1999; Tsamardinos et al., 2006). Ordyniak and Szeider (2013) give positive complexity results for the case when the remaining DAGs are characterized by a structure with constant treewidth.

Many researchers have turned to exhaustive enumeration to identify the highest-scoring model (Gillispie and Perlman, 2001; Koivisto and Sood 2004; Silander and Myllymäki, 2006; Kojima et al, 2010). There are many complexity results for other model classes. Karger and Srebro (2001) show that finding the optimal Markov network is NP-complete for treewidth  $> 1$ . Narasimhan and Bilmes (2004) and Shahaf, Chechetka and Guestrin (2009) show how to learn approximate limited-treewidth models in polynomial time. Abeel, Koller and Ng (2005) show how to learn factor graphs in polynomial time.

## 3 NOTATION AND BACKGROUND

We denote a variable by an upper case letter (e.g.,  $A$ ) and a state or value of that variable by the same letter in lower case (e.g.,  $a$ ). We denote a set of variables by a bold-face capitalized letter or letters (e.g.,  $\mathbf{X}$ ). We use a corresponding bold-face lower-case letter or letters (e.g.,  $\mathbf{x}$ ) to denote an assignment of state or value to each variable in a given set. We use calligraphic letters (e.g.,  $\mathcal{G}, \mathcal{E}$ ) to denote statistical models and graphs.

A *Bayesian-network model* for a set of variables  $U$  is a pair  $(\mathcal{G}, \theta)$ .  $\mathcal{G} = (\mathbf{V}, \mathbf{E})$  is a directed acyclic graph—or *DAG* for short—consisting of nodes in one-to-one correspondence with the variables and directed edges that connect

those nodes.  $\theta$  is a set of parameter values that specify all of the conditional probability distributions. The Bayesian network represents a joint distribution over  $\mathbf{U}$  that factors according to the structure  $\mathcal{G}$ .

The structure  $\mathcal{G}$  of a Bayesian-network model represents the independence constraints that must hold in the distribution. The set of all independence constraints implied by the structure  $\mathcal{G}$  can be characterized by the *Markov conditions*, which are the constraints that each variable is independent of its non-descendants given its parents. All other independence constraints follow from properties of independence. A distribution defined over the variables from  $\mathcal{G}$  is *perfect with respect to  $\mathcal{G}$*  if the set of independences in the distribution is equal to the set of independences implied by the structure  $\mathcal{G}$ .

Two DAGs  $\mathcal{G}$  and  $\mathcal{G}'$  are *equivalent*<sup>1</sup>—denoted  $\mathcal{G} \approx \mathcal{G}'$ —if the independence constraints in the two DAGs are identical. Because equivalence is reflexive, symmetric, and transitive, the relation defines a set of equivalence classes over network structures. We use  $[\mathcal{G}]_{\approx}$  to denote the equivalence class of DAGs to which  $\mathcal{G}$  belongs.

An equivalence class of DAGs  $\mathcal{F}$  is an *independence map (IMAP)* of another equivalence class of DAGs  $\mathcal{E}$  if all independence constraints implied by  $\mathcal{F}$  are also implied by  $\mathcal{E}$ . For two DAGs  $\mathcal{G}$  and  $\mathcal{H}$ , we use  $\mathcal{G} \leq \mathcal{H}$  to denote that  $[\mathcal{H}]_{\approx}$  is an IMAP of  $[\mathcal{G}]_{\approx}$ ; we use  $\mathcal{G} < \mathcal{H}$  when  $\mathcal{G} \leq \mathcal{H}$  and  $[\mathcal{H}]_{\approx} \neq [\mathcal{G}]_{\approx}$ .

Verma and Pearl (1991) show that two DAGs are equivalent if and only if they have the same *skeleton* (i.e., the graph resulting from ignoring the directionality of the edges) and the same *v-structures* (i.e., pairs of edges  $X \rightarrow Y$  and  $Y \leftarrow Z$  where  $X$  and  $Z$  are not adjacent). As a result, we can use a *partially directed acyclic graph*—or *PDAG* for short—to represent an equivalence class of DAGs: for a PDAG  $\mathcal{P}$ , the equivalence class of DAGs is the set that has the same skeleton and the same v-structures as  $\mathcal{P}$ <sup>2</sup>.

We extend our notation for DAG equivalence and the DAG IMAP relation to include the more general PDAG structure. In particular, for a PDAG  $\mathcal{P}$ , we use  $[\mathcal{P}]_{\approx}$  to denote the corresponding equivalence class of DAGs. For any pair of PDAGs  $\mathcal{P}$  and  $\mathcal{Q}$ —where one or both may be a DAG—we use  $\mathcal{P} \approx \mathcal{Q}$  to denote  $[\mathcal{Q}]_{\approx} = [\mathcal{P}]_{\approx}$  and we use  $\mathcal{P} \leq \mathcal{Q}$  to denote  $[\mathcal{Q}]_{\approx}$  is an IMAP of  $[\mathcal{P}]_{\approx}$ . To avoid confusion, for the remainder of the paper we will reserve the symbols  $\mathcal{G}$  and  $\mathcal{H}$  for DAGs.

For any PDAG  $\mathcal{P}$  and subset of nodes  $\mathbf{V}$ , we use  $\mathcal{P}[\mathbf{V}]$  to denote the subgraph of  $\mathcal{P}$  induced by  $\mathbf{V}$ ; that is,  $\mathcal{P}[\mathbf{V}]$  has

<sup>1</sup>We make the standard conditional-distribution assumptions of multinomials for discrete variables and Gaussians for continuous variables so that if two DAGs have the same independence constraints, then they can also model the same set of distributions.

<sup>2</sup>The definitions for the skeleton and set of v-structures for a PDAG are the obvious extensions to these definitions for DAGs.

as nodes the set  $\mathbf{V}$  and has as edges all those from  $\mathcal{P}$  that connect nodes in  $\mathbf{V}$ . We use  $\text{NA}_{X,Y}$  to denote, within a PDAG, the set of nodes that are *neighbors* of  $X$  (i.e., connected with an undirected edge) and also adjacent to  $Y$  (i.e., without regard to whether the connecting edge is directed or undirected).

An edge in  $\mathcal{G}$  is *compelled* if it exists in every DAG that is equivalent to  $\mathcal{G}$ . If an edge in  $\mathcal{G}$  is not compelled, we say that it is *reversible*. A *completed PDAG (CPDAG)*  $\mathcal{C}$  is a PDAG with two additional properties: (1) for every directed edge in  $\mathcal{C}$ , the corresponding edge in  $\mathcal{G}$  is compelled and (2) for every undirected edge in  $\mathcal{C}$  the corresponding edge in  $\mathcal{G}$  is reversible. Unlike non-completed PDAGs, the CPDAG representation of an equivalence class is unique. We use  $\text{Pa}_Y^{\mathcal{P}}$  to denote the *parents* of node  $Y$  in  $\mathcal{P}$ . An edge  $X \rightarrow Y$  is *covered* in a DAG if  $X$  and  $Y$  have the same parents, with the exception that  $X$  is not a parent of itself.

Figure 1: Pseudo-code for the GES algorithm.

The GES algorithm, shown in Figure 1, performs a two-phase greedy search through the space of DAG equivalence classes. GES represents each search state with a CPDAG, and performs transformation operators to this representation to traverse between states. Each operator corresponds to a DAG edge modification, and is scored using a DAG scoring function that we assume has three properties. First, we assume the scoring function is *score equivalent*, which means that it assigns the same score to equivalent DAGs. Second, we assume the scoring function is *locally consistent*, which means that, given enough data, (1) if the current state *is not* an IMAP of  $\mathcal{G}$ , the score prefers edge additions that remove incorrect independences, and (2) if the current state *is* an IMAP of  $\mathcal{G}$ , the score prefers edge deletions that remove incorrect dependences. Finally, we assume the scoring function is *decomposable*, which means we can express it as:

$$\text{Score}(\mathcal{G}, \mathbf{D}) = \sum_{i=1}^n \text{Score}(X_i, \text{Pa}_i^{\mathcal{G}}) \quad (1)$$

Note that the data  $\mathbf{D}$  is implicit in the right-hand side Equation 1. Most scores in the literature have these properties.

For the remainder of this paper, we assume they hold for our scoring function.

All of the CPDAG operators from GES are scored using differences in the DAG scoring function, and in the limit of large data, these scores are positive precisely for those operators that remove incorrect independences and incorrect dependences.

The first phase of the GES—called *forward equivalence search* or *FES*—starts with an empty (i.e., no-edge) CPDAG and greedily applies *GES insert* operators until no operator has a positive score; these operators correspond precisely to the union of all single-edge additions to all DAG members of the current (equivalence-class) state. After FES reaches a local maximum, GES switches to the second phase—called *backward equivalence search* or *BES*—and greedily applies *GES delete* operators until no operator has a positive score; these operators correspond precisely to the union of all single-edge deletions from all DAG members of the current state.

**Theorem 1. (Chickering, 2002)** *Let  $\mathcal{C}$  be the CPDAG that results from applying the GES algorithm to  $m$  records sampled from a distribution that is perfect with respect to DAG  $\mathcal{G}$ . Then in the limit of large  $m$ ,  $\mathcal{C} \approx \mathcal{G}$ .*

The role of FES in the large-sample limit is only to identify a state  $\mathcal{C}$  for which  $\mathcal{G} \leq \mathcal{C}$ ; Theorem 1 holds for GES under any implementation of FES that results in an IMAP of  $\mathcal{G}$ . The implementation details can be important in practice because what constitutes a “large” amount of data depends on the number of parameters in the model. In theory, however, we could simply replace FES with a (constant-time) algorithm that sets  $\mathcal{C}$  to be the no-independence equivalence class.

The focus of our analysis in the next section is on a modified version of BES, and the details of the delete operator used in this phase are important. In Figure 2, we show the preconditions, scoring function, and transformation algorithm for a delete operator. We note that we do not need to make any CPDAG transformations when *scoring* the operators; it is only once we have identified the highest-scoring (non-negative) delete that we need to make the transformation shown in the figure. After applying the edge modifications described in the **foreach** loop, the resulting PDAG  $\mathcal{P}$  is not necessarily completed and hence we may have to convert  $\mathcal{P}$  into the corresponding CPDAG representation. As shown by Chickering (2002), this conversion can be accomplished easily by using the structure of  $\mathcal{P}$  to extract a DAG that we then convert into a CPDAG by undirecting all reversible edges. The complexity of this procedure for a  $\mathcal{P}$  with  $n$  nodes and  $e$  edges is  $O(n \cdot e)$ , and requires no calls to the scoring function.

## 4 SELECTIVE GREEDY EQUIVALENCE SEARCH

In this section, we define a variant of the GES algorithm called *selective GES*—or *SGES* for short—that uses a subset of the BES operators. The subset is chosen based on a given property  $\Pi$  that is known to hold for the generative structure  $\mathcal{G}$ . Just like GES, SGES—shown in Figure 3—has a forward phase and a backward phase.

For the forward phase of SGES, it suffices for our theoretical analysis that we use a method that returns an IMAP of  $\mathcal{G}$  (in the large-sample limit) using only a polynomial number of insert-operator score calls. For this reason, we call this phase *poly-FES*. A simple implementation of poly-FES is to return the no-independence CPDAG (with no score calls), but other implementations are likely more useful in practice.

The backward phase of SGES—which we call *selective backward equivalence search (SBES)*—uses only a subset of the BES delete operators. This subset must necessarily include all  $\Pi$ -consistent delete operators—defined below—in order to maintain the large-sample consistency of GES, but the subset can (and will) include additional operators for the sake of efficient enumeration.

The DAG properties used by SGES must be *equivalence invariant*, meaning that for any pair of equivalent DAGs, either the property holds for both of them or it holds for neither of them. Thus, for any equivalence-invariant DAG property  $\Pi$ , it makes sense to say that  $\Pi$  either holds or does not hold for a PDAG. As shown by Chickering (1995), a DAG property is equivalence invariant if and only if it is invariant to covered-edge reversals; it follows that the prop-

erty that each node has at most  $k$  parents is equivalence invariant, whereas the property that the length of the longest directed path is at least  $k$  is not. Furthermore, the properties for SGES must also be *hereditary*, which means that if  $\Pi$  holds for a PDAG  $\mathcal{P}$  it must also hold for all induced subgraphs of  $\mathcal{P}$ . For example, the max-parent property is hereditary, whereas the property that each node has *at least*  $k$  parents is not. We use *EIH property* to refer to a property that is equivalence invariant and hereditary.

**Definition 1.  $\Pi$ -Consistent GES Delete**

A GES delete operator  $Delete(X, Y, \mathbf{H})$  is  $\Pi$  consistent for CPDAG  $\mathcal{C}$  if, for the set of common descendants  $\mathbf{W}$  of  $X$  and  $Y$  in the resulting CPDAG  $\mathcal{C}'$ , the property holds for the induced subgraph  $\mathcal{C}'[X \cup Y \cup \mathbf{W}]$ .

In other words, after the delete, the property holds for the subgraph defined by  $X$ ,  $Y$ , and their common descendants.

**4.1 LARGE-SAMPLE CORRECTNESS**

The following theorem establishes a graph-theoretic justification for considering only the  $\Pi$ -consistent deletions at each step of SBES.

**Theorem 2.** *If  $\mathcal{G} < \mathcal{C}$  for CPDAG  $\mathcal{C}$  and DAG  $\mathcal{G}$ , then for any EIH property  $\Pi$  that holds on  $\mathcal{G}$ , there exists a  $\Pi$ -consistent  $Delete(X, Y, \mathbf{H})$  that when applied to  $\mathcal{C}$  results in the CPDAG  $\mathcal{C}'$  for which  $\mathcal{G} \leq \mathcal{C}'$ .*

The proof of Theorem 2 can be found in Chickering and Meek (2015), an expanded version of this paper. The result is a consequence of an explicit characterization of, for a

given pair of DAGs  $\mathcal{G}$  and  $\mathcal{H}$  such that  $\mathcal{G} < \mathcal{H}$ , an edge in  $\mathcal{H}$  that we can either reverse or delete in  $\mathcal{H}$  such that for the resulting DAG  $\mathcal{H}'$ , we have  $\mathcal{G} \leq \mathcal{H}'^3$ .

**Theorem 3.** *Let  $\mathcal{C}$  be the CPDAG that results from applying the SGES algorithm to (1)  $m$  records sampled from a distribution that is perfect with respect to DAG  $\mathcal{G}$  and (2) EIH property  $\Pi$  that holds on  $\mathcal{G}$ . Then in the limit of large  $m$ ,  $\mathcal{C} \approx \mathcal{G}$ .*

**Proof:** Because the scoring function is locally consistent, we know poly-FES must return an IMAP of  $\mathcal{G}$ . Because SBES includes all the  $\Pi$ -consistent delete operators, Theorem 2 guarantees that, unless  $\mathcal{C} \approx \mathcal{G}$ , there will be a positive-scoring operator.  $\square$

**4.2 COMPLEXITY MEASURES**

In this section, we discuss a number of distributional assumptions that we can use with Theorem 3 to limit the number of operators that SGES needs to score. As discussed in Section 2, when we assume the generative distribution is perfect with respect to a DAG  $\mathcal{G}$ , then graph-theoretic assumptions about  $\mathcal{G}$  can lead to more efficient training algorithms. Common assumptions used include (1) a maximum parent-set size for any node, (2) a maximum-clique<sup>4</sup> size among any nodes and (3) a maximum treewidth. Treewidth is important because the complexity of exact inference is exponential in this measure.

We can associate a property with each of these assumptions that holds precisely when the DAG  $\mathcal{G}$  satisfies that assumption. Consider the constraint that the maximum number of parents for any node in  $\mathcal{G}$  is some constant  $k$ . Then, using “PS” to denote parent size, we can define the property  $\Pi_{PS}^k$  to be true precisely for those DAGs in which each node has at most  $k$  parents. Similarly we can define  $\Pi_{CL}^k$  and  $\Pi_{TW}^k$  to correspond to maximum-clique size and maximum treewidth, respectively.

For two properties  $\Pi$  and  $\Pi'$ , we write  $\Pi \subseteq \Pi'$  if for every DAG  $\mathcal{G}$  for which  $\Pi$  holds,  $\Pi'$  also holds. In other words,  $\Pi$  is a *more constraining* property than is  $\Pi'$ . Because the lowest node in any clique has all other nodes in the clique as parents, it is easy to see that  $\Pi_{PS}^k \subseteq \Pi_{CL}^{k-1}$ . Because the treewidth for DAG  $\mathcal{G}$  is defined to be the size of the largest clique minus one in a graph whose cliques are at least as large as those in  $\mathcal{G}$ , we also have  $\Pi_{TW}^k \subseteq \Pi_{CL}^{k-1}$ . Which property to use will typically be a trade-off between how reasonable the assumption is (i.e, less constraining properties are more reasonable) and the efficiency of the resulting algorithm (i.e., more constraining properties lead to faster algorithms).

<sup>3</sup>Chickering (2002) characterizes the *reverse* transformation of reversals/additions in  $\mathcal{G}$ , which provides an *implicit* characterization of reversals/deletions in  $\mathcal{H}$ .

<sup>4</sup>We use *clique* in a DAG to mean a set of nodes in which all pairs are adjacent.

We now consider a new complexity measure called  $v$ -width, whose corresponding property is less constraining than the previous three. For a DAG  $\mathcal{G}$ , the  $v$ -width is defined to be the maximum of, over all pairs of non-adjacent nodes  $X$  and  $Y$ , the size of the largest clique among common children of  $X$  and  $Y$ . In other words,  $v$ -width is similar to the maximum-clique-size bound, except that the bound only applies to cliques of nodes that are shared children of some pair of non-adjacent nodes. With this understanding it is easy to see that, for the property  $\Pi_{VW}^k$  corresponding to a bound on the  $v$ -width, we have  $\Pi_{CL}^k \subseteq \Pi_{VW}^k$ .

To illustrate the difference between  $v$ -width and the other complexity measures, consider the two DAGs in Figure 5. The DAG in Figure 5(a) has a clique of size  $K$ , and consequently a maximum-clique size of  $K$  and a maximum parent-set size of  $K - 1$ . Thus, if  $K$  is  $O(n)$  for a large graph of  $n$  nodes, any algorithm that is exponential in these measures will not be efficient. The  $v$ -width, however, is zero for this DAG. The DAG in Figure 5(b), on the other hand, has a  $v$ -width of  $K$ .

Figure 5: Two DAGs (a) and (b) having identical maximum clique sizes, similar maximum number of parents, and divergent  $v$ -widths.

In order to use a property with SGES, we need to establish that it is EIH. For  $\Pi_{PS}^k$ ,  $\Pi_{CL}^k$  and  $\Pi_{VW}^k$ , equivalence-invariance follows from the fact that all three properties are covered-edge invariant, and hereditary follows because the corresponding measures cannot increase when we remove nodes and edges from a DAG. Although we can establish EIH for the treewidth property  $\Pi_{TW}^k$  with more work, we omit further consideration of treewidth for the sake of space.

### 4.3 GENERATING DELETIONS

In this section, we show how to generate a set of deletion operators for SBES such that all  $\Pi$ -consistent deletion operators are included, for any  $\Pi \in \{\Pi_{PS}^k, \Pi_{CL}^k, \Pi_{VW}^k\}$ . Furthermore, the total number of deletion operators we generate is polynomial in the number of nodes in the domain and exponential in  $k$ .

Our approach is to restrict the  $Delete(X, Y, \mathbf{H})$  operators based on the  $\mathbf{H}$  sets and the resulting CPDAG  $\mathcal{C}'$ . In par-

ticular, we *rule out* candidate  $\mathbf{H}$  sets for which  $\Pi$  does not hold on the induced subgraph  $\mathcal{C}'[\mathbf{H} \cup X \cup Y]$ ; because all nodes in  $\mathbf{H}$  will be common children of  $X$  and  $Y$  in  $\mathcal{C}'$ —and thus a subset of the common descendants of  $X$  and  $Y$ —we know from Definition 1 (and the fact that  $\Pi$  is hereditary) that none of the dropped operators can be  $\Pi$ -consistent.

Before presenting our restricted-enumeration algorithm, we now discuss how to enumerate delete operators without restrictions. As shown by Andersson et al. (1997), a CPDAG is a chain graph whose undirected components are chordal. This means that the induced sub-graph defined over  $\mathbf{NA}_{Y,X}$ —which is a subset of the neighbors of  $Y$ —is an undirected chordal graph. A useful property of chordal graphs is that we can identify, in polynomial time, a set of *maximal cliques* over these nodes<sup>5</sup>; let  $\mathbf{C}_1, \dots, \mathbf{C}_m$  denote the nodes contained within these  $m$  maximal cliques, and let  $\bar{\mathbf{H}} = \mathbf{NA}_{Y,X} \setminus \mathbf{H}$  be the complement of the shared neighbors with respect to the candidate  $\mathbf{H}$ . Recall from Figure 2 that the preconditions for any  $Delete(X, Y, \mathbf{H})$  include the requirement that  $\bar{\mathbf{H}}$  is a clique. This means that for any valid  $\mathbf{H}$ , there must be some maximal clique  $\mathbf{C}_i$  that contains the entirety of  $\bar{\mathbf{H}}$ ; thus, we can generate all operators (without regard to any property) by stepping through each maximal clique  $\mathbf{C}_i$  in turn, initializing  $\mathbf{H}$  to be all nodes *not* in  $\mathbf{C}_i$ , and then generating a new operator corresponding to expanding  $\mathbf{H}$  by all subsets of nodes in  $\mathbf{C}_i$ . Note that if  $\mathbf{NA}_{Y,X}$  is itself a clique, we are enumerating over all  $2^{|\mathbf{NA}_{Y,X}|}$  operators.

As we show below, all three of the properties of interest impose a bound on the maximum clique size among nodes in  $\bar{\mathbf{H}}$ . If we are given such a bound  $s$ , we know that any “expansion” subset for a clique that has size greater than  $s$  will result in an operator that is not valid. Thus, we can implement the above operator-enumeration approach more efficiently by only generating subsets within each clique that have size at most  $s$ . This allows us to process each clique  $\mathbf{C}_i$  with only  $O(|\mathbf{C}_i + 1|^s)$  calls to the scoring function. In addition, we need not enumerate over *any* of the subsets of  $\mathbf{C}_i$  if, after removing this clique from the graph, there remains a clique of size greater than  $s$ ; we define the function  $FilterCliques(\{\mathbf{C}_1, \dots, \mathbf{C}_m\}, s)$  to be the subset of cliques that remain after imposing this constraint. With this function, we can define SELECTIVE-GENERATE-OPS as shown in Figure 6 to leverage the max-clique-size constraint when generating operators; this algorithm will in turn be used to generate all of the CPDAG operators during SBES.

**Example:** In Figure 7, we show an example CPDAG  $\mathcal{C}$  for which to run  $SELECTIVE-GENERATE-OPS(\mathcal{C}, X, Y, s)$  for various values of  $s$ . In the example, there is a single clique

<sup>5</sup>Blair and Peyton (1993) provide a good survey on chordal graphs and detail how to identify the maximal cliques while running maximum-cardinality search.

---

Algorithm SELECTIVE-GENERATE-OPS( $\mathcal{C}, X, Y, s$ )

---

**Input** : CPDAG  $\mathcal{C}$  with adjacent  $X, Y$  and limit  $s$

**Output**:  $\text{Ops} = \{\mathbf{H}_1, \dots, \mathbf{H}_m\}$

```

 $\text{Ops} \leftarrow \emptyset$ 
Generate maximal cliques  $\mathbf{C}_1, \dots, \mathbf{C}_m$  from  $\text{NA}_{Y,X}$ 
 $\mathbf{S} \leftarrow \text{FilterCliques}(\{\mathbf{C}_1, \dots, \mathbf{C}_m\}, s)$ 
foreach  $\mathbf{C}_i \in \mathbf{S}$  do
     $\mathbf{H}_0 \leftarrow \text{NA}_{Y,X} \setminus \mathbf{C}_i$ 
    foreach  $\mathbf{C} \subseteq \mathbf{C}_i$  with  $|\mathbf{C}| \leq s$  do
        Add  $\mathbf{H}_0 \cup \mathbf{C}$  to  $\text{Ops}$ 
    end
end
return  $\text{Ops}$ 

```

---

Figure 6: Algorithm to generate clique-size limited delete operators.

$\mathbf{C} = \{A, B\}$  in the set  $\text{NA}_{Y,X}$ , and thus at the top of the outer **foreach** loop, the set  $\mathbf{H}_0$  is initialized to the empty set. If  $s = 0$ , the only subset of  $\mathbf{C}$  with size zero is the empty set, and so that is added to  $\text{Ops}$  and the algorithm returns. If  $s = 1$  we add, in addition to the empty set, all singleton subsets of  $\mathbf{C}$ . For  $s \geq 2$ , we add all subsets of  $\mathbf{C}$ .  $\square$

Now we discuss how each of the three properties impose a constraint  $s$  on the maximum clique among nodes in  $\mathbf{H}$ , and consequently the selective-generation algorithm in Figure 6 can be used with each one, given an appropriate bound  $s$ . For both  $\Pi_{VW}^k$  and  $\Pi_{CL}^k$ , the  $k$  given imposes an explicit bound on  $s$  (i.e.,  $s = k$  for both). Because any clique in  $\mathbf{H}$  of size  $r$  will result in a DAG member of the resulting equivalence class having a node in that clique with at least  $r + 1$  parents (i.e.,  $r - 1$  from the other nodes in the clique, plus both  $X$  and  $Y$ ), we have for  $\Pi_{PS}^k$ ,  $s = k - 1$ .

We summarize the discussion above in the following proposition.

**Proposition 1.** *Algorithm SELECTIVE-GENERATE-OPS applied to all edges using clique-size bound  $s$  generates all  $\Pi$ -consistent delete operators for  $\Pi \in \{\Pi_{PS}^{s+1}, \Pi_{CL}^s, \Pi_{VW}^s\}$ .*

We now argue that running SBES on a domain of  $n$  variables when using Algorithm SELECTIVE-GENERATE-OPS with a bound  $s$  requires only a polynomial number in  $n$  of calls to the scoring function. Each clique in the inner loop of the algorithm can contain at most  $n$  nodes, and therefore we generate and score at most  $(n + 1)^s$  operators, requiring at most  $2(n + 1)^s$  calls to the scoring function. Because the cliques are maximal, there can be at most  $n$  of them considered in the outer loop. Because there are never more than  $n^2$  edges in a CPDAG, and we will delete at most all of them, we conclude that even if we decided to rescore ev-

ery operator after every edge deletion, we will only make a polynomial number of calls to the scoring function.

From the above discussion and the fact that SBES completes using at most a polynomial number of calls to the scoring function, we get the following result for the full SGEN algorithm.

**Proposition 2.** *The SGEN algorithm, when run over a domain of  $n$  variables and given  $\Pi \in \{\Pi_{PS}^{s+1}, \Pi_{CL}^s, \Pi_{VW}^s\}$ , runs to completion using a number of calls to the DAG scoring function that is polynomial in  $n$  and exponential in  $s$ .*

Figure 7: An example CPDAG  $\mathcal{C}$  and the resulting operators generated by SELECTIVE-GENERATE-OPS( $\mathcal{C}, X, Y, s$ ) for various values of  $s$ .

## 5 EXPERIMENTS

In this section, we present a simple synthetic experiment comparing SBES and BES that demonstrates the value of pruning operators. In our experiment we used an *oracle* scoring function. In particular, given a generative model  $\mathcal{G}$ , our scoring function computes the minimum-description-length score assuming a data size of five billion records, but without actually sampling any data: instead, we use exact inference in  $\mathcal{G}$  (i.e., instead of counting from data) to compute the conditional probabilities needed to compute the expected log loss. This allows us to get near-asymptotic behavior without the need to sample data. To evaluate the cost of running each algorithm, we counted the number of times the scoring function was called on a unique node and parent-set combination; we cached these scores away so that if they were needed multiple times during a run of the algorithm, they were only computed (and counted) once.

In Figure 8, we show the average number of scoring-function calls required to complete BES and SBES when starting from a complete graph over a domain of  $n$  binary variables, for varying values of  $n$ . Each average is taken over ten trials, corresponding to ten random generative models. We generated the structure of each generative model as follows. First, we ordered all node pairs by randomly permuting the nodes and taking each node in turn with each of its predecessors in turn. For each node pair, we chose to attempt an edge insertion with probability one half. For each attempt, we added an edge if doing so (1)

did not create a cycle and (2) did not result in a node having more than two parents; if an edge could be added in either direction, we chose the direction at random. We sampled the conditional distributions for each node and each parent configuration from a uniform Dirichlet distribution with equivalent-sample size of one. We ran SBES with  $\Pi_{PS}^2$ .

Figure 8: Number of score evaluations needed to run BES and SBES, starting from the complete graph, for a range of domain sizes.

Our results show clearly the exponential dependence of BES on the number of nodes in the clique, and the increasing savings we get with SBES by leveraging the fact that  $\Pi_{PS}^2$  holds in the generative structure.

Note that to realize large savings in practice, when GES runs FES instead of starting from a dense graph, a (relatively sparse) generative distribution must lead FES to an equivalence class containing a (relatively dense) undirected clique that is subsequently “thinned” during BES. We can synthesize challenging grid distributions to force FES into such states, but it is not clear how realistic such distributions are in practice. When we re-run the clique experiment above, but where we instead start both BES and SBES from the model that results from running FES (i.e., with no polynomial-time guarantee), the savings from SBES are small due to the fact that the subsequent equivalence classes do not contain large cliques.

## 6 CONCLUSION

We introduced a restricted version of the GES algorithm, SGES, that leverages graph-theoretic complexity properties to prune the backward-phase operators. We showed that for a particular class of properties—which includes maximum-clique size, maximum number of parents, and  $v$ -width—we can guarantee that the number of score evaluations is polynomial in the number of nodes in the domain.

The fact that we can use our approach to selectively choose operators for any hereditary and equivalence invariant graph-theoretic property provides the opportunity to explore alternative complexity measures. Another candidate complexity measure is the maximum number of  $v$ -structures. Although the corresponding property does not limit the maximum size of a *clique* in  $\mathbf{H}$ , it limits directly the size  $|\mathbf{H}|$  for every operator and thus it is easy to enumerate these operators efficiently. Another complexity measure of interest is *treewidth*, due to the fact that exact inference in a Bayesian-network model is takes time exponential in this measure.

The results we have presented are for the general Bayesian-network learning problem. It is interesting to consider the implications of our results for the problem of learning particular subsets of Bayesian networks. One natural class that we discussed in Section 2 is that of polytrees. If we assume that the generative distribution is perfect with respect to a polytree then we know the  $v$ -width of the generative graph is one. This implies, in the limit of large data, that we can recover the structure of the generative graph with a polynomial number of score evaluations. This provides a score-based recovery algorithm analogous to the constraint-based approach of Geiger et al. (1990).

We presented a simple complexity analysis for the purpose of demonstrating that SGES uses a only polynomial number of calls to the scoring function. We leave as future work a more careful analysis that establishes useful constants in this polynomial. In particular, we can derive tighter bounds on the total number of node-and-parent-configurations that are needed to score all the operators for each CPDAG, and by caching these configuration scores we can further take advantage of the fact that most operators remain valid (i.e., the preconditions still hold) and have the same score after each transformation.

Finally, we plan to investigate practical implementations of poly-FES that have the polynomial-time guarantees needed for SGES.

## Abstract

Spectral methods are a powerful tool for inferring the parameters of certain classes of probability distributions by means of standard eigenvalue-eigenvector decompositions. Spectral algorithms can be orders of magnitude faster than log-likelihood based and related iterative methods, and, thanks to the uniqueness of the spectral decomposition, they enjoy global optimality guarantees. In practice, however, the applicability of spectral methods is limited due to their sensitivity to model misspecification, which can cause instability issues in the case of non-exact models. We present a new spectral approach that is based on the Schur triangularization of an observable matrix, and we carry out the corresponding theoretical analysis. Our main result is a bound on the estimation error that is shown to depend linearly on the condition number of the ground-truth conditional probability matrix and inversely on the eigengap of an observable matrix. Numerical experiments show that the proposed method is more stable, and performs better in general, than the classical spectral approach using direct matrix diagonalization.

## 1 INTRODUCTION

The problem of learning mixtures of probability distributions from sampled data is central in the statistical literature (Titterton, 1985; Lindsay, 1995). In pioneering work, Chang (1996) showed that it is possible to learn a mixture of product distributions via the spectral decomposition of ‘observable’ matrices, that is, matrices that can be estimated directly from the data using suitable combinations of the empirical joint probability distributions (Chang, 1996). Extensions and improvements of this idea have been developed more recently in a series of works, where the spectral technique is applied to a larger class of probability distribu-

tions, including Gaussian mixtures, Hidden Markov models, stochastic languages, and others (Mossel and Roch, 2006; Hsu et al., 2012; Anandkumar et al., 2012a,c; Balle et al., 2014; Kuleshov et al., 2015). Some of the most widely studied algorithms include Chang’s spectral technique (Chang, 1996; Mossel and Roch, 2006), a tensor decomposition approach (Anandkumar et al., 2012a), and an indirect learning method for inferring the parameters of Hidden Markov Models (Hsu et al., 2012).

Spectral algorithms are typically much faster than iterative solvers such as the EM algorithm (Dempster et al., 1977), and thanks to the uniqueness of the spectral decomposition, they enjoy strong optimality guarantees. However, spectral algorithms are more sensitive to model misspecification than algorithms that maximize log-likelihood. Studies in the field of linear system subspace identification have shown that the solutions obtained via matrix decomposition methods can be suboptimal (Favoreel et al., 2000; Buesing et al., 2012). On the other hand, good results have been obtained by using the output of a spectral algorithm to initialize the EM algorithm (Zhang et al., 2014).

The practical implementation of the spectral idea is a non-trivial task because the stability of spectral decomposition strongly depends on the spacing between the eigenvalues of the empirical matrices (Anandkumar et al., 2012a; Hsu and Kakade, 2012). Mossel and Roch (2006) obtain certain eigenvalue separation guarantees for Chang’s spectral technique via the contraction of higher (order three) moments through Gaussian random vectors. Anandkumar et al. (2012a) describe a tensor decomposition method that generalizes deflation methods for matrix diagonalization to the case of symmetric tensors of order three. Another algorithmic variant involves replacing the random contracting vector of Chang’s spectral technique with an ‘anchor observation’, which guarantees the presence of at least one well separated eigenvalue (Arora et al., 2012; Song and Chen, 2014) (See also Kuleshov et al. (2015) for a similar idea). Finally, Zou et al. (2013) have presented a technique for learning mixtures of product distributions in the presence of a background model.

In this article we propose an alternative and more stable approach to Chang’s method that is based on Schur decomposition (Konstantinov et al., 1994). We show that an approximate triangularization of all observables matrices appearing in Chang’s spectral method can be obtained by means of the orthogonal matrices appearing in the Schur decomposition of their linear combination, an idea that has been suggested earlier (Corless et al., 1997; Anandkumar et al., 2012a). Our main result is a theoretical bound on the estimation error that is based on a perturbation analysis of Schur decomposition (Konstantinov et al., 1994). In analogy to related results in the literature, the bound is shown to depend directly on the model misspecification error and inversely on an eigenvalue separation gap. However, the major advantage of the Schur approach is that the bound depends very mildly on the condition number of the ground-truth conditional probability matrix (see discussion after Theorem 1). We compare numerically the proposed Schur decomposition approach with the standard spectral technique (Chang, 1996; Mossel and Roch, 2006), and we show that the proposed method is more stable and does a better job in recovering the parameters of misspecified mixtures of product distributions.

## 2 SPECTRAL LEARNING VIA SCHUR DECOMPOSITION

Here we discuss the standard spectral technique (Chang, 1996; Mossel and Roch, 2006), and the proposed Schur decomposition, in the context of learning mixtures of product distributions. The complete algorithm is shown in Algorithm 1. Its main difference to previous algorithms is step 13 (Schur decomposition).

**The spectral approach in a nutshell.** Consider  $\ell$  distinct variables taking values in a discrete set with finite number of elements  $\{1, \dots, d\}$ , and a sample  $S$  consisting of a number of independent joint observations. The empirical distribution corresponding to these observations is computed by counting the frequencies of all possible joint events in the sample (step 3), and it is modeled (approximated) by a mixture of product distributions with a given number  $p$  of mixture components. For every  $p < d$ , spectral methods allow one to recover the parameters of this approximation by means of the simultaneous diagonalisation of a set of ‘observable’ nearly diagonalizable matrices  $\{\hat{M}_1, \dots, \hat{M}_p\}$ , computed from the sample  $S$  (step 10).

If the sample is drawn exactly from a mixture of  $p$  components, and in the limit of an infinite amount of data, the mixture parameters, i.e., the conditional probability distributions and the mixing weights of the mixture, are contained exactly in the eigenvalues of the matrices  $\hat{M}_i$  (Chang, 1996). If the sample is not drawn exactly from a mixture of  $p$  product distributions, and in the typical finite

---

sample setting, the model is only an approximation to the empirical distribution, and as a result, the matrices  $\hat{M}_i$  are no longer simultaneously diagonalizable and an approximate diagonalisation technique is required. The standard approach consists of choosing one particular observable matrix in the set, or a linear combination of all matrices, and use its eigenvectors to diagonalize each  $\hat{M}_i$  (Mossel and Roch, 2006).

Here we propose a new approach that is based on the Schur decomposition of a linear combination of the observable matrices. In particular, we first mix the matrices  $\hat{M}_i$  to compute a candidate matrix  $\hat{M}$  (step 12), and then we apply Schur decomposition to  $\hat{M}$  (step 13). The eigenvalues of each  $\hat{M}_i$ , and thereby the model parameters, are then extracted using the orthogonal matrix  $\hat{U}$  of the Schur decomposition (steps 15-16). Effectively we exploit the fact that the real eigenvalues of a matrix  $A$  always appear on the diagonal of its Schur triangularization  $T = U^T A U$ , even though the entries of the strictly upper diagonal part of  $T$  may not be unique. Using the perturbation analysis of the Schur system of a matrix by Konstantinov et al. (1994), we obtain a theoretical bound on the error of such eigenvalue estimation as a function of the model misspecification error, the condition number of the ground-truth matrix  $X$ , and the separation of the eigenvalues of  $\hat{M}$  (Theorem 1).

**Detailed description and the Schur approach.** Consider for simplicity a sample  $S$  of independent observations  $s = [x, y, z]$  of three distinct variables taking values in the discrete set  $\{1, \dots, d\}$ . The empirical distribution associated to the sample  $S$  is defined as

$$\hat{P}_{i,j,k} = \frac{1}{|S|} \sum_{s \in S} \delta_{x,i} \delta_{y,j} \delta_{z,k} \quad (1)$$

where  $|S|$  is the number of elements in  $S$  and  $\delta_{ab} = 1$  if  $a = b$  and zero otherwise. The empirical distribution  $\hat{P}$  is a nonnegative order-3 tensor whose entries sum to one. Its nonnegative rank  $\text{rank}_+(\hat{P})$  is the minimum number of rank-1 tensors, i.e., mixture components, required to express  $\hat{P}$  as a mixture of product distributions. Such a decomposition of  $\hat{P}$  (exact or approximate) is always possible (Lim and Comon, 2009). Hence, for any choice of  $p \leq \text{rank}_+(\hat{P})$ , we can hypothesize that  $\hat{P}$  is generated by a model

$$\hat{P} = P + \epsilon \Delta P, \quad \epsilon \geq 0 \quad (2)$$

where  $P \in [0, 1]^{d_x \times d_y \times d_z}$  is a nonnegative rank- $p$  approximation of  $\hat{P}$ ,  $\epsilon$  is a model misspecification parameter, and  $\Delta P \in [0, 1]^{d_x \times d_y \times d_z}$  is a nonnegative tensor whose entries sum to one. The rank- $p$  component  $P$  is interpreted as the mixture of product distributions that approximates the empirical distribution, and it can be written

$$P_{ijk} = \sum_{h=1}^p w_h X_{ih} Y_{jh} Z_{kh}, \quad (3)$$

where  $w_h \in [0, 1]$  for all  $h = 1, \dots, p$ , and we have defined the conditional probability matrices

$$X \in [0, 1]^{d \times p}, \quad \mathbf{1}_d^T X = \mathbf{1}_p^T, \quad (4)$$

(and similarly for  $Y, Z$ ), where  $\mathbf{1}_n$  is a vector of  $n$  ones. The columns of the matrices  $X, Y, Z$  encode the conditional probabilities associated with the  $p$  mixture components, and the mixing weights satisfy  $\sum_h w_h + \epsilon = 1$ .

The conditional probability matrices  $X, Y, Z$  and the mixing weight  $w$  of the rank- $p$  mixture can be estimated from the approximate eigenvalues of a set of observable matrices  $\hat{M}_i$ , for  $i = 1, \dots, p$ , that are computed as follows. Let for simplicity  $p = d$  and consider the matrices  $[\hat{P}_i^Y]_{jk} = \hat{P}_{jik}$  (step 6) and  $[\hat{P}_{xz}] = \sum_i [\hat{P}_i^Y]$  (step 8). Assuming that  $\hat{P}_{xz}$  is invertible, we define (step 10)

$$\hat{M}_i = \hat{P}_i^Y \hat{P}_{xz}^{-1} \quad (5)$$

for  $i = 1, \dots, d$ . Under the model assumption  $\hat{P} = P + \epsilon \Delta P$ , it is easy to show that

$$\hat{M}_i = M_i + \Delta M_i + o(\epsilon^2) \quad (6)$$

where  $\Delta M_i \in \mathbf{R}^{d \times d}$  is linear in the misspecification parameter  $\epsilon$ , and

$$M_i = X \text{diag}(Y_{i1}, \dots, Y_{ip}) X^{-1} \quad (7)$$

where  $\text{diag}(v_1, \dots, v_d)$  denotes a diagonal matrix whose diagonal entries are  $v_1, \dots, v_d$ . If the model is exact, i.e.,  $p = \text{rank}_+(\hat{P})$  or equivalently  $\epsilon = 0$ , the matrices  $\{\hat{M}_i\}$  are simultaneously diagonalizable and the entries of the conditional probability matrix  $Y$  are given (up to normalization of its columns) by

$$Y_{ij} \propto [V^{-1} \hat{M}_i V]_{jj}, \quad i, j = 1, \dots, d \quad (8)$$

where  $V$  is the matrix of the eigenvectors shared by all  $\hat{M}_i$ .

When  $\epsilon \neq 0$ , the matrices  $\hat{M}_i$  are no longer simultaneously diagonalizable and an approximate simultaneous diagonalisation scheme is needed. The standard procedure consists of selecting a representative matrix  $\hat{M}$ , compute its eigenvectors  $\hat{V}$ , and use the matrix  $\hat{V}$  to obtain the approximate eigenvalues of all matrices  $\hat{M}_i$  and thereby estimate  $Y_{ij}$  (Mossel and Roch, 2006; Hsu et al., 2012; Anandkumar et al., 2012b). In this case, the estimation error is known to depend on the model misspecification parameter  $\epsilon$  and on the inverse of an eigenvalue separation  $\gamma$  (see, e.g., eq. (12)). Using matrix perturbation theorems and properties of the Gaussian distribution, Mossel and Roch (2006) have shown that a certain separation  $\gamma > \alpha$  is guaranteed with probability proportional to  $(1 - \alpha)$  if  $\hat{V}$  is the matrix of the eigenvectors of some  $\hat{M} = \sum_i \theta_i \hat{M}_i$ , with  $\theta$  sampled from a Gaussian distribution of zero mean and unit variance. In practice, however, this approach can give rise to

instabilities (such as negative or imaginary values for  $Y_{ij}$ ), especially when the size of the empirical matrices grows.

Here we propose instead to triangularize the matrices  $\hat{M}_i$  by means of the Schur decomposition of their linear combination  $\hat{M} = \sum_i \theta_i \hat{M}_i$ , for an appropriate  $\theta$  (steps 12-13). The orthogonal matrix  $\hat{U}$  obtained from the Schur decomposition  $\hat{M} = \hat{U} \hat{T} \hat{U}^T$  is then used in place of the eigenvectors matrix of  $\hat{M}$  to approximately triangularize all the observable matrices  $\hat{M}_i$  and thereby recover the mixture parameters (steps 15 and 24, 25). For example, the conditional probability matrix  $Y$  is estimated as

$$\hat{Y}_{ij} \propto [\hat{U}^T \hat{M}_i \hat{U}]_{jj}, \quad i, j = 1, \dots, d \quad (9)$$

and normalized so that its columns sum to one. Let  $\|\cdot\|$  denote the Frobenius norm. Our main result is the following:

**Theorem 1.** *Let  $\hat{M}_i$  and  $M_i$  be the real  $d \times d$  matrices defined in (5) and (6). Suppose it is possible to find  $\theta \in \mathbf{R}^d$  such that  $\hat{M} = \sum_k \theta_k \hat{M}_k$  has real distinct eigenvalues. Then, for all  $j = 1, \dots, d$ , there exists a permutation  $\pi$  such that*

$$|\hat{Y}_{ij} - Y_{i\pi(j)}| \leq \left( a_1 \frac{k(X) \lambda_{\max}}{\hat{\gamma}} + 1 \right) E + o(E^2) \quad (10)$$

where  $k(X) = \frac{\sigma_{\max}(X)}{\sigma_{\min}(X)}$  is the condition number of the ground-truth conditional probability matrix  $X$ ,  $\lambda_{\max} = \max_{i,j} Y_{i,j}$ ,

$$\hat{\gamma} = \min_{i \neq j} |\lambda_i(\hat{M}) - \lambda_j(\hat{M})| > 0 \quad (11)$$

with  $\lambda_i(\hat{M})$  being the  $i$ th eigenvalue of  $\hat{M}$ ,  $a_1 = \|\theta\| \sqrt{\frac{2^3 d^2}{d-1}}$ , and  $E = \max_i \|\Delta M_i\| = \max_i \|\hat{M}_i - M_i\|$ .

*Proof.* See appendix.  $\square$

The analogous bound for the diagonalization approach is (Anandkumar et al., 2012c, Section B6, eq. 11)

$$|\hat{Y}_{ij} - Y_{i\pi(j)}| \leq \left( a_2 k(X)^4 \frac{\tilde{\lambda}_{\max}}{\gamma} + a_3 k(X)^2 \right) E, \quad (12)$$

where  $\gamma = \min_{i \neq j} |\lambda_i(\sum_k \theta_k M_k) - \lambda_j(\sum_k \theta_k M_k)|$ ,  $\tilde{\lambda}_{\max} = \max(\max_i [\theta^T Y]_i, \max_{i,j} Y_{i,j})$ , and  $a_2, a_3$  are constants that depend on the dimensions of the involved matrices.

When the model misspecification error  $E$  is not too large, the error bound under the Schur approach (10) is characterized by a much smoother dependence on  $k(X)$  than the error bound (12). Moreover, the Schur bound depends on the eigenvalue gap  $\hat{\gamma}$  of an observable matrix, and hence it can be controlled in practice by optimizing  $\theta$ . The simplified dependence on  $k(X)$  of the Schur bound is due to

the good perturbation properties of the orthogonal matrices involved in the Schur decomposition, as compared to the eigenvector matrices of the Chang approach. The difference in the bounds suggests that, for a randomly generated true model, a spectral algorithm based on the Schur decomposition is expected to be more stable and accurate in practice than an algorithm based on matrix diagonalization. Intuitively, the key to the improved stability of the Schur approach comes from the freedom to ignore the non-unique off-diagonal parts in Schur triangulation.

During the reviewing process we were made aware of the work of Kuleshov et al. (2015), who propose computing a tensor factorization from the simultaneous diagonalization of a set of matrices obtained by projections of the tensor along random directions. Kuleshov et al. (2015) establish an error bound that is independent of the eigenvalue gap, but their approach does not come with global optimality guarantees (but the authors report good results in practice). It would be of interest to see whether such random projections combined with a simultaneous Schur decomposition (see, e.g., De Lathauwer et al. (2004)) could offer improved bounds.

### 3 EXPERIMENTS

We have compared the performance of the proposed spectral algorithm based on Schur decomposition with the classical spectral method based on eigenvalue decomposition. The two algorithms that we tested are equivalent except for line 13 of Algorithm 1, which in the classical spectral approach should be “find  $V$  such that  $V^{-1} M V = D$ , with  $D$  diagonal”. In all experiments we used the same code with decompositions performed via the two Matlab functions `schur(M)` and `eig(M)` respectively. We tested the two algorithms on simulated real multi-view and Hidden Markov Model data. In what follows we denote by ‘schur’ the algorithm based on the Schur decomposition and by ‘eig’ the algorithm based on the eigenvalues-eigenvector decomposition.

In the first set of experiments we generated multi-view data from a mixture of product distributions of  $p$  mixture components in  $d$  dimensions. For each experiment, we created two different datasets  $\mathcal{N} = \{[x_n y_n z_n] \in [1, \dots, d]^3\}$ , and  $\mathcal{N}_{test}$ , one for training and one for testing, the latter containing the labels  $L \in [1, \dots, p]^{| \mathcal{N}_{test} |}$  of the mixture components that generated each instance. The output was evaluated by measuring the distance between the estimated conditional probability distributions  $\hat{X}, \hat{Y}, \hat{Z}$  and the corresponding ground-truth values  $X, Y, Z$ :

$$E = \|\hat{X} - X\|^2 + \|\hat{Y} - Y\|^2 + \|\hat{Z} - Z\|^2. \quad (13)$$

Since the order of the columns in  $\hat{X}, \hat{Y}, \hat{Z}$  may be different from  $X, Y, Z$ , the norms were computed after obtaining the best permutation. We also tested according to a

| $ \mathcal{N} (d = 10, p = 5)$ | $E_{schur}$          | $E_{eig}$      | $S_{schur}$           | $S_{eig}$            | $\ \hat{T}_{schur} - T\ $ | $\ \hat{T}_{eig} - T\ $ |

Table 1: Columns recovery error  $E$ , classification score  $S$ , and distance of the approximate distribution  $\|\hat{T} - T\|$  for multi-view datasets of increasing size. The algorithm based on Schur decomposition obtained the best scores on almost all datasets.

classification rule where the estimated conditional probability matrices  $[\hat{X}, \hat{Y}, \hat{Z}]$  were used to assign each triple in the test dataset to one of the mixture components. For every run, we obtained a classification score by counting the number of successful predictions divided by the number of elements in the test dataset:

$$S = \frac{1}{|\mathcal{N}_{test}|} \sum_{n \in \mathcal{N}_{test}} f(n), \quad (14)$$

$$f(n) = \begin{cases} 0 & \arg \max_i \hat{X}_{x_n i} \hat{Y}_{y_n i} \hat{Z}_{z_n i} \neq L(n) \\ 1 & \arg \max_i \hat{X}_{x_n i} \hat{Y}_{y_n i} \hat{Z}_{z_n i} = L(n) \end{cases}. \quad (15)$$

Finally we computed the distance in norm between the recovered tensor

$$\hat{T}_{ijk} = \sum_r \hat{w}_r [\hat{X}]_{ir} [\hat{Y}]_{jr} [\hat{Z}]_{kr} \quad (16)$$

and the original tensor

$$T_{ijk} = \sum_r [w]_r [X]_{ir} [Y]_{jr} [Z]_{kr} \quad (17)$$

as follows

$$\|\hat{T} - T\| = \sqrt{\sum_{i,j,k} [\hat{T} - T]_{ijk}^2}. \quad (18)$$

In Table 1 we show the results obtained by the two algorithms for  $d = 10, p = 5$  and increasing size of the training dataset  $|\mathcal{N}|$ . In the table we report the average score over 10 analogous runs and the corresponding standard deviation in brackets. When the recovered matrices contained infinite values we have set  $E = \|X\|^2 + \|Y\|^2 + \|Z\|^2$ , and  $\|\hat{T} - T\| = \|T\|$ . The proposed algorithm based on Schur decomposition obtained the best scores on almost all datasets.

In the second set of experiments we tested the two algorithms on datasets generated by a  $d$ -dimensional Hidden Markov Model with  $p$  hidden states. For each experiment we randomly picked a model  $M_{true} = M_{true}(O_{true}, R_{true}, h_{true})$ , where  $O_{true} \in [0, 1]^{d \times p}$  is the observation matrix,  $R_{true} \in [0, 1]^{p \times p}$  is the transition

matrix, and  $h_{true} \in [0, 1]^p$  is the starting distribution, and we generated two sample datasets, one for training and one for testing. All sequences  $s_n$  were simulated starting from an initial hidden state drawn from  $h_{true}$  and following the dynamics of the model according to  $R_{true}$  and  $O_{true}$ . The length of the sequences in the training and testing datasets was set to 20. We evaluated the two algorithms based on the columns recovery error  $E$  as in the previous set of experiments. Also, letting  $O_{true} = [o_{true1}, \dots, o_{truep}]$  and  $O = [o_1, \dots, o_p]$ , we considered a recovery ratio  $R(M) = \frac{r}{p}$ , where  $r$  is the number of columns satisfying

$$\|o_{truei} - o_i\|^2 < \xi, \quad \xi = 0.05^2 * d. \quad (19)$$

In Table 2 we show the results for recovering a  $d = \{5, 10, 20, 30\}$  HMM with  $p = 5$  hidden states. All values are computed by averaging over 10 experiments and the corresponding standard variation is reported between brackets. The Schur algorithm is in general better than the classical approach. We note that, for a fixed number of hidden states, the inference of the HMM parameters becomes harder as the dimensionality of the space decreases. As the recovery ratio  $R$  shows, in the limit situation  $d = p$  both algorithms fail (values  $R = 0$  imply unstable solutions).

## 4 CONCLUSIONS

We have presented a new spectral algorithm for learning multi-view mixture models that is based on the Schur decomposition of an observable matrix. Our main result is a theoretical bound on the estimation error (Theorem 1), which is shown to depend very mildly (and much more smoothly than in previous results) on the condition number of the ground-truth conditional probability matrix, and inversely on the eigengap of an observable matrix. Numerical experiments show that the proposed method is more stable, and performs better in general, than the classical spectral approach using direct matrix diagonalization.

Table 2: Columns recovery error  $E$  and recovery ratio  $R$  for recovering HMMs of various dimensionality and hidden states using the Schur and the standard spectral approach. See text for details.

Then, for all  $j = 1, \dots, d$ , there exists a permutation  $\pi$  such that

$$|\hat{Y}_{ij} - Y_{i\pi(j)}| \leq \left( a_1 \frac{k(X) \lambda_{\max}}{\hat{\gamma}} + 1 \right) E + o(E^2) \quad (20)$$

with  $\hat{Y}$  estimated from (9), and where  $k(X) = \frac{\sigma_{\max}(X)}{\sigma_{\min}(X)}$  is the condition number of the ground-truth conditional probability matrix  $X$ ,  $\lambda_{\max} = \max_{i,j} Y_{i,j}$ ,

$$\hat{\gamma} = \min_{i \neq j} |\lambda_i(\hat{M}) - \lambda_j(\hat{M})| > 0 \quad (21)$$

with  $\lambda_i(\hat{M})$  being the  $i$ th eigenvalue of  $\hat{M}$ ,  $a_1 = \|\theta\| \sqrt{\frac{2^3 d^2}{d-1}}$ , and  $E = \max_i \|\Delta M_i\| = \max_i \|\hat{M}_i - M_i\|$ .

*Proof.* Consider the set of real commuting matrices  $M_i$ ,  $i = 1, \dots, d$ , and their random perturbations  $\hat{M}_i = M_i + \Delta M_i$  defined in (5) and (6). Assume that  $\|\Delta M_i\| < E$  for all  $i = 1, \dots, d$  and that  $\theta \in \mathbf{R}^d$  is such that the eigenvalues of  $\hat{M} = M + \Delta M = \sum_i \theta_i (M_i + \Delta M_i)$  are real and non-degenerate. Let  $\hat{U}$  be the orthogonal matrix defined by the Schur decomposition of  $\hat{M} = \hat{U}^T \hat{T} \hat{U}$  computed by the matrix decomposition subroutine in Algorithm 1. Note that  $\hat{U}$  may not be unique and different choices of  $\hat{U}$  lead to different entries in the strictly upper-diagonal part of  $\hat{T}$ . However, for any given  $\hat{U}$  such that  $\hat{U}^T \hat{T} \hat{U}$  is upper triangular, there exists an orthogonal matrix  $U$  and a real matrix  $\Delta U \in \mathbf{R}^{d,d}$  such that  $U = \hat{U} + \Delta U$  and

$$U^T M U = (\hat{U} + \Delta U)^T (\hat{M} - \Delta M) (\hat{U} + \Delta U) \quad (22)$$

$$= \hat{T} - \Delta T \quad (23)$$

$$= T \quad (24)$$

with  $T$  upper triangular. Let  $Y_{i,j}$  be the ground-truth matrix defined in (3) and  $\hat{Y}$  the estimation output by Algorithm 1. Then, assuming that  $\Delta M$  and  $\Delta U$  are small, there exists a permutation of the indexes  $\pi$  such that, for all  $i, j = 1, \dots, d$

$$\delta_y = |\hat{Y}_{ij} - Y_{i\pi(j)}| \quad (25)$$

$$= |[\hat{U}^T \hat{M}_i \hat{U}]_{jj} - [U^T M_i U]_{\pi(j)\pi(j)}| \quad (26)$$

$$\leq \|(U - \Delta U)^T (M_i + \Delta M_i) (U - \Delta U) - T_i\| \quad (27)$$

$$= \|\Delta U^T U T_i + T_i U^T \Delta U - U^T \Delta M_i U + o(\Delta^2)\| \quad (28)$$

$$= \|x T_i - T_i x + U^T \Delta M_i U + o(\Delta^2)\| \quad (29)$$

$$\leq 2 \|x\| \|T_i\| + \|\Delta M_i\| + o(\|\Delta^2\|) \quad (30)$$

$$\leq 2 \|x\| \mu + E + o(\|\Delta^2\|) \quad (31)$$

where we have defined  $x = U^T \Delta U$ ,  $\mu = \max_i \|M_i\|$  and used  $1 = (U + \Delta U)^T (U + \Delta U) = 1 + x^T + x + o(\Delta^2)$  where  $o(\Delta^2) = o(x^2) + o(\Delta M x)$ .

Following (Konstantinov et al., 1994), a linear bound of  $\|x\|$  can be estimated as follows. First, observe that the Schur decomposition of  $M$  in (24) implies

$$\text{low}(\hat{T} \hat{x} - \hat{x} \hat{T}) = \text{low}(\hat{U}^T \Delta M \hat{U}) + o(\Delta^2) \quad (32)$$

where  $\text{low}(A)$  denotes the strictly lower diagonal part of  $A$  and  $\hat{x} = \hat{U}^T \Delta U$ . Since  $\hat{T}$  is upper triangular, one has  $\text{low}(\hat{T} \hat{x} - \hat{x} \hat{T}) = \text{low}(\hat{T} \text{low}(\hat{x}) - \text{low}(\hat{x}) \hat{T})$ , i.e. the linear operator defined by  $\mathcal{L}_{\hat{T}}(\hat{x}) = \text{low}(\hat{T} \hat{x} - \hat{x} \hat{T})$  maps strictly lower-triangular matrices to strictly lower-triangular matrices. Let  $\tilde{\mathcal{L}}_{\hat{T}}(\cdot)$  be the restriction of  $\mathcal{L}_{\hat{T}}(\cdot)$  to the subspace

of lower-triangular matrices, then from (32) one has

$$\widetilde{\mathcal{L}}_{\hat{T}}(\text{low}(\hat{x})) = \text{low}(\hat{U}^T \Delta M \hat{U}) + o(\Delta^2) \quad (33)$$

and the operator  $\widetilde{\mathcal{L}}_{\hat{T}}$  is invertible. The invertibility of  $\widetilde{\mathcal{L}}_{\hat{T}}$  follows from the non-singularity of its matrix representation  $\text{mat}(\widetilde{\mathcal{L}}_{\hat{T}})$  defined by

$$\text{vec}\left(\widetilde{\mathcal{L}}_{\hat{T}}(\text{low}(\hat{x}))\right) = \text{mat}(\widetilde{\mathcal{L}}_{\hat{T}})L \text{vec}(\text{low}(\hat{x})) \quad (34)$$

where  $\text{vec}(A)$  is the columnwise vector representation of  $A$  and  $L = [L_{ij}] \in [0, 1]^{\frac{d(d-1)}{2} \times d^2}$  the projector to the subspace of vectorized lower-triangular matrices

$$L_{ij} \in [0, 1]^{d-i \times d}, \quad i, j = 1, \dots, d-1 \quad (35)$$

$$L_{ij} = \begin{cases} 0_{d-i, d} & i \neq j \\ [0_{d-i, i}, 1_{d-i}] & i = j \end{cases} \quad (36)$$

More explicitly,  $\text{mat}(\widetilde{\mathcal{L}}_{\hat{T}}) = L(1 \otimes \hat{T} - \hat{T}^T \otimes 1)L^T$  is a block lower-triangular matrix  $\text{mat}(\widetilde{\mathcal{L}}_{\hat{T}}) = [\mathcal{M}_{ij}] \in \mathbf{R}^{\frac{d(d-1)}{2} \times \frac{d(d-1)}{2}}$  where

$$[\mathcal{M}_{ij}] \in \mathbf{R}^{d-i \times d-j}, \quad i, j = 1, \dots, d-1 \quad (37)$$

$$\mathcal{M}_{ij} = \begin{cases} [0_{d-i, i-j}, 1_{d-j}] & i > j \\ [m_i] & i = j \\ 0 & i < j \end{cases} \quad (38)$$

$$[m_i]_{jk} = \begin{cases} \hat{T}_{j+i-1, k+i} & j < k \\ \hat{T}_{j+i, j+i} - T_{i, i} & j = k \\ 0 & j > k \end{cases} \quad (39)$$

for  $i, j = 1, \dots, d-1$ . The determinant of  $\mathcal{M}$  is the product of the determinants of its diagonal blocks, *i.e.*

$$\det(M) = \prod_{i>j} (\hat{T}_{ii} - \hat{T}_{jj}) \quad (40)$$

and is not null provided that the eigenvalues of  $\hat{T}$  are real separated. In this case, the matrix  $\mathcal{M}$  and hence the operator  $\widetilde{\mathcal{L}}_{\hat{T}}(\cdot)$  are invertible. From (32) one has

$$\text{low}(\hat{x}) = \widetilde{\mathcal{L}}_{\hat{T}}^{-1} \text{low}(\hat{U}^T \Delta M \hat{U}) + o(\Delta^2) \quad (41)$$

and in particular

$$\|\hat{x}\| = \sqrt{2} \|\text{low}(\hat{x})\| \quad (42)$$

$$= \sqrt{2} \|\widetilde{\mathcal{L}}_{\hat{T}}^{-1}\|_F \|\Delta M\| + o(\|\Delta\|^2) \quad (43)$$

where the first equality is obtained using the linear approximation  $\hat{x} = -\hat{x}^T$  and  $\|A\|^2 = \|\text{low}(A)\|^2 + \|\text{diag}(A)\|^2 + \|\text{up}(A)\|^2$ , with  $\text{diag}(A)$  and  $\text{up}(A)$  denoting the diagonal and upper-diagonal parts of  $A$ . The norm of the inverse operator can be bound using its matrix realization, *i.e.*

$$\|\widetilde{\mathcal{L}}_{\hat{T}}^{-1}\|_F = \|\mathcal{M}^{-1}\| \leq \frac{1}{\sigma_{\min}(\mathcal{M})} \quad (44)$$

where  $\sigma_{\min}(A)$  is the smallest singular value of  $A$ . We can estimate  $\sigma_{\min}(\mathcal{M})$  by using the following lemma

$$\sigma_{\min}(A) = \min_{\text{rank}(B) < n} \|A - B\|, \quad \text{rank}(A) = n \quad (45)$$

and observing that the rank deficient matrix closest to  $\mathcal{M}$  is obtained by setting  $\hat{T} = T_{\text{singular}}$  in (38), where  $T_{\text{singular}}$  is defined by

$$[T_{\text{singular}}]_{i,j} = \begin{cases} \hat{T}_{j^*, j^*} & \text{if } i = j = i^* \\ \hat{T}_{i, j} & \text{otherwise} \end{cases} \quad (46)$$

with  $(i^*, j^*) = \arg \min_{i \neq j} |\hat{T}_{ii} - \hat{T}_{jj}|$ . One has

$$\sigma_{\min}(\mathcal{M}) = \|\mathcal{M} - \mathcal{M}_{\text{singular}}\| \quad (47)$$

$$= \sqrt{\sum_{i,j} (\mathcal{M} - \mathcal{M}_{\text{singular}})_{i,j}^2} \quad (48)$$

$$= \sqrt{d-1} \hat{\gamma} \quad (49)$$

$$\hat{\gamma} = |\hat{T}_{i^* i^*} - \hat{T}_{j^* j^*}| = \min_{i \neq j} |\hat{T}_{ii} - \hat{T}_{jj}| \quad (50)$$

where the last equality is obtained by noting that, for all  $i = 1, \dots, d$ , the element  $\hat{T}_{ii}$  appears  $d-1$  times in  $\mathcal{M}$ .

The norm upper bound  $\mu$  in (31) obeys

$$\mu = \max_i \|M_i\| \quad (51)$$

$$= \max_i \|X \text{diag}(Y_{i1}, \dots, Y_{id}) X^{-1}\| \quad (52)$$

$$\leq \|X\| \|X^{-1}\| \max_i \|\text{diag}(Y_{i1}, \dots, Y_{id})\| \quad (53)$$

$$\leq k(X) \sqrt{d} \max_{i,j} Y_{ij} \quad (54)$$

$$= k(X) \sqrt{d} \lambda_{\max}. \quad (55)$$

where  $X$  is the ground-truth matrix defined in (3) and  $k(X) = \frac{\sigma_{\max}(X)}{\sigma_{\min}(X)}$  is the condition number of  $X$ .

Finally, the statement (10) follows from (31), (43),  $\|\hat{x}\| = \|x\|$ , (44), (49), (55) and

$$\|\Delta M\|^2 = \left\| \sum_i \theta_i \Delta M_i \right\|^2 \quad (56)$$

$$= \sum_{j,k} \left| \sum_i \theta_i [\Delta M_i]_{jk} \right|^2 \quad (57)$$

$$\leq \sum_{j,k} \|\theta\|^2 \sum_i [\Delta M_i]_{jk}^2 \quad (58)$$

$$= \|\theta\|^2 \sum_i \|\Delta M_i\|^2 \quad (59)$$

$$\leq d \|\theta\|^2 E^2 \quad (60)$$

where we have used the Cauchy-Schwarz inequality and the definition of  $E$ . In particular, for all higher orders terms contained in  $\Delta^2$ , one has  $o(\|\Delta^2\|) = o(\|x\|^2) + o(\|\Delta M\|^2) = o(E^2)$ .  $\square$

## Abstract

Propagating input uncertainty through non-linear Gaussian process (GP) mappings is intractable. This hinders the task of training GPs using uncertain and partially observed inputs. In this paper we refer to this task as “semi-described learning”. We then introduce a GP framework that solves both, the semi-described and the semi-supervised learning problems (where missing values occur in the *outputs*). Auto-regressive state space simulation is also recognised as a special case of semi-described learning. To achieve our goal we develop variational methods for handling semi-described inputs in GPs, and couple them with algorithms that allow for imputing the missing values while treating the uncertainty in a principled, Bayesian manner. Extensive experiments on simulated and real-world data study the problems of iterative forecasting and regression/classification with missing values. The results suggest that the principled propagation of uncertainty stemming from our framework can significantly improve performance in these tasks.

## 1 INTRODUCTION

In many real-world applications missing values can occur in the data, for example when measurements come from unreliable sensors. Correctly accounting for the partially observed instances is important in order to exploit all available information and increase the strength of the inference model. The focus of this paper is on Gaussian process (GP) models that allow for Bayesian, non-parametric inference.

When the missing values occur in the outputs, the corresponding learning task is known as *semi-supervised learning*. For example, consider the task of learning to classify images where the labelled set is much smaller than the total set. Bootstrapping is a potential solution to this problem [Rosenberg et al., 2005], according to which a model

trained on fully observed data imputes the missing outputs. Previous work in semi-supervised GP learning involved the cluster assumption [Lawrence and Jordan, 2005] for classification. Here we consider an approach which uses the manifold assumption [Chapelle et al., 2006; Kingma et al., 2014] which assumes that the observed, complex data are really generated by a compressed, less-noisy latent space.

The other often encountered missing data problem has to do with unobserved *input* features (e.g. missing pixels in input images). In statistics, a popular approach is to impute missing inputs using a combination of different educated guesses [Rubin, 2004]. In machine learning, Ghahramani and Jordan [1994] learn the joint density of the input and output data and integrate over the missing values. For Gaussian process models the missing input case has received only little attention, due to the challenge of propagating the input uncertainty through the non-linear GP mapping. In this paper we introduce the notion of *semi-described learning* to generalise this scenario. Specifically, we define semi-described learning to be the task of learning from inputs that can have missing or uncertain values. Our approach to dealing with missing inputs in semi-described GP learning is, algorithmically, closer to data imputation methods. However, in contrast to past approaches, the missing values are imputed in a fully probabilistic manner by considering explicit distributions in the input space.

Our aim in this paper is to develop a general framework that solves the semi-supervised and semi-described GP learning. We also consider the related *forecasting regression* problem, which is seen as a pipeline where predictions are obtained iteratively in an auto-regressive manner, while propagating the uncertainty across the predictive sequence, as in [Girard et al., 2003; Quiñero-Candela et al., 2003]. Here, we cast the auto-regressive GP learning as a particular type of semi-described learning. We seek to solve all tasks within a single coherent framework that preserves the fully Bayesian property of the GP methodology.

To achieve our goals we need three methodological tools. Firstly, we need approximations allowing us to consider and communicate uncertainty between the inputs and

the outputs of the non-linear GP model. For this, we build on the variational approach of Titsias and Lawrence [2010] which allows for approximately propagating densities throughout the nodes of GP-based directed graphical models. The resulting representation is particularly advantageous, because the whole input domain is now coherently associated with posterior distributions. We can then sample from the input space in a principled manner so as to populate small initial labelled sets in semi-supervised learning scenarios. In that way, we avoid heuristic self-training methods [Rosenberg et al., 2005] that rely on bootstrapping and present problems due to over-confidence. Previously suggested approaches for modelling input uncertainty in GPs also lack the feature of considering an explicit input distribution for both training and test instances. Specifically, [Girard et al., 2003; Quiñonero-Candela et al., 2003] consider the case of input uncertainty *only at test time*. Propagating the test input uncertainty through a non-linear GP results in a non-Gaussian predictive density, but Girard et al. [2003]; Quiñonero-Candela et al. [2003]; Quiñonero-Candela [2004] rely on moment matching to obtain the predictive mean and covariance. On the other hand, Oakley and O’Hagan [2002] do not derive analytic expressions but, rather, develop a scheme based on simulations. McHutchon and Rasmussen [2011] rely on local approximations inside the latent mapping function, rather than modelling the approximate posterior densities directly. Dallaire et al. [2009] do not propagate the uncertainty of the inputs all the way through the GP mapping but, rather, amend the kernel computations to account for the input uncertainty. [Quiñonero-Candela and Roweis, 2003] can be seen as a special case of our developed framework, when the data imputation is performed using a standard GP-LVM [Lawrence, 2006]. Another advantage of our framework is that it allows us to consider different levels of input uncertainty per point and per dimension without, in principle, increasing the danger of under/overfitting, since input uncertainty is modelled through a set of *variational* rather than model parameters.

The second methodological tool needed to achieve our goals has to do with the need to incorporate partial or uncertain observations into the variational framework. For this, we develop a *variational constraint* mechanism which constrains the distribution of the input space given the observed noisy values. This approach is fast, and the whole framework can be incorporated into a parallel inference algorithm [Gal et al., 2014; Dai et al., 2014]. In contrast, Damianou et al. [2011] consider a separate process for modelling the input distribution. However, that approach cannot easily be extended for the data imputation purposes that concern us, since we cannot consider different uncertainty levels per input and per dimension and, additionally, computation scales cubically with the number of datapoints, even within sparse GP frameworks. The constraints framework that we propose is interesting not only as an inference

tool but also as a modelling approach: if the inputs are constrained with the outputs, then we obtain the Bayesian version of the back-constraints framework of Lawrence and Quiñonero Candela [2006] and Ek et al. [2008]. However, in contrast to these approaches, the constraint defined here is a *variational* one, and operates upon a distribution, rather than single points. Zhu et al. [2012] also follow the idea of constraining the posterior distribution with rich side information, albeit for a completely different application. In contrast, Osborne and Roberts [2007] handle partially missing sensor inputs by modelling correlations in the input space through special covariance functions.

Thirdly, the variational methods developed here need to be encapsulated into algorithms that perform data imputation while correctly accounting for the introduced uncertainty. We develop such algorithms after showing how the considered applications can be cast as learning pipelines that rely on correct propagation of uncertainty between each stage.

In summary, our contributions in this paper are the following; firstly, by building on the Bayesian GP-LVM [Titsias and Lawrence, 2010] and developing a variational constraint mechanism we demonstrate how uncertain GP inputs can be explicitly represented as distributions in both training and test time. Secondly, we couple our variational methodology with algorithms that allow us to solve problems associated with partial or uncertain observations: semi-supervised learning, auto-regressive iterative forecasting and, finally, a newly studied type of GP learning which we refer to as “semi-described” learning. We solve these applications within a single framework, allowing for handling the uncertainty in semi-supervised and semi-described problems in a coherent way. The software accompanying this paper can be found at: <http://git.io/A3TN>. This paper extends our previous workshop paper [Damianou and Lawrence, 2014].

## 2 UNCERTAIN INPUTS REFORMULATION OF GP MODELS

Assume a dataset of input–output pairs stored by rows in matrices  $\mathbf{X} \in \mathbb{R}^{n \times q}$  and  $\mathbf{Y} \in \mathbb{R}^{n \times p}$  respectively. Throughout this paper we will denote rows of the above matrices as  $\{\mathbf{y}_{i,:}, \mathbf{x}_{i,:}\}$  and columns (dimensions) as  $\{\mathbf{y}_j, \mathbf{x}_j\}$ , while single elements (e.g.  $y_{i,j}$ ) will be denoted with a double subscript. We first outline the standard GP formulation, where all variables are fully observed. By assuming that outputs are corrupted by zero-mean Gaussian noise, denoted by  $\epsilon_f$ , we obtain the following generative model:

$$y_{i,j} = \mathbf{f}_j(\mathbf{x}_{i,:}) + (\epsilon_f)_{i,j}, \quad (\epsilon_f)_{i,j} \sim \mathcal{N}(0, \beta^{-1}). \quad (1)$$

We place GP priors on the mapping  $\mathbf{f}$ , so that the function instantiations  $\mathbf{F} = \{\mathbf{f}_j\}_{j=1}^p$  follow a Gaussian distribution  $p(\mathbf{f}_j|\mathbf{X}) = \mathcal{N}(\mathbf{f}_j|\mathbf{0}, \mathbf{K})$ , where  $\mathbf{K}$  is the covariance matrix obtained by evaluating the GP covariance function  $k_f$  on

the inputs  $\mathbf{X}$ . Therefore, the model likelihood  $p(\mathbf{Y}|\mathbf{X})$  is:

$$\int_{\mathbf{F}} p(\mathbf{Y}|\mathbf{F})p(\mathbf{F}|\mathbf{X}) = \prod_{j=1}^p \mathcal{N}(\mathbf{y}_j|\mathbf{0}, \mathbf{K} + \beta^{-1}\mathbf{I}). \quad (2)$$

In the other end of the spectrum is the GP-LVM [Lawrence, 2006], where the inputs are fully unobserved (i.e. *latent*). This corresponds to the unsupervised GP setting. In the absence of observed inputs, the likelihood  $p(\mathbf{Y}|\mathbf{X})$  takes the same form as in equation (2) but the inputs  $\mathbf{X}$  now need to be recovered from the outputs  $\mathbf{Y}$  through maximum likelihood. The Bayesian GP-LVM proceeds by additionally placing a Gaussian prior on the latent space,  $p(\mathbf{X}) = \prod_{i=1}^n \mathcal{N}(\mathbf{x}_{i,:}|\mathbf{0}, \mathbf{I})$ , and approximately integrating it out by constructing a variational lower bound  $\mathcal{F}$ , where

$$\mathcal{F} \leq \log p(\mathbf{Y}) = \log \int_{\mathbf{X}} p(\mathbf{Y}|\mathbf{X})p(\mathbf{X}),$$

and by introducing a variational distribution

$$q(\mathbf{X}) = \prod_{i=1}^n q(\mathbf{x}_{i,:}) = \prod_{i=1}^n \mathcal{N}(\mathbf{x}_{i,:}|\boldsymbol{\mu}_{i,:}, \mathbf{S}_{i,:}),$$

where  $\mathbf{S}_{i,:}$  is a diagonal matrix, so that  $\boldsymbol{\mu}_{i,:}, \text{diag}(\mathbf{S}_{i,:}) \in \mathbb{R}^q$ . We can derive an expression for this variational bound,

$$\mathcal{F} = \langle \log p(\mathbf{Y}|\mathbf{X}) \rangle_{q(\mathbf{X})} - \text{KL}(q(\mathbf{X}) \| p(\mathbf{X})), \quad (3)$$

where  $\langle \cdot \rangle_{q(\mathbf{X})}$  denotes an expectation with respect to  $q(\mathbf{X})$ . Since  $\mathbf{X}$  appears non-linearly inside  $p(\mathbf{Y}|\mathbf{X})$  (in the inverse of the covariance matrix  $\mathbf{K} + \beta^{-1}\mathbf{I}$ ), the first term of the above variational bound is intractable. However, we can follow [Titsias and Lawrence, 2010] to approximate the intractable expectation analytically.

In this paper we wish to define a general framework that operates in the whole range of the two aforementioned extrema, i.e. the fully observed and fully unobserved inputs case. The first step to obtaining such a framework is to allow for uncertainty in the inputs. We assume that the inputs  $\mathbf{X}$  are not observed directly but, rather, we only have access to their noisy versions  $\{\mathbf{z}_{i,:}\}_{i=1}^n = \mathbf{Z} \in \mathbb{R}^{n \times q}$ . The relationship between the noisy and true inputs is given by assuming Gaussian noise:

$$\mathbf{x}_{i,:} = \mathbf{z}_{i,:} + (\boldsymbol{\epsilon}_x)_{i,:}, \quad (\boldsymbol{\epsilon}_x)_{i,:} \sim \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma}_x), \quad (4)$$

so that  $p(\mathbf{X}|\mathbf{Z}) = \prod_{i=1}^n \mathcal{N}(\mathbf{x}_{i,:}|\mathbf{z}_{i,:}, \boldsymbol{\Sigma}_x)$ . Obviously, when this distribution collapses to a delta function we recover the standard GP case, and when  $\mathbf{Z}$  is not given we recover the GP-LVM. The problem with the modelling assumption of equation (4) is that now we cannot use equation (1), since the inputs are not available. On the other hand, if we replace  $\mathbf{x}_{i,:}$  in that equation with  $\mathbf{z}_{i,:}$ , then we effectively ignore the input noise. McHutchon and Rasmussen [2011] proceed by combining equations (1) and (4) to obtain the GP mapping  $\mathbf{f}_j(\mathbf{x}_{i,:} - (\boldsymbol{\epsilon}_x)_{i,:})$  which is then

treated using local approximations. However, our aim in this paper is to consider an explicit input distribution. One way to achieve this is to treat the unobserved true inputs as latent variables to be estimated from the marginal likelihood  $p(\mathbf{Y}|\mathbf{Z}) = \int_{\mathbf{X}} p(\mathbf{Y}|\mathbf{X})p(\mathbf{X}|\mathbf{Z})$ . Following Damianou et al. [2011] we can obtain a variational lower bound  $\mathcal{F} \leq \log p(\mathbf{Y}|\mathbf{Z})$ , with:

$$\mathcal{F} = \langle \log p(\mathbf{Y}|\mathbf{X}) \rangle_{q(\mathbf{X})} - \text{KL}(q(\mathbf{X}) \| p(\mathbf{X}|\mathbf{Z})). \quad (5)$$

This formulation corresponds to the graphical model of Figure 1(a). However, with this approach one needs to additionally estimate the noise parameters  $\boldsymbol{\Sigma}_x$ , which might be challenging given their large number and their interplay with the variational noise parameters  $\{\mathbf{S}_{i,:}\}_{i=1}^n$ . Therefore we considered an alternative solution which we found to result in better performance.

Figure 1: Incorporating uncertain inputs  $\mathbf{Z}$  in GPs through an intermediate input space  $\mathbf{X}$  by considering: (a) a Gaussian prior on  $\mathbf{X}$ , centered on  $\mathbf{Z}$  and (b) a variational constraint (dashed line) on the approximate posterior. Figure (c) represents our two-stage approach to dealing with missing outputs for classification, where the dotted line represents a discriminative mapping.

## 2.1 VARIATIONAL CONSTRAINT

An alternative way of relating the true with the noisy inputs can be obtained by focusing on the *posterior* rather than the prior distribution. To start with, we re-express the variational lower bound of equation (5) as:

$$\log p(\mathbf{Y}|\mathbf{Z}) \geq \int_{\mathbf{X}} q(\mathbf{X}) \log \frac{p(\mathbf{Y}|\mathbf{Z})p(\mathbf{X}|\mathbf{Y}, \mathbf{Z})}{q(\mathbf{X})} = \mathcal{F}$$

from where we break the logarithm to obtain:

$$\mathcal{F} = \log p(\mathbf{Y}|\mathbf{Z}) - \text{KL}(q(\mathbf{X}) \| p(\mathbf{X}|\mathbf{Y}, \mathbf{Z})).$$

We see that the lower bound becomes exact when the variational distribution  $q(\mathbf{X})$  matches the true posterior distribution of the noise-free latent inputs given the observed inputs and outputs. To allow for this approximation we introduce a simple variational constraint which operates on the factorised distribution, which is now written as  $q(\mathbf{X}|\mathbf{Z})$  to highlight its dependency on  $\mathbf{Z}$ . In the simplest case

where all inputs are observed but uncertain, the constraint just consists of replacing the variational means  $\mu_{i,:}$  of each factor  $q(\mathbf{x}_{i,:})$  with the corresponding observed input  $\mathbf{z}_{i,:}$ . The variational parameters  $\mathbf{S}_{i,:}$  then account for the uncertainty. Similarly to the back-constraint of Lawrence and Quiñonero Candela [2006]; Ek et al. [2008], our variational constraint does not constitute a probabilistic mapping. However, it allows us to encode the input noise directly in the approximate posterior without having to specify additional noise parameters or sacrifice scalability. Next, we elaborate on the exact form of the constraint.

In the general case, namely having inputs that are only partially observed, we can define a similar constraint which specifies a variational distribution as a mix of Gaussian and Dirac delta distributions. Notationally we consider data to be split into fully and partially observed subsets, e.g.  $\mathbf{Z} = (\mathbf{Z}^\circ, \mathbf{Z}^\mathcal{U})$ , where  $\circ$  and  $\mathcal{U}$  denote fully and partially observed sets respectively. The features missing in  $\mathbf{Z}^\mathcal{U}$  can appear in different dimension(s) for each individual point  $\mathbf{z}_{i,:}^\mathcal{U}$ , but for notational clarity  $\mathcal{U}$  will index rows containing at least one missing dimension. In this case, the variational distribution is constrained to have the form

$$q(\mathbf{X}|\mathbf{Z}, \{\circ, \mathcal{U}\}) = q(\mathbf{X}^\circ|\mathbf{Z}^\circ) q(\mathbf{X}^\mathcal{U}|\mathbf{Z}^\mathcal{U}) \\ = \prod_{i \in \circ} \mathcal{N}(\mathbf{x}_{i,:}^\circ | \mathbf{z}_{i,:}^\circ, \varepsilon \mathbf{I}) \prod_{i \in \mathcal{U}} \mathcal{N}(\mathbf{x}_{i,:}^\mathcal{U} | \boldsymbol{\mu}_{i,:}^\mathcal{U}, \mathbf{S}_{i,:}^\mathcal{U}), \quad (6)$$

where  $\varepsilon \rightarrow 0$ , so that the corresponding distributions approximate a Dirac delta. Notice that for a partially observed row  $\mathbf{z}_{i,:}^\mathcal{U}$ , we can still replace an observed dimension  $j$  with its corresponding observation in the second set of factors of equation (6), i.e.  $\mu_{i,j}^\mathcal{U} = z_{i,j}^\mathcal{U}$ , so  $q(\mathbf{X}^\mathcal{U}|\mathbf{Z}^\mathcal{U}) \neq q(\mathbf{X}^\mathcal{U})$ . Given the above, as well as a spherical Gaussian prior for  $p(\mathbf{X})$ , the required intractable density  $\log p(\mathbf{Y}|\mathbf{Z})$  is approximated with a variational lower bound:

$$\mathcal{F} = \langle \log p(\mathbf{Y}|\mathbf{X}) \rangle_{q(\mathbf{X}|\mathbf{Z})} - \text{KL}(q(\mathbf{X}|\mathbf{Z}) \| p(\mathbf{X})), \quad (7)$$

where for clarity we dropped the dependency on  $\{\circ, \mathcal{U}\}$  from our expressions. Since the Dirac functions are approximated with sharply peaked Gaussians inside the posterior  $q(\mathbf{X}|\mathbf{Z})$ , the above variational bound can be computed in the same manner as the Bayesian GP-LVM bound of equation (3). Specifically, the KL term is tractable, since it only involves Gaussians.

As for the first term of equation (7), we follow the Bayesian GP-LVM methodology and we augment the probability space with  $m$  extra samples  $\mathbf{U} = \{\mathbf{u}_i\}_{i=1}^m$  of the latent function  $f$  evaluated at a set of pseudo-inputs (known as ‘‘inducing points’’)  $\mathbf{X}_u$ , so that  $\mathbf{U} \in \mathbb{R}^{m \times p}$  and  $\mathbf{X}_u \in \mathbb{R}^{m \times q}$ . Due to the consistency of GPs,  $p(\mathbf{U}|\mathbf{X}_u)$  is a Gaussian distribution. From now on we omit dependence on  $\mathbf{X}_u$  from our expressions. The likelihood then becomes:

$$p(\mathbf{Y}, \mathbf{F}, \mathbf{U}|\mathbf{X}) = p(\mathbf{Y}|\mathbf{F})p(\mathbf{F}|\mathbf{U}, \mathbf{X})p(\mathbf{U}).$$

Then, the marginal  $p(\mathbf{Y}|\mathbf{X})$  can be obtained from Jensen’s inequality after introducing a variational distribution  $q(\mathbf{F}, \mathbf{U})$ , so that  $\hat{\mathcal{F}} \leq \log p(\mathbf{Y}|\mathbf{X})$ , where:

$$\hat{\mathcal{F}} = \int_{\mathbf{F}, \mathbf{U}} q(\mathbf{F}, \mathbf{U}) \log \frac{p(\mathbf{Y}|\mathbf{F})p(\mathbf{F}|\mathbf{U}, \mathbf{X})p(\mathbf{U})}{q(\mathbf{F}, \mathbf{U})}. \quad (8)$$

Now the first term of equation (7) is approximated as  $\langle p(\mathbf{Y}|\mathbf{X}) \rangle_{q(\mathbf{X}|\mathbf{Z})} \geq \langle \hat{\mathcal{F}} \rangle_{q(\mathbf{X}|\mathbf{Z})}$ . However, this approximation is still intractable, since the problematic term  $p(\mathbf{F}|\mathbf{U}, \mathbf{X})$  still appears inside  $\hat{\mathcal{F}}$  and contains  $\mathbf{X}$  in the inverse of the covariance matrix, thus rendering the expectation intractable. The trick of Titsias and Lawrence [2010] is to define a variational distribution of the form:

$$q(\mathbf{F}, \mathbf{U}) = p(\mathbf{F}|\mathbf{U}, \mathbf{X})q(\mathbf{U}). \quad (9)$$

Replacing equation (9) inside the bound of equation (8) results in the cancellation of  $p(\mathbf{F}|\mathbf{U}, \mathbf{X})$ , leaving us with a tractable (partial) bound, which takes the form:

$$\langle p(\mathbf{Y}|\mathbf{X}) \rangle_{q(\mathbf{X}|\mathbf{Z})} \geq \langle \hat{\mathcal{F}} \rangle_{q(\mathbf{X}|\mathbf{Z})} = -\text{KL}(q(\mathbf{U}) \| p(\mathbf{U})) \\ + \int_{\mathbf{X}, \mathbf{U}} \left[ q(\mathbf{X}|\mathbf{Z})q(\mathbf{U}) \int_{\mathbf{F}} p(\mathbf{F}|\mathbf{U}, \mathbf{X}) \log p(\mathbf{Y}|\mathbf{F}) \right] \quad (10)$$

The augmentation trick decouples the latent function values given the inducing points, so that any uncertainty in the inputs can be propagated through the nested integral. After this operation, the inducing outputs  $\mathbf{U}$  can be marginalised out. Therefore, the above integral is analytically tractable, since the nested integral is tractable and results in a Gaussian where  $\mathbf{X}$  no longer appears in the inverse of the covariance matrix. The final lower bound to use as an objective function is thus obtained by using the partial bound of eq. (10) in place of the first term of equation (7), thus obtaining a new, final bound (more details in the Appendix):

$$\mathcal{F}_2 = \langle \hat{\mathcal{F}} \rangle_{q(\mathbf{X}|\mathbf{Z})} - \text{KL}(q(\mathbf{X}|\mathbf{Z}) \| p(\mathbf{X})). \quad (11)$$

To summarise, the variational methodology seeks to approximate the true posterior with a variational distribution  $q(\mathbf{F}, \mathbf{U}, \mathbf{X}) = q(\mathbf{F})q(\mathbf{U})q(\mathbf{X})$ . To achieve this,  $q(\mathbf{F})$  is constrained to take the exact form  $p(\mathbf{F}|\mathbf{U}, \mathbf{X})$ . This term is then ‘‘eliminated’’, giving us tractability, but its effect is re-introduced through the variational distribution (in the nested integral of eq. (10)). Contrast this with the variational constraint on  $q(\mathbf{X})$ : that approximate posterior factor is constrained according to  $\mathbf{Z}$ , so that the effect of  $\mathbf{Z}$  is considered only through the  $q(\mathbf{X}|\mathbf{Z})$  (eq. (11)). The above comparison gives insight in the conceptual similarity of the variational approach followed to obtain tractability and the one followed for handling partially observed inputs.

The variationally constrained model is shown in fig. 1(b). The total set of parameters to be optimised in the objective function  $\mathcal{F}_2$  of equation (11) (e.g. using a gradient-based optimiser) are the model parameters  $(\boldsymbol{\theta}_f, \beta)$ , where  $\boldsymbol{\theta}_f$  denotes the hyper-parameters of the covariance function  $k_f$ ,

and the variational parameters  $(\mathbf{X}_u, \{\boldsymbol{\mu}_{i,:}^u, \mathbf{S}_{i,:}^u\}_{i \in \mathcal{U}})$  ( $q(\mathbf{U})$  can be optimally eliminated, see Appendix). Depending on the application and corresponding learning algorithm, certain dimensions of  $\{\boldsymbol{\mu}_{i,:}^u, \mathbf{S}_{i,:}^u\}$  can be treated as observed. Such algorithms are discussed in the following sections.

### 3 GP LEARNING WITH MISSING VALUES

We formulate both the semi-described and semi-supervised learning as particular instances of learning a mapping function where the inputs are associated with uncertainty. In both cases, we devise a two-step strategy based on our uncertain inputs GP framework, which allows to efficiently take into account the partial information in the given datasets to improve the predictive performance. For brevity, we refer to the framework described in the previous section as a *variationally constrained GP*, from where a semi-described, an auto-regressive and a semi-supervised GP approach are obtained as special cases, given the algorithms that will be explained in this section.

#### 3.1 SEMI-DESCRIBED LEARNING

We assume a set of observed outputs  $\mathbf{Y}$  that correspond to fully observed inputs  $\mathbf{Z}^\circ$  and partially observed inputs  $\mathbf{Z}^u$ , so that  $\mathbf{Z} = (\mathbf{Z}^\circ, \mathbf{Z}^u)$ . To make the correspondence clearer, we also split the observed *outputs* according to the sets  $\{\circ, u\}$ , so that  $\mathbf{Y} = (\mathbf{Y}^\circ, \mathbf{Y}^u)$ , but note that both output sets are fully observed. We are then interested in learning a regression function from  $\mathbf{Z}$  to  $\mathbf{Y}$  by using all available information. Since in the variationally constrained GP the inputs are replaced by distributions  $q(\mathbf{X}^\circ | \mathbf{Z}^\circ)$  and  $q(\mathbf{X}^u | \mathbf{Z}^u)$ , the uncertainty over  $\mathbf{Z}^u$  can be taken into account naturally through this variational distribution. In this context, we formulate a data imputation-based approach which is inspired by self-training methods; nevertheless, it is more principled in the handling of uncertainty.

Specifically, the algorithm has two stages; in the first step, we use the fully observed data subset  $(\mathbf{Z}^\circ, \mathbf{Y}^\circ)$  to train an initial variationally constrained GP model which encapsulates the sharply peaked variational distribution  $q(\mathbf{X}^\circ | \mathbf{Z}^\circ)$  given in equation (6). Given this model, we can then use  $\mathbf{Y}^u$  to estimate the predictive posterior<sup>1</sup>  $q(\mathbf{X}^u | \mathbf{Z}^u)$  in the missing locations of  $\mathbf{Z}^u$  (for the observed locations we match the mean with the observations in a sharply peaked marginal, as for  $\mathbf{Z}^\circ$ ). Essentially, we replace the missing locations of the variational means  $\boldsymbol{\mu}_{i,:}^u$  and variances  $\mathbf{S}_{i,:}^u$  of  $q(\mathbf{X}^u | \mathbf{Z}^u)$  with the predictive mean and variance obtained through the “self-training” step. This selection for  $\{\boldsymbol{\mu}_{i,:}^u, \mathbf{S}_{i,:}^u\}$  constitutes nevertheless only an initialisation. In

<sup>1</sup>The predictive posterior for test data  $\mathbf{Y}_*$  is obtained by maximising a variational lower bound similar to the training one (eq. (11)), but  $\mathbf{X}$  and  $\mathbf{Y}$  are now replaced with  $(\mathbf{X}, \mathbf{X}_*)$  and  $(\mathbf{Y}, \mathbf{Y}_*)$ .

the next step, these parameters are further optimised together with the fully observed data. Specifically, after initializing  $q(\mathbf{X} | \mathbf{Z}) = q(\mathbf{X}^\circ, \mathbf{X}^u | \mathbf{Z})$  as explained in step 1, we proceed to train a variationally constrained GP model on the full (extended) training set  $((\mathbf{Z}^\circ, \mathbf{Z}^u), (\mathbf{Y}^\circ, \mathbf{Y}^u))$ , which contains fully and partially observed inputs.

Algorithm 1 outlines the approach in more detail. This formulation defines a *semi-described GP* approach which naturally incorporates fully and partially observed examples by communicating the uncertainty throughout the relevant parts of the model in a principled way. Indeed, the predictive uncertainty obtained when imputing missing values in the first step of the pipeline is incorporated as input uncertainty in the second step of the pipeline. In extreme cases resulting in very non-confident predictions, for example in the presence of outliers, the corresponding locations will simply be ignored automatically due to the large uncertainty. This mechanism, together with the subsequent optimisation of the parameters of  $q(\mathbf{X}^u | \mathbf{Z}^u)$  in stage 2, guards against reinforcing bad predictions when imputing missing values based on a smaller training set. The model includes GP regression and the GP-LVM as special cases. In particular, in the limit of having no observed values our semi-described GP is equivalent to the GP-LVM and when there are no missing values it is equivalent to GP regression.

There are some similarities to traditional self-training [Rosenberg et al., 2005], but as there are no straightforward mechanisms to propagate uncertainty in that domain, they typically rely on bootstrapping followed by thresholding “bad” samples to prevent model over-confidence. In our framework, the predictions made by the initial model only constitute initialisations which are later optimised along with model parameters and, hence, we refer to this step as *partial* self-training. Further, the predictive uncertainty is not used as a hard measure of discarding unconfident predictions; instead, we allow all values to contribute according to an optimised uncertainty measure, that is, the input variances  $\mathbf{S}_i$ . Therefore, the way in which uncertainty is handled makes the self-training part of our algorithm principled compared to many bootstrap-based approaches.

#### DEMONSTRATION

We considered simulated and real-world data to demonstrate our semi-described GP algorithm. The simulated data were created by sampling inputs  $\mathbf{Z}$  from a GP (which was unknown to the competing models) and then giving these samples as input to another unknown GP, to obtain corresponding outputs  $\mathbf{Y}$ . For the real-world data demonstration we considered a motion capture dataset taken from subject 35 in the CMU motion capture database. We selected a subset of walk and run motions of a human body represented as a set of 59 joint locations. We formulated a regression problem where the first 20 dimensions of the original data are used as targets and the remaining 39 as

- 1: *Given:* Fully and partially observed inputs,  $\mathbf{Z}^\circ$  and  $\mathbf{Z}^\mathcal{U}$  respectively, corresponding to fully observed outputs  $\mathbf{Y}^\circ$  and  $\mathbf{Y}^\mathcal{U}$ .
  - 2: Construct  $q(\mathbf{X}^\circ|\mathbf{Z}^\circ) = \prod_{i=1}^n \mathcal{N}(\mathbf{x}_{i,:}^\circ|\mathbf{z}_{i,:}^\circ, \varepsilon\mathbf{I})$ , where:  $\varepsilon \rightarrow 0$
  - 3: Fix  $q(\mathbf{X}^\circ|\mathbf{Z}^\circ)$  in the optimiser # (i.e.  $q(\mathbf{X}^\circ|\mathbf{Z}^\circ)$  has no free parameters)
  - 4: Train a variationally constrained GP model  $\mathcal{M}^\circ$  with inputs  $q(\mathbf{X}^\circ|\mathbf{Z}^\circ)$  and outputs  $\mathbf{Y}^\circ$
  - 5: **for**  $i = 1, \dots, |\mathbf{Y}^\mathcal{U}|$  **do**
  - 6:   Predict the distribution  $\mathcal{N}(\mathbf{x}_{i,:}^\mathcal{U}|\hat{\boldsymbol{\mu}}_{i,:}^\mathcal{U}, \hat{\mathbf{S}}_i^\mathcal{U}) \approx p(\mathbf{x}_{i,:}^\mathcal{U}|\mathbf{y}_{i,:}^\mathcal{U}, \mathcal{M}^\circ)$  from the approximate posterior of model  $\mathcal{M}^\circ$ .
  - 7:   Initialise parameters  $\{\boldsymbol{\mu}_{i,:}^\mathcal{U}, \mathbf{S}_i^\mathcal{U}\}$  of  $q(\mathbf{x}_{i,:}^\mathcal{U}|\mathbf{z}_{i,:}^\mathcal{U}) = \mathcal{N}(\mathbf{x}_{i,:}^\mathcal{U}|\boldsymbol{\mu}_{i,:}^\mathcal{U}, \mathbf{S}_i^\mathcal{U})$  as follows:
  - 8:   **for**  $j = 1, \dots, q$  **do**
  - 9:     **if**  $z_{i,j}^\mathcal{U}$  is observed **then**
  - 10:        $\mu_{i,j}^\mathcal{U} = z_{i,j}^\mathcal{U}$  and  $(\mathbf{S}_i^\mathcal{U})_{j,j} = \varepsilon$ , where:  $\varepsilon \rightarrow 0$
  - 11:       Fix  $\mu_{i,j}^\mathcal{U}, (\mathbf{S}_i^\mathcal{U})_{j,j}$  in the optimiser # (i.e. they don't constitute parameters)
  - 12:     **else**
  - 13:        $\mu_{i,j}^\mathcal{U} = \hat{\mu}_{i,j}^\mathcal{U}$  and  $(\mathbf{S}_i^\mathcal{U})_{j,j} = (\hat{\mathbf{S}}_i^\mathcal{U})_{j,j}$
  - 14: Train model  $\mathcal{M}^{\circ,\mathcal{U}}$  with inputs  $q(\mathbf{X}^{\{\circ,\mathcal{U}\}}|\mathbf{Z}^{\{\circ,\mathcal{U}\}})$  and outputs  $(\mathbf{Y}^\circ, \mathbf{Y}^\mathcal{U})$ . The input distribution  $q(\mathbf{X}^{\{\circ,\mathcal{U}\}}|\mathbf{Z}^{\{\circ,\mathcal{U}\}}) = q(\mathbf{X}^\circ|\mathbf{Z}^\circ)q(\mathbf{X}^\mathcal{U}|\mathbf{Z}^\mathcal{U})$  is constructed in steps 2, 5-13 and further optimised in the non-fixed locations.
  - 15: Model  $\mathcal{M}^{\circ,\mathcal{U}}$  now constitutes the semi-described GP and can be used for all required prediction tasks.
- 

inputs. That is, given a partial joint representation of the human body, the task is to infer the rest of the representation. For both datasets, simulated and motion capture, we selected a portion of the training inputs, denoted as  $\mathbf{Z}^\mathcal{U}$ , to have randomly missing features. The extended dataset  $((\mathbf{Z}^\circ, \mathbf{Z}^\mathcal{U}), (\mathbf{Y}^\circ, \mathbf{Y}^\mathcal{U}))$  was used to train: a) our method, referred to as semi-described GP (SD-GP) b) multiple linear regression (MLR) c) regression by performing nearest neighbour (NN) search between the test and training instances, in the observed input locations d) performing data imputation using the standard GP-LVM. Not taking into account the predictive uncertainty during imputation was found to have catastrophic results in the simulated data, as the training set was not robust against bad predictions. Therefore, the ‘‘GP-LVM’’ variant was not considered in the real data experiment. We also considered: e) a standard GP which cannot handle missing inputs straightforwardly and so was trained only on the observed data  $(\mathbf{Z}^\circ, \mathbf{Y}^\circ)$ . The goal was to reconstruct test outputs  $\mathbf{Y}_*$  given fully observed test inputs  $\mathbf{Z}_*$ . For the simulated data we used the following sizes:  $|\mathbf{Z}^\circ| = 40$ ,  $|\mathbf{Z}^\mathcal{U}| = 60$  and  $|\mathbf{Z}_*| = 100$ . The dimensionality of the inputs is  $q = 15$  and of the outputs is  $p = 5$ . For the motion capture data we used  $|\mathbf{Z}^\circ| = 50$ ,  $|\mathbf{Z}^\mathcal{U}| = 80$  and  $|\mathbf{Z}_*| = 200$ . In fig. 2 we plot the MSE obtained by the competing methods for a varying percentage of missing features in  $\mathbf{Z}^\mathcal{U}$ . For the simulated data experiment, each of the points in the plot is an average of 4 runs which considered different random seeds. For clarity, the  $y$ -axis limit is fixed in figure 2, because some methods produced huge errors. The full picture is in figure 5 (Appendix). As can be seen in the figures, the semi-described GP is able to handle the extra data and make much better predictions, even if a very large portion is missing. Indeed, its performance starts to converge to that of a standard GP when there are 90% missing values in  $\mathbf{Z}^\mathcal{U}$  and performs

identically to the standard GP when 100% of the values are missing. We found that when  $q$  is large compared to  $p$  and  $n$ , then the data imputation step can be problematic as the percentage of missing features in  $\mathbf{Z}^\mathcal{U}$  approaches 100% i.e. the method is reliant on having some covariates available. Appendix D discusses this behaviour, but a more systematic investigation is left as future work.

### 3.2 AUTO-REGRESSIVE GAUSSIAN PROCESSES

Having a method which implicitly models the uncertainty in the inputs of a GP also allows for doing predictions in an autoregressive manner [Oakley and O’Hagan, 2002] while propagating the uncertainty through the predictive sequence [Girard et al., 2003; Quiñonero-Candela et al., 2003]. Specifically, assuming that the given data  $\mathbf{Y}$  constitute a multivariate timeseries where the observed time vector  $\mathbf{t}$  is equally spaced, and given a time-window of length  $\tau$ , we can reformat  $\mathbf{Y}$  into input-output collections of pairs  $\hat{\mathbf{Z}}$  and  $\hat{\mathbf{Y}}$  as follows: the first input to the model,  $\hat{\mathbf{z}}_{1,:}$ , will be given by the stacked vector  $[\mathbf{y}_{1,:}, \dots, \mathbf{y}_{\tau,:}]$  and the first output,  $\hat{\mathbf{y}}_{1,:}$ , will be given by  $\mathbf{y}_{\tau+1,:}$  and similarly for the other data in  $\hat{\mathbf{Z}}$  and  $\hat{\mathbf{Y}}$ , so that:

$$\begin{aligned} [\hat{\mathbf{z}}_{1,:}, \hat{\mathbf{z}}_{2,:}, \dots, \hat{\mathbf{z}}_{n-\tau,:}] &= \\ & [[\mathbf{y}_{1,:}, \mathbf{y}_{2,:}, \dots, \mathbf{y}_{\tau,:}], [\mathbf{y}_{2,:}, \mathbf{y}_{3,:}, \dots, \mathbf{y}_{\tau+1,:}], \dots], \\ [\hat{\mathbf{y}}_{1,:}, \hat{\mathbf{y}}_{2,:}, \dots, \hat{\mathbf{y}}_{n-\tau,:}] &= [\mathbf{y}_{\tau+1,:}, \mathbf{y}_{\tau+2,:}, \dots, \mathbf{y}_{n,:}]. \end{aligned}$$

To perform extrapolation we first train the model on the modified dataset  $(\hat{\mathbf{Z}}, \hat{\mathbf{Y}})$ . By referring to the semi-described formulation described in Section 3.1, we assign all training inputs to the observed set  $\mathcal{O}$ . After training, we can perform iterative prediction to find a future sequence  $\hat{\mathbf{Z}}_* := [\mathbf{y}_{n+1,:}, \mathbf{y}_{n+2,:}, \dots]$  where, similarly to the approach taken by Girard et al. [2003], the predictive variance in each

Figure 2: MSE for predictions obtained by different methods on semi-described learning. GP cannot handle partial observations, thus the uncertainty ( $2\sigma$ ) is constant; for clarity, the errorbar is plotted separately on the right of the dashed vertical line (for nonsensical  $x$  values). The results for simulated data are obtained from 4 trials. For clarity, the limits on the  $y$ -axis are fixed, so when the errors become too big for certain methods they get off the chart. The errorbars for the GPLVM-based approach are also too large and not plotted. The full picture is given in figure 5 (Appendix).

step is accounted for and propagated in the subsequent predictions. The algorithm makes iterative 1-step predictions in the future; initially, the output  $\hat{\mathbf{z}}_{1,*} := \mathbf{y}_{n+1,:}$  will be predicted (given the training set) with predictive variance  $\hat{\mathbf{S}}_{*,1}$ . In the next step, the “observations” set will be augmented to include the distribution of predictions over  $\mathbf{y}_{n+1,:}$ , by defining  $q(\mathbf{x}_{n+1,:} | \hat{\mathbf{z}}_{1,*}) = \mathcal{N}(\mathbf{x}_{n+1,:} | \hat{\mathbf{z}}_{*,1}, \hat{\mathbf{S}}_{*,1})$ , and so on. This simulation process can be seen as constructing a predictive sequence step by step, i.e. the newly inserted input points constitute parts of the (test) predictive sequence and not training points. Therefore, this procedure can be seen as an iterative version of semi-described learning.

Note that it is straightforward to extend this model by applying this auto-regressive mechanism in a latent space of a stacked model or, more generally, as a deep GP [Damianou and Lawrence, 2013]. By additionally introducing functions that map from this latent space nonlinearly to an observation space, we obtain a fully nonlinear state space model in the manner of Deisenroth et al. [2012]. For our model, uncertainty is encoded in both the states and the nonlinear transition functions. Correct propagation of uncertainty is vital in well calibrated models of future system behavior, and automatic determination of the structure of the model (e.g. the window size) can be informative in describing the order of the underlying dynamical system.

### DEMONSTRATION: ITERATIVE FORECASTING

Here we demonstrate our framework in the simulation of a state space model. We consider the Mackey-Glass chaotic time series, a standard benchmark which was also considered by Girard et al. [2003]. The data is one-dimensional so that the timeseries can be represented as pairs of values  $\{\mathbf{y}, \mathbf{t}\}$ ,  $t = 1, 2, \dots, n$  and simulates the process:

$$\frac{d\zeta(t)}{dt} = -b\zeta(t) + \alpha \frac{\zeta(t-T)}{1+\zeta(t-T)^{10}}, (\alpha, b, T) = (0.2, 0.1, 17).$$

Obviously the generating process is very non-linear, rendering this dataset challenging. We trained the autoregressive model on data from this series, where the modified dataset  $\{\hat{\mathbf{z}}, \hat{\mathbf{y}}\}$  was created with  $\tau = 18$  and we used the first  $4\tau = 72$  points to train the model and predicted the subsequent 1110 points through iterative free simulation.

We compared our method with a “naive autoregressive” GP model where the input-output pairs were given by the autoregressive modification of the dataset  $\{\hat{\mathbf{z}}, \hat{\mathbf{y}}\}$ . For that model, the predictions are made iteratively and the predicted values after each predictive step are added to the “observation” set. However, this standard GP model has no straight forward way of incorporating/propagating the uncertainty and, therefore, the input uncertainty is zero for every step of the iterative predictions. We also compared against the method of Girard et al. [2003]<sup>2</sup>, denoted in the plots as “GP<sub>uncert</sub>”. Figure 3 shows the results for the last 310 steps (i.e.  $t = 800$  onwards) of the full free simulation (1110-step ahead forecasting); figure 6 (Appendix) gives a more complete picture. As can be seen in the variances plot, both our method and GP<sub>uncert</sub> are more robust in handling the uncertainty throughout the predictions; the “naive” GP method underestimates the uncertainty. Consequently, as can be seen in figure 6, in the first few predictions all methods give the same answer. However, once the predictions of the “naive” method diverge a little by the true values, the error is carried on and amplified due to underestimating the uncertainty. On the other hand, GP<sub>uncert</sub> perhaps overestimates the uncertainty and, therefore, is more conservative in its predictions, resulting in higher errors. Quantification of the error is shown in Table 1 (Appendix).

<sup>2</sup>We implemented the basic moment matching approach, although in the original paper the authors use additional approximations, namely Taylor expansion around the predictive moments.

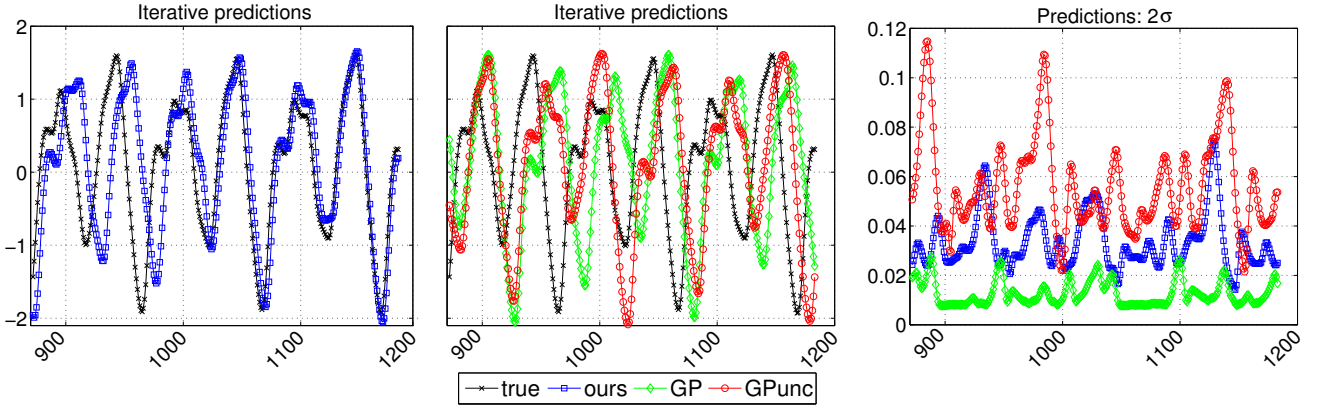

Figure 3: Chaotic timeseries: forecasting 1110 steps ahead by iterative prediction. The first 800 steps are not shown here, but figure 6 (Appendix) gives the complete picture. Comparing: a “naive autoregressive” GP which does not propagate (and hence underestimates) the uncertainties; the method of Girard et al. [2003], referred to as  $\text{GP}_{\text{uncert}}$ ; and our approach, which closely tracks the true test sequence until the last steps of the extrapolation. The comparative depiction of the predictions is split into two plots (for clarity), left and center. The rightmost plot shows the predictive uncertainties ( $2\sigma$ ).  $x$ -axis is the prediction step ( $t$ ) and  $y$ -axis is the function value,  $f(t)$ .

### 3.3 SEMI-SUPERVISED LEARNING

In this section we study semi-supervised learning which, in contrast to semi-described learning, is for handling missing values in the outputs. This scenario is typically encountered in classification settings. Therefore, we introduce the sets  $\{\mathcal{L}, \mathcal{M}\}$  that index respectively the *labelled* and *missing* (unlabelled) rows of the outputs (labels)  $\mathbf{Y}$ . Accordingly, the full dataset is split so that  $\mathbf{Z} = (\mathbf{Z}^{\mathcal{L}}, \mathbf{Z}^{\mathcal{M}})$  and  $\mathbf{Y} = (\mathbf{Y}^{\mathcal{L}}, \mathbf{Y}^{\mathcal{M}})$ , where  $\mathbf{Z}$  is now fully observed. The task is then to devise a method that improves classification performance by using both labelled and unlabelled data.

Inspired by Kingma et al. [2014] we define a semi-supervised GP framework where features are extracted from all available information and, subsequently, are given as inputs to a discriminative classifier. Specifically, using the whole input space  $\mathbf{Z}$ , we learn a low-dimensional latent space  $\mathbf{X}$  through an approximate posterior  $q(\mathbf{X}) \approx p(\mathbf{X}|\mathbf{Z})$ . Obviously, this specific case where the input space is uncertain but totally unobserved (i.e. a latent space) just reduces to the Bayesian GP-LVM model. Notice that the posterior  $q(\mathbf{X})$  is no longer constrained with  $\mathbf{Z}$  but, rather, directly approximates  $p(\mathbf{X}|\mathbf{Z})$ , since we now have a forward *probabilistic* mapping from  $\mathbf{X}$  to  $\mathbf{Z}$  and  $\mathbf{Z}$  is treated as a random variable with  $p(\mathbf{Z}|\mathbf{X})$  being a Gaussian distribution, i.e. exactly the same setting used in the GP-LVM. Since there is one-to-one correspondence between  $\mathbf{X}$ ,  $\mathbf{Z}$  and  $\mathbf{Y}$ , we can notationally write  $\mathbf{X} = (\mathbf{X}^{\mathcal{L}}, \mathbf{X}^{\mathcal{M}})$ . Further, since we assume that  $q(\mathbf{X})$  is factorised across datapoints, we can write  $q(\mathbf{X}) = q(\mathbf{X}^{\mathcal{L}})q(\mathbf{X}^{\mathcal{M}})$ .

In the second step of our semi-supervised algorithm, we train a discriminative classifier from  $q(\mathbf{X}^{\mathcal{L}})$  to the observed labelled space,  $\mathbf{Y}^{\mathcal{L}}$ . The main idea is that, by including the inputs  $\mathbf{Z}^{\mathcal{M}}$  in the first learning step, we manage to de-

fine a better latent embedding from which we can extract a more useful set of features for the discriminative classifier. Notice that what we would ideally use as input to the discriminative classifier is a whole distribution, rather than single point estimates. Therefore, we wish to take advantage of the associated uncertainty; specifically, we can populate the labelled set by sampling from the distribution  $q(\mathbf{X}^{\mathcal{L}})$ . For example, if a latent point  $\mathbf{x}_{i,:}^{\mathcal{L}}$  corresponds to the input-output pair  $(\mathbf{z}_{i,:}^{\mathcal{L}}, \mathbf{y}_{i,:}^{\mathcal{L}})$ , then a sample from  $q(\mathbf{x}_{i,:}^{\mathcal{L}})$  will be assigned the label  $\mathbf{y}_{i,:}^{\mathcal{L}}$ .

The two inference steps described above are graphically depicted in Figure 1c. This is exactly the same setting suggested by Kingma et al. [2014], but here we wish to investigate its applicability in a non-parametric, Gaussian process based framework. The very encouraging results reported below point towards the future direction of applying this technique in the framework of deep Gaussian processes [Damianou and Lawrence, 2013], so as to be able to compare to [Kingma et al., 2014] who considered deep, generative (but nevertheless parametric) models.

### DEMONSTRATION

We evaluated our semi-supervised GP algorithm in two datasets: firstly, we considered 2000 examples from the USPS handwritten digit database [Hull, 1994]. These examples contained the digits  $\{0, 2, 4, 6\}$  and were split so that 800 instances were used as a test set. From the remaining 1200 instances, we selected various portions to be labelled and the rest to be unlabelled. The experiment was repeated 8 times (each time involving different subsets due to different random seeds), so that we can include errorbars in our plots. Secondly, we considered the oil flow data [Bishop and James, 1993] that consist of 1000, 12 dimen-

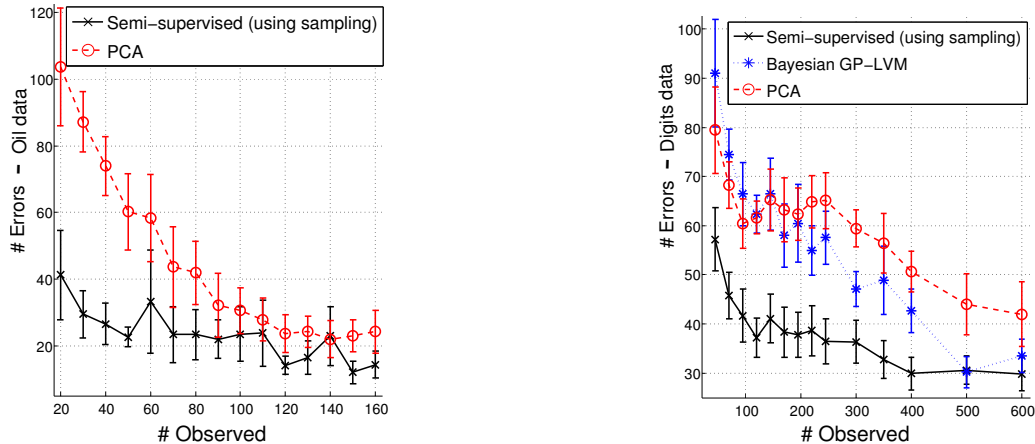

Figure 4: Plots of the number of incorrectly classified test points as a function of  $|\mathbf{Z}^{\mathcal{L}}|$ . Multiple trials were performed, but the resulting errorbars are shown at one standard deviation. In small training sets large errorbars are expected because, occasionally, very challenging instances/outliers can be included and result in high error rates (for all methods) that affect the overall standard deviation. The Bayesian GP-LVM baseline struggled with small training sets and performed very badly in the oil dataset; thus, it is not plotted for clarity.

sional observations belonging to three known classes corresponding to different phases of oil flow. In each of the 10 performed trials, 700 instances were used as a test set whereas the rest were split to different proportions of labelled/unlabelled sets. Multi-label data can also be handled by our method, but this case was not considered here.

Our method learned a low-dimensional embedding  $q(\mathbf{X})$  from all available inputs, and a logistic regression classifier was then trained from the relevant parts of the embedding to the corresponding class space. We experimented with taking different numbers of samples from  $q(\mathbf{X}^{\mathcal{L}})$  for populating the initial labelled set; the difference after increasing over 6 samples was minimal. Also, when using only the mean of  $q(\mathbf{X}^{\mathcal{L}})$  (as opposed to using multiple samples) we obtained worse results (especially in the digits data), but this method still outperformed the baselines. We compared with training the classifier on features learned by (a) a standard Bayesian GP-LVM and (b) PCA, both applied in  $\mathbf{Z}^{\mathcal{L}}$ . Both of the baselines do not take  $\mathbf{Z}^{\mathcal{M}}$  into account, nor do they populate small training sets using sampling. Figure 4 presents results suggesting that our approach manages to effectively take into account unlabelled data. The gain in performance is significant, and our method copes very well even when labelled data is extremely scarce. Notice that all methods would perform better if a more robust classifier was used, but logistic regression was a convenient choice for performing multiple trials fast. Therefore, our conclusions can be safely drawn from the obtained relative errors, since all methods were compared on equal footing.

## 4 DISCUSSION AND FUTURE WORK

We have defined semi-described learning as the scenario where missing and uncertain values occur in the inputs. We

considered semi-described problems to be part of a general class of missing value problems that also includes semi-supervised learning and auto-regressive future state simulation. A principled method for including input uncertainty and partial inputs in Gaussian process models was also introduced to solve these problems within a single, coherent framework. We explicitly represent this uncertainty as approximate posterior distributions which are variationally constrained. This allowed us to further define algorithms for casting the missing value problems as particular instances of learning pipelines which use our variationally constrained GP formulation as a building block. Our algorithms resulted in significant performance improvement in forecasting, regression and classification. We believe that our contribution paves the way for building powerful models for representation learning from real-world, heterogeneous data. In particular, this can be achieved by combining our method with deep Gaussian process models [Damianou and Lawrence, 2013] that use relevance determination techniques [Damianou et al., 2012], so as to consolidate semi-described hierarchies of features that are gradually abstracted to concepts. We plan to investigate the application of these models in settings where control [Deisenroth et al., 2014] or robotic systems learn by simulating future states in an auto-regressive manner and by using incomplete data with minimal human intervention. Transfer learning is another promising direction for applying these models.

## ACKNOWLEDGEMENTS

## Abstract

We give a detailed characterization of optimal trades under budget constraints in a prediction market with a cost-function-based automated market maker. We study how the budget constraints of individual traders affect their ability to impact the market price. As a concrete application of our characterization, we give sufficient conditions for a property we call *budget additivity*: two traders with budgets  $B$  and  $B'$  and the same beliefs would have a combined impact equal to a single trader with budget  $B + B'$ . That way, even if a single trader cannot move the market much, a crowd of like-minded traders can have the same desired effect. When the set of payoff vectors associated with outcomes, with coordinates corresponding to securities, is affinely independent, we obtain that a generalization of the heavily-used logarithmic market scoring rule is budget additive, but the quadratic market scoring rule is not. Our results may be used both descriptively, to understand if a particular market maker is affected by budget constraints or not, and prescriptively, as a recipe to construct markets.

## 1 INTRODUCTION

A prediction market is a central clearinghouse for people with differing opinions about the likelihood of an event—say Hillary Clinton to win the 2016 U.S. Presidential election—to trade monetary stakes in the outcome with one another. At equilibrium, the price to buy a contract paying \$1 if Clinton wins reflects a consensus of sorts on the probability of the event. At that price, and given the wagers already placed, no agent is willing to push the price further up or down. Prediction markets have a good track record of forecast accuracy in many domains [11, 19].

The design of *combinatorial* markets spanning multiple

logically-related events raises many interesting questions. What information can be elicited—the full probability distribution, or specific properties of the distribution? What securities can the market allow traders to buy and sell? How can the market support and ensure a variety of trades? For example, in addition to the likelihood of Clinton winning the election, we may want to elicit information about the distribution of her electoral votes.<sup>1</sup> If we create one security for each possible outcome between 0 and 538, each paying \$1 iff Clinton gets exactly that many electoral votes, the market is called *complete*, allowing us to elicit a full probability distribution. Alternatively, if we create just two securities, one paying out  $\$x$  if Clinton wins  $x$  electoral votes, and the other paying out  $\$x^2$ , we cannot elicit a full distribution, but we can still elicit the mean and variance of the number of electoral votes.

When agents are constrained in how much they can trade only by risk aversion, prediction market prices can be interpreted as a weighted average of traders' beliefs [2, 20], a natural reflection of the “wisdom of the crowd” with a good empirical track record [14] and theoretical support [2]. However, when agents are budget constrained, discontinuities and idiosyncratic results can arise [7, 16] that call into question whether the equilibrium prices can be trusted to reflect any kind of useful aggregation.

We consider prediction markets with an automated market maker [1, 4, 13] that maintains standing offers to trade every security at some price. Unlike a peer-to-peer exchange, all transactions route through the market maker. The common market makers have bounded loss and are (myopically) incentive compatible: the best (immediate) strategy is for a trader to move the market prices of all securities to equal his own belief. The design of such an automated market maker boils down to choosing a convex *cost function* [1]. This amount of design freedom presents an opportunity to seek cost functions that satisfy additional desiderata such as computational tractability [1, 6].

---

<sup>1</sup> A U.S. Presidential candidate receives a number of electoral votes between 0 and 538. The candidate who receives a plurality of electoral votes wins the election.

Most of the literature assumes either risk-neutral or risk-averse traders with unbounded budgets. In this paper, we consider how agents with budget constraints trade in such markets, a practical reality in almost all prediction markets denominated in both real and virtual currencies. Our results help with a systematic study of the market’s *liquidity parameter*, or the parameter controlling the sensitivity of prices to trading volume. Setting the liquidity is a nearly universal practical concern and, at present, is more (black) art than science. We adopt the notion of the “natural budget constraint” introduced by Fortnow and Sami [8]: the agent is allowed only those trades for which the maximum loss for any possible outcome does not exceed the budget.

The main contribution of this paper is a rich, geometric characterization of the impact of budget constraints. Price vectors, outcomes and trader beliefs are embedded in the space of the same dimension as the number of securities. Outcome vectors enumerate security payoffs; belief vectors enumerate the traders’ expectations of payoffs. We consider, for a fixed belief, the locus of the resulting price vectors of an optimal trade as a function of the budget. We show that the price vector moves in the convex hull of the belief and the set of tight outcomes, in a direction that is perpendicular to the set of tight outcomes. We also introduce the concept of *budget additivity*: two agents with budgets  $B$  and  $B'$  and the same beliefs have the same power to move the prices as a single agent with the same belief and budget  $B+B'$ . An absence of budget additivity points to an inefficiency in incorporating information from the traders. We show that budget additivity is a non-trivial property by giving examples of market makers that do not satisfy budget additivity. We give a set of sufficient conditions on the market maker and the set of securities offered which guarantee budget additivity. Further, for two of the most commonly used market makers (the quadratic and logarithmic market scoring rules), we show sufficient conditions on the set of securities that guarantee budget additivity.

Of greatest practical interest is the application of our results to markets consisting of several independent questions, with each question priced according to a separate logarithmic market scoring rule. This setup constitutes a de facto industry standard, and the companies that use (or used) it include Inkling Markets,<sup>2</sup> Consensus Point,<sup>3</sup> Microsoft and Yahoo! [17]. Our Theorems 5.6 and 5.8 show that these markets are budget additive.

Previously, Fortnow and Sami [8] considered a different question: do budget-constrained bidders always move the market prices in the direction of their beliefs? They showed that the answer to this is no: there always exist market prices, beliefs and budgets such that the direction of price movement is not towards the belief. We give a richer char-

acterization of how the market prices move in the presence of budget constraints, by charting the path the prices take with increasing budgets. The impossibility result of Fortnow and Sami [8] can be easily derived from our characterization (see Appendix D).<sup>4</sup>

A designer of a prediction market has a lot of freedom but little guidance, and our results can be used both descriptively and prescriptively. As a descriptive tool, our results enable us to analyze commonly used market makers and understand if budget constraints hamper information aggregation in these markets. As a prescriptive tool, our results can be used to construct markets that are budget additive. In particular, we speculate that budget additivity simplifies the choice of the liquidity parameter in the markets, because it allows considering trader budgets in aggregate.

**Proof overview and techniques.** Our analysis borrows heavily from techniques in convex analysis and builds on the notion of Bregman divergence. We use the special case of Euclidean distance (corresponding to a quadratic market scoring rule) to form our geometric intuition which we then extend to arbitrary Bregman divergences. For the sake of an example, consider a complete market over a finite set of outcomes, where the market prices lie in a simplex, exactly coinciding with the set of probability distributions over outcomes. Every possible outcome imposes a constraint on the set of prices to which a trader can move the market, because the trader is not allowed to exceed the budget if that outcome occurs. The prices satisfying this constraint form a ball with the outcome at its center. The set of feasible prices to which the trader can move the market is therefore the intersection of these balls (see Figure 1).

The key structural result we obtain is the chart of the price movement. Suppose that there is an infinite sequence of agents with infinitesimally small budgets all with the same belief. What is the path along which the prices move from some initial values? This is determined by the agents’ belief and the set of budget constraints that are tight at any point, corresponding to the highest risk outcomes (outcomes with the highest potential loss). We show that the price vector can always be written as a convex combination of these highest risk outcomes and the agents’ belief. Further, the market prices move in a direction that is perpendicular to the affine space of these outcomes.

The agents’ belief partitions the simplex interior into regions, where each region is the interior of the convex hull of the agent belief and a particular subset of outcomes. For a region that is full-dimensional, every interior point can be uniquely written as a convex combination of the agent belief and all except one outcome. Assume that the current price vector lies in this region. In the anticipation of the further development, we call this outcome *profitable* and others *risky*. Motivated by the characterization above, we

<sup>4</sup>The full version of this paper on arXiv includes the appendix.

Figure 1: *Left*:  $\circ$  —current state,  $\times$  —belief,  $\diamond$  —optimal action for a given belief and budget. Three circles bound the allowed final states for budget 0.1. We plot optimal actions for two different beliefs. *Right*: A path from the initial state to the belief, consisting of optimal actions for increasing budgets.

move perpendicular to the risky outcomes in the direction towards the agents’ belief. As a result, we increase the risk of risky outcomes (equally for all outcomes), while getting closer to the one profitable outcome (and hence increasing its profit). The characterization then guarantees that the prices along this path are indeed those chosen by traders at increasing budgets, because the risky outcomes yield tight constraints.

We would like the same to be true for the lower dimensional regions as well; that is, for the set of tight constraints to be exactly the corresponding set of outcomes defining the convex hull. In fact, this property is sufficient to guarantee budget additivity. The markets for which the tight constraints are exactly the minimal set of outcomes that define the region the price lies in are budget additive. (We conjecture that the converse holds as well.) The entire path is then as follows: w.l.o.g. you start at a full-dimensional region, move along the perpendicular until you hit the boundary of the region and you are in a lower-dimensional region, move along the perpendicular in this lower-dimensional region, and so on until you reach the belief (see Figure 1). The set of tight constraints is monotonically decreasing. We show that such markets are characterized by a certain *acute angles assumption* on the set of possible outcomes. Loosely speaking, this assumption guarantees that outcomes outside the minimal set behave as the profitable outcome in the above example.

**Other related work.** There is a rich literature on scoring rules and prediction markets. Two of the most studied scoring rules are the quadratic scoring rule [3] and the logarithmic market scoring rule [13]. We consider cost-function-based prediction markets [4, 12], a fully general class under reasonable assumptions [1, 5]. Their equivalence with proper scoring rules has been implicitly noted by Gneiting and Raftery [10]. Several authors have studied relationships between utility functions and price dynamics in prediction markets, drawing a parallel to online learning [2, 5, 9]. Our analysis touches on the problem of setting the

market maker’s liquidity parameter [15, 17], which determines how (in)sensitive prices are to trading volume. With budget additivity, the market designer can optimize liquidity according to aggregate budgets, without worrying about how budgets are partitioned among traders.

## 2 PRELIMINARIES

**Securities and payoffs.** Consider a probability space with a finite set of outcomes  $\Omega \subseteq \mathbb{R}^n$ . A *security* is a financial instrument whose payoff depends on the realization of an outcome in  $\Omega$ . In other words, the payoff of a security is a random variable of the probability space. We consider trading with  $n$  securities corresponding to  $n$  coordinates of the outcomes  $\omega \in \Omega$ . A security can be traded before the realization is observed with the intention that the price of a security serves as a prediction for the expected payoff, i.e., the expected value of the corresponding coordinate.

**Cost function, prices and utilities.** An *automated market maker* always offers to trade securities, for the right price. In fact the price vector is the current prediction of the market maker for the expectation of  $\omega$ . A cost function based market maker is based on a differentiable convex *cost function*,  $C : \mathbb{R}^n \rightarrow \mathbb{R}$ . It is a scalar function of an  $n$ -dimensional vector  $q \in \mathbb{R}^n$  representing the *number of outstanding shares*<sup>5</sup> for our  $n$  securities. We also refer to  $q$  as the *state* of the market.

The vector of *instantaneous prices* of the securities is simply the gradient of  $C$  at  $q$ , denoted by  $p(q) := \nabla C(q)$ . The prices of securities change continuously as the securities are traded, so it is useful to consider the cost of trading a given quantity of securities. The cost of buying  $\delta \in \mathbb{R}^n$  units of securities (where a negative value corresponds to selling) is determined by the path integral  $\int_{\pi} p(\bar{q}) \cdot d\bar{q} = C(q + \delta) - C(q)$ , where  $\pi$  is any smooth

<sup>5</sup>We allow trading fractions of a security. Negative values correspond to short-selling.

curve from  $q$  to  $q + \delta$ .

When the outcome  $\omega$  is realized, the vector of  $\delta$  units of securities pays off an amount of  $\delta \cdot \omega$ . Thus, the realized utility of a trader whose trade  $\delta$  moved the market state from  $q$  to  $q' = q + \delta$  is

$$U(q', \omega; q) := (q' - q) \cdot \omega - C(q') + C(q) .$$

We make a standard assumption that the maximum achievable utility, which is also the maximum loss of the market maker, is bounded by a finite constant (in Section 4, we introduce a standard approach to check this easily). Let  $\mathcal{M}$  be the convex hull of the payoff vectors,  $\mathcal{M} := \text{conv}(\Omega)$ . It is easy to see that  $\mathcal{M}$  contains exactly the vectors  $\mu \in \mathbb{R}^n$  which can be realized as expected payoffs  $\mathbb{E}[\omega]$  for some probability distribution over  $\Omega$ . For a trader who believes that  $\mathbb{E}[\omega] = \mu$ , the expected utility takes form

$$U(q', \mu; q) := \mathbb{E}[U(q', \omega; q)] = (q' - q) \cdot \mu - C(q') + C(q) .$$

Throughout, we consider a single *myopic* trader who trades as if he were the last to trade. A key property satisfied by expected utility is *path independence*: for any  $q, \bar{q}, q' \in \mathbb{R}^n$ ,  $U(q', \mu; \bar{q}) + U(\bar{q}, \mu; q) = U(q', \mu; q)$ , that is, risk-neutral traders have no incentive to split their trades. For a risk-neutral trader,  $q' \in \mathbb{R}^n$  is an optimal action if and only if  $\mu = \nabla C(q') = p(q')$  (this follows from the first-order optimality conditions). In other words, the trader is incentivized to move the market to the prices corresponding to his belief as long as such prices exist. In general, there may be multiple states yielding the same prices, so the inverse map  $p^{-1}(\mu)$  returns a *set*, which can be empty if no state yields the price vector  $\mu$ .

Commonly-used cost functions include the quadratic cost, logarithmic market-scoring rule (LSMR) and the log-partition function. They are described in detail in Appendix A. The quadratic cost is defined by  $C(q) = \frac{1}{2} \|q\|_2^2$  and  $p(q) = q$ . Log-partition function is defined as  $C(q) = \ln(\sum_{\omega \in \Omega} e^{q \cdot \omega})$ . It subsumes LSMR as a special case for the *complete market* with the outcomes corresponding to vertices of the simplex. The prices under log-partition cost correspond to the expected value of  $\omega$  under the distribution  $P_q(\omega) = e^{q \cdot \omega - C(q)}$  over  $\Omega$ , i.e.,  $p(q) = \mathbb{E}_{P_q}[\omega]$ .

**Budget constraints.** Trading in prediction markets needs an investment of capital. It is possible that an agent loses money on the trade, in particular  $U(q', \omega; q)$  could be negative for some  $\omega$ . One restriction on how an agent trades could be that he is unable to sustain a big loss, due to a budget constraint. We consider the notion of *natural budget constraint* defined by Fortnow and Sami [8] which states that the loss of the agent is at most his budget, for all  $\omega \in \Omega$ . Given a starting market state  $q_0$  and a budget of  $B \geq 0$ , a trader with the belief  $\mu \in \mathcal{M}$  then solves the problem:

$$\begin{aligned} \max_{q \in \mathbb{R}^n} & U(q, \mu; q_0) \\ \text{s.t.} & U(q, \omega; q_0) \geq -B \quad \forall \omega \in \Omega . \end{aligned} \quad (2.1)$$

For quadratic costs, each constraint corresponds to a sphere with one of the outcomes at its center, so the feasible region is an intersection of these spheres. We will later see that this generalizes to an intersection of balls w.r.t. a Bregman divergence for general costs.

In general, there may be multiple  $q$  optimizing this objective. In the following definition we introduce notation for various solution sets we will be analyzing. The belief  $\mu$  is fixed throughout most of the discussion, so we suppress the dependence on  $\mu$ .

**Definition 2.1** (Solution sets). Let  $\hat{Q}(B; q_0)$  denote the set of solutions of Convex Program (2.1) for a fixed initial state and budget. Let  $\hat{Q}(q_0) = \bigcup_{B \geq 0} \hat{Q}(B; q_0)$  denote the set of solutions of (2.1) for a fixed initial state across all budgets. Let  $\hat{Q}(\nu; q_0) = p^{-1}(\nu) \cap \hat{Q}(q_0)$  denote the set of states  $q$  that optimize (2.1) for some budget  $B$  and yield the market price vector  $\nu$ .

The next theorem shows that solutions for a fixed initial state and budget always yield the same price vector. It is proved in Appendix B.

**Theorem 2.2.** *If  $q, q' \in \hat{Q}(B; q_0)$ , then  $p(q) = p(q')$ .*

**Geometry of linear spaces.** We finish this section by reviewing a few standard geometric definitions we use in next sections. Let  $X \subseteq \mathbb{R}^n$ . Then  $\text{aff}(X)$  denotes the *affine hull* of the set  $X$  (i.e., the smallest affine space including  $X$ ). We write  $X^\perp$  to denote the *orthogonal complement* of  $X$ :  $X^\perp := \{u \in \mathbb{R}^n : u \cdot (x' - x) = 0 \text{ for all } x, x' \in X\}$ . We use the convention  $\emptyset^\perp = \mathbb{R}^n$ . A set  $\mathcal{K} \in \mathbb{R}^n$  is called a *cone* if it is closed under multiplication by positive scalars. If a cone is convex, it is also closed under addition. Since  $\Omega$  is finite, the realizable set  $\mathcal{M} = \text{conv}(\Omega)$  is a polytope. Its boundary can be decomposed into *faces*. More precisely,  $X \subseteq \Omega$ ,  $X \neq \emptyset$ , forms a *face* of  $\mathcal{M}$  if  $X$  is the set of maximizers over  $\Omega$  of some linear function.<sup>6</sup> We also view  $X = \emptyset$  as a face of  $\mathcal{M}$ . With this definition, for any two faces  $X, X'$ , also their intersection  $X \cap X'$  is a face.

### 3 CHARACTERIZING SOLUTION SETS

We start with the optimality (KKT) conditions for the Convex Program (2.1), as characterized by the next lemma. One of the key conditions is that the solution prices must be in the convex hull of the belief  $\mu$  and all the  $\omega$ 's for which the budget constraints are *tight*. The set of tight constraints is always a face of the polytope  $\mathcal{M}$ . We allow an empty set as a face, which corresponds to the case when none of the constraints are tight and the solution prices coincide with  $\mu$ . The proof follows by analyzing KKT conditions (see Appendix C of the full version for details).

<sup>6</sup>Strictly speaking, this is the definition of an *exposed face*, but all faces of a polytope are exposed, so the distinction does not matter here. The exposed face is typically defined to be  $\text{conv}(X)$ , but in this paper, it is more convenient to work with  $X$  directly.

**Lemma 3.1** (KKT lemma). *Let  $q_0 \in \mathbb{R}^n$ . Then  $q \in \hat{Q}(B; q_0)$  if and only if there exists a face  $X \subseteq \Omega$  such that the following conditions hold:*

- (a)  $U(q, x; q_0) = U(q, x'; q_0)$ , or equivalently  $(q - q_0) \cdot (x' - x) = 0$ , for all  $x, x' \in X$
- (b)  $U(q, \omega; q_0) \geq U(q, x; q_0)$ , or equivalently  $(q - q_0) \cdot (\omega - x) \geq 0$ , for all  $x \in X, \omega \in \Omega \setminus X$
- (c)  $p(q) \in \text{conv}(X \cup \{\mu\})$
- (d)  $B = -U(q, x; q_0)$  for all  $x \in X$  if  $X \neq \emptyset$ , or  $B \geq \max_{\omega \in \Omega} [-U(q, \omega; q_0)]$  if  $X = \emptyset$

where conditions (a) and (b) hold vacuously for  $X = \emptyset$ .

The condition (a) requires that  $q - q_0$  be orthogonal to the active set  $X$ . The set of points satisfying conditions (a) and (c) will be called the Bregman perpendicular and will be defined in the next section. The condition (b) is a statement about acuteness of the angle between  $q - q_0$  (the perpendicular) and the outcomes. It will be the basis of our *acute angles* assumption. The condition (d) just states how the budget is related to the active set  $X$ .

**Witness cones and minimal faces.** We now introduce some notation to help us state reinterpretations of the conditions in Lemma 3.1. First of all, given a face  $X$ , what is the set of  $q$ 's that satisfy conditions (a) and (b)? This is captured by what we call the *witness cone*.

**Definition 3.2.** The *witness cone* for a face  $X \subseteq \Omega$  is defined as  $\mathcal{K}(X) := \{u \in \mathbb{R}^n : u \cdot (\omega - x) \geq 0 \text{ for all } x \in X, \omega \in \Omega\}$  if  $X \neq \emptyset$ , and  $\mathcal{K}(X) := \mathbb{R}^n$  if  $X = \emptyset$ .

The following two properties of witness cones are immediate from the definition:

- *Anti-monotonicity:* if  $X \subseteq X'$ , then  $\mathcal{K}(X) \supseteq \mathcal{K}(X')$ .
- *Orthogonality:*  $\mathcal{K}(X) \subseteq X^\perp$ .

A state  $q$  satisfies conditions (a) and (b) for a given face  $X$  if and only if  $q - q_0 \in \mathcal{K}(X)$ . Now given a state  $q$ , consider the set of faces that could satisfy condition (c). This set has a useful structure, namely that there is a unique minimal face (proved in Appendix C of the full version).

**Definition 3.3.** Given a price vector  $\nu \in \mathcal{M}$ , the *minimal face* for  $\nu$  is the minimal face  $X$  (under inclusion) s.t.  $\nu \in \text{conv}(X \cup \{\mu\})$ . The minimal face for  $\nu$  is denoted as  $X_\nu$ .

With the existence of a minimal face and the anti-monotonicity of the witness sets, it follows that if  $q$  and  $X$  satisfy conditions (a), (b) and (c), then so do  $q$  and  $X_{p(q)}$ . Thus we obtain the following version of Lemma 3.1 (proved in Appendix C of the full version).

**Theorem 3.4** (Characterization of Solution Sets).  $q \in \hat{Q}(q_0)$  if and only if  $q \in [q_0 + \mathcal{K}(X_{p(q)})]$ .

Using Theorem 3.4, we immediately obtain a characterization of when a price vector  $\nu$  could be the price vector of an optimal solution to (2.1).

**Corollary 3.5.**  $\hat{Q}(\nu; q_0) = p^{-1}(\nu) \cap [q_0 + \mathcal{K}(X_\nu)]$ . In particular,  $\nu$  is the price vector of an optimal solution to (2.1) if and only if  $p^{-1}(\nu) \cap [q_0 + \mathcal{K}(X_\nu)] \neq \emptyset$ .

We now study an example using the above characterization. More examples can be found in Appendix E of the full version.

**Example 3.6** (Quadratic cost on an obtuse triangle; see Example E.2 in the full version for details). Consider the following outcome space, belief, and the sequence of market states (depicted in Figure 2):

$$\begin{aligned} \omega_1 &= (0.0, 0.0) & q_0 = \nu_0 &= \frac{11}{14}\omega_2 + \frac{3}{14}\omega_3 \\ \omega_2 &= (1.8, 0.0) & q_1 = \nu_1 &= \frac{1}{3}\omega_2 + \frac{2}{3}\mu \\ \omega_3 &= (6.0, 4.2) & q_2 = \nu_2 &= \frac{1}{9}\omega_1 + \frac{8}{9}\mu \\ \mu = q_\mu &= (2.7, 1.8) & q_3 = \nu_3 &\approx \frac{1}{19}\omega_1 + \frac{18}{19}\mu \end{aligned}$$

Using the KKT lemma, we can show for  $j = 1, 2, 3$ , that  $q_j = \nu_j$  is an optimal action at  $q_{j-1} = \nu_{j-1}$  under belief  $\mu$ , with the corresponding budgets as:

|                        | $\omega_1$ | $\omega_2$ | $\omega_3$ |                    |
|------------------------|------------|------------|------------|--------------------|
| $U(q_1, \cdot; q_0)$   | 0.45       | -0.09      | -0.09      | $B_{01} = 0.09$    |
| $U(q_2, \cdot; q_1)$   | -0.56      | -0.56      | 1.12       | $B_{12} = 0.56$    |
| $U(q_3, \cdot; q_2)$   | -0.565     | -0.28      | 0.82       | $B_{23} = 0.565$   |
| $U(q_\mu, \cdot; q_0)$ | -1.215     | -1.215     | 2.565      | $B_{0\mu} = 1.215$ |

The above table also shows that the budget  $B_{0\mu} = 1.215$  suffices to move directly from  $q_0$  to  $q_\mu$ . However, note that the sum  $B_{01} + B_{12} + B_{23} = 1.215 = B_{0\mu}$ , but  $\nu_3 \neq \mu$ , i.e., after the sequence of optimal actions with budgets  $B_{01}$ ,  $B_{12}$ , and  $B_{23}$ , the market is still not at the belief shared by all agents, even though with the budget  $B_{0\mu}$ , it would have reached it.

**Budget additivity.** The above example suggests that multiple traders with the same belief may have less power in moving the market state towards their belief compared to a single trader with the same belief and the combined budget. Since prediction markets aim to efficiently aggregate information from agents, it is natural to ask under what conditions multiple traders with the same beliefs do have a combined impact equal to a single trader with the combined budget.

Next, we formally define this property as *budget additivity*. We then define the Euclidean version of the acute angles condition that we show is sufficient for budget additivity.

**Definition 3.7** (Budget additivity). We say that a prediction market is budget additive on  $\mathcal{M}' \subseteq \mathcal{M}$  if for all beliefs  $\mu \in \mathcal{M}'$  and all initial states  $q_0 \in p^{-1}(\mathcal{M}')$  the following holds: For any budgets  $B, B' \geq 0$  and any sequence of solutions  $q \in \hat{Q}(B; q_0)$  and  $q' \in \hat{Q}(B'; q)$ , we have  $p(q), p(q') \in \mathcal{M}'$  and  $q' \in \hat{Q}(B + B'; q_0)$ .

In other words, the market is budget additive if the sequence of optimal actions of two agents with the same be-

Figure 2: *Left*: An example of non-additive budgets when payoffs form obtuse angles (see Example 3.6 and its extended version Example E.2 in the full version). *Right*: An examples of a non-linear perpendicular for the log-partition cost.

lief and budgets  $B$  and  $B'$  is also an optimal action of a single agent with the same belief and a larger budget  $B + B'$ . Thanks to Theorem 2.2 we then also obtain that the price vector following the sequence of optimal actions by the two agents is the same as the price vector after the optimal action by an agent with the combined budget (all with the same beliefs).

We now state the acute angles assumption for the Euclidean case, to give an intuition. Our acute angles assumption (Definition 5.1) is a generalization of this. We later show that the acute angles property is sufficient for budget additivity (Theorem 5.2).

**Definition 3.8.** We say that the *Euclidean acute angles* hold for a face  $X$ , if the angle between any point  $\bar{\nu} \in \mathcal{M}$ , its projection on the affine hull of  $X$  and any payoff  $\omega \in \Omega$  is non-obtuse (the angle is measured at the projection).

Based on the above example, one may hypothesize that the obtuse angles are to blame for the lack of budget additivity. In the following sections we will show that this is indeed the case, but that the notion of obtuse/acute angles depends on the Bregman divergence. In particular, the above example would have been budget-additive if we used the log-partition cost instead of the quadratic cost.

## 4 BREGMAN DIVERGENCE AND PERPENDICULARS

We will see next that the utility function  $U$  can be written as the difference of two terms measuring the distance between the belief and the market state before and after the trade. This distance measure is the mixed *Bregman divergence*.<sup>7</sup> To define the Bregman divergence, first let  $C^* : \mathbb{R}^n \rightarrow (-\infty, \infty]$  be the convex conjugate of  $C$  defined as  $C^*(\nu) := \sup_{q' \in \mathbb{R}^n} [q' \cdot \nu - C(q')]$ . Since  $C^*$  is a supremum of linear functions, it is convex lower semi-continuous. Up to a constant, it characterizes the maximum achievable utility on an outcome  $\omega$  for a fixed initial state  $q$

<sup>7</sup>Our notion of Bregman divergence is more general than typically assumed in the literature.

as  $\sup_{q' \in \mathbb{R}^n} U(q', \omega; q) = C^*(\omega) + [C(q) - q \cdot \omega]$ . The term in the brackets is always finite, but  $C^*$  might be positive infinite. We make a standard assumption that  $C^*(\omega) < \infty$  for all  $\omega \in \Omega$ , i.e., that the maximum achievable utility, which is also the maximum loss of the market maker, is bounded by a finite constant. By convexity, this implies that  $C^*(\mu) < \infty$  for all  $\mu \in \mathcal{M}$ . The *Bregman divergence* derived from  $C$  is a function  $D : \mathbb{R}^n \times \mathbb{R}^n \rightarrow (-\infty, \infty]$  measuring the maximum expected utility under belief  $\mu$  at a state  $q$

$$D(q, \mu) := C(q) + C^*(\mu) - q \cdot \mu = \sup_{q' \in \mathbb{R}^n} U(q', \mu; q) .$$

From the convexity of  $C$  and  $C^*$  and the definition of  $C^*$ , it is clear that: (i)  $D$  is convex and lower semi-continuous in each argument separately; (ii)  $D$  is non-negative; and (iii)  $D$  is zero iff  $p(q) = \nabla C(q) = \mu$ . By the bounded loss assumption, Bregman divergence is finite on  $\mu \in \mathcal{M}$ . For  $\mu \in \mathcal{M}$ , we can write

$$U(q', \mu; q) = D(q, \mu) - D(q', \mu) . \quad (4.1)$$

Thus, maximizing the expected utility is the same as minimizing the Bregman divergence between the state  $q'$  and the belief  $\mu$ . From Eq. (4.1) it is also clear that each constraint in (2.1) is equivalent to  $D(q, \omega) \leq D(q_0, \omega) + B$ , and the geometric interpretation is that the agent seeks to find the state closest to his belief, within the intersection of Bregman balls

For the quadratic cost, we have  $C^*(\nu) = \frac{1}{2} \|\nu\|^2$  and  $D(q, \nu) = \frac{1}{2} \|q - \nu\|^2$ , i.e., the Bregman divergence coincides with the Euclidean distance squared. For log-partition cost, we have  $C^*(\nu) = \sum_{\omega \in \Omega} P_\nu(\omega) \ln P_\nu(\omega)$  where  $P_\nu$  is the distribution maximizing entropy among  $P$  satisfying  $\mathbb{E}_P[\omega] = \nu$ . The Bregman divergence is the KL-divergence between  $P_q$  and  $P_\nu$ :  $D(q, \nu) = \text{KL}(P_\nu \| P_q)$ .

**Convex analysis.** We overview a few standard definitions and results from convex analysis. For  $X \subseteq \mathbb{R}^n$ , we write  $\text{ri} X$  for the *relative interior* of  $X$  (i.e., the interior relative to the affine hull). For a convex function  $F : \mathbb{R}^n \rightarrow (-\infty, \infty]$ , we define its *effective domain*

as  $\text{dom } F := \{u \in \mathbb{R}^n : F(u) < \infty\}$  (i.e., the set of points where it is finite). The *subdifferential* of  $F$  at a point  $u$  is the set  $\partial F(u) := \{v \in \mathbb{R}^n : F(u') \geq F(u) + (u' - u) \cdot v \text{ for all } u' \in \mathbb{R}^n\}$ . We say that  $F$  is *subdifferentiable* at  $u$  if  $\partial F(u) \neq \emptyset$ . A standard result of convex analysis states that  $F$  is always subdifferentiable on a superset of  $\text{ri dom } F$ . If  $F$  is not only convex, but also lower semi-continuous, then  $\partial F$  and  $\partial F^*$  are inverses in the sense that  $v \in \partial F(u)$  iff  $u \in \partial F^*(v)$ . If  $F$  is *differentiable* everywhere on  $\mathbb{R}^n$ , then  $F^*$  is strictly convex on  $\text{ri dom } F^*$ .

Let  $\text{im } p := \{p(q) : q \in \mathbb{R}^n\}$  denote the set of prices that can be expressed by market states. The implications for our setting are that: (i)  $C^*$  is subdifferentiable on  $\text{im } p$ ; (ii)  $p^{-1}(\nu) = \partial C^*(\nu)$  for all  $\nu \in \mathbb{R}^n$ ; (iii) all beliefs in  $\text{ri dom } C^*$  can be expressed by some state  $q$ ; (iv)  $C^*$  is strictly convex on  $\text{ri dom } C^*$ , and similarly  $D(q, \nu)$  is strictly convex on  $\text{ri dom } C^*$  as a function of the second argument.

#### Assumptions on the cost function.

- *Convexity and differentiability on  $\mathbb{R}^n$ .*  $C$  is convex and differentiable on  $\mathbb{R}^n$ .
- *Finite loss.*  $\mathcal{M} \subseteq \text{dom } C^*$ , i.e.,  $C^*$  is finite on  $\mathcal{M}$ .
- *Inclusion of the relative interior.*  $\text{ri } \mathcal{M} \subseteq \text{ri dom } C^*$ .

The first two assumptions are standard. The third assumption is a regularity condition that we require in our results. Here we briefly discuss how it compares with the finite loss assumption. While the two assumptions look similar, neither of them implies the other. For example, if  $\text{dom } C^*$  is an  $n$ -dimensional simplex and  $\mathcal{M}$  is one of its lower dimensional faces, which are lower dimensional simplices, then the finite loss assumption holds, but the inclusion assumption does not. Similarly, for  $n = 1$  and  $\mathcal{M} = [0, 1]$ , the inclusion assumption is satisfied by the conjugate  $C^*(\nu) = 1/\nu + 1/(1 - \nu)$  on  $\nu \in (0, 1)$  and  $C^*(\nu) = \infty$  on  $\nu \notin (0, 1)$ , but this conjugate does not satisfy the finite loss assumption.

We do not view the inclusion assumption as very restrictive, since it is satisfied by many common cost functions. For instance, it always holds when  $C$  is constructed as in [1], because their construction guarantees  $\text{dom } C^* = \mathcal{M}$ . However, the inclusion assumption might not hold for cost functions that allow arbitrage (e.g., [6]).

Our main result relies on strict convexity of  $C^*$  on  $\text{ri dom } C^*$ , so some of our statements will require that the market prices and beliefs lie in that set. The inclusion assumption above guarantees that at the minimum  $\text{ri } \mathcal{M} \subseteq \text{ri dom } C^*$ , but the boundary of  $\mathcal{M}$  is not necessarily included. To allow some generality beyond  $\text{ri } \mathcal{M}$ , we define the set

$$\tilde{\mathcal{M}} := \begin{cases} \mathcal{M} & \text{if } \mathcal{M} \subseteq \text{ri dom } C^* \\ \text{ri } \mathcal{M} & \text{otherwise.} \end{cases}$$

In either case we obtain that  $\tilde{\mathcal{M}} \subseteq \text{ri dom } C^* \subseteq \text{im } p$ , i.e., beliefs in  $\tilde{\mathcal{M}}$  can be expressed by some state  $q$ . For the quadratic cost,  $\tilde{\mathcal{M}} = \mathcal{M}$ . For the log-partition cost,  $\tilde{\mathcal{M}} = \text{ri } \mathcal{M}$ .

**Perpendiculars.** We now define the notion of a Bregman perpendicular to an affine space. This is a *constructive* definition. It plays a central role in the definition of the acute angles assumption, and also in the proof of the main result (Theorem 5.2). We will see that the set of optimal price vectors for different budgets is a sequence of Bregman perpendiculars. Naturally, perpendiculars are closely related to the conditions in Lemma 3.1; in particular to the set of  $q$ 's that satisfy conditions (a) and (c) for a given face  $X$ .

For quadratic costs, Bregman perpendiculars coincide with the usual Euclidean perpendiculars. Consider an affine space and a point not in it. A projection of the point onto the space is the point in the space that is closest in Euclidean distance to the given point. Now consider moving this affine space towards the projected point. The locus of the projection as we move the space is the perpendicular to the space through the given point. We extend this definition to arbitrary Bregman divergences by defining the projection using the corresponding Bregman divergence.

A Bregman perpendicular is determined by three geometric objects within the affine hull  $\text{aff}(\text{dom } C^*)$ . The first of these is an affine space, say  $A_0 \subseteq \text{aff}(\text{dom } C^*)$ . The second is a point  $a_1 \in \text{aff}(\text{dom } C^*) \setminus A_0$ . The affine space  $A = \text{aff}(A_0 \cup \{a_1\}) \subseteq \text{aff}(\text{dom } C^*)$  will be the ambient space that will contain the perpendicular. Define parallel spaces to  $A_0$  in  $A$ , for an arbitrary point  $a_0 \in A_0$ , as  $A_\lambda := A_0 + \lambda(a_1 - a_0)$  for  $\lambda \in \mathbb{R}$ . Note that the definition of  $A_\lambda$  is independent of the choice of  $a_0$ . The third geometric object is a market state  $q \in \mathbb{R}^n$  such that  $p(q) \in A$ . For technical reasons, we will define a perpendicular at  $q$  rather than a more natural notion, which would be at  $p(q)$ . Our reason for switching into  $q$ -space is that inner products, defining optimality of the Bregman projection, are between elements of  $q$ -space and  $\nu$ -space (the two spaces coincide for Euclidean distance). For all  $\lambda \in \mathbb{R}$  define a Bregman projection of  $q$  onto  $A_\lambda$  as

$$\nu_\lambda := \underset{\nu \in A_\lambda}{\text{argmin}} D(q, \nu) .$$

Since  $D(q, \nu)$  is bounded from below and lower semi-continuous, the minimum is always attained (but it may be equal to  $\infty$ ). If it is attained at more than one point, we choose an arbitrary minimizer. Whenever we can choose  $\nu_\lambda \in \text{ri dom } C^*$ , this  $\nu_\lambda$  must be the unique minimizer by strict convexity of  $D(q, \cdot)$  on  $\text{ri dom } C^*$ , and the minimum is finite. We use these  $\nu_\lambda$ 's to define the perpendicular:

**Definition 4.1.** Given  $A_0$ ,  $a_1$  and  $q$  as above, the  $a_1$ -perpendicular to  $A_0$  at  $q$  is a map  $\gamma : \lambda \mapsto \nu_\lambda$  defined over  $\Lambda := \{\lambda \in \mathbb{R} : \nu_\lambda \in \text{ri dom } C^*\}$ . We call  $\Lambda$  the domain of the perpendicular. We define a total order on

$\nu_\lambda, \nu_{\lambda'} \in \text{im } \gamma$  as  $\nu_\lambda \preceq \nu_{\lambda'}$  iff  $\lambda \leq \lambda'$ .

In Appendix F.2 of the full version, we show that perpendiculars are continuous maps. The name perpendicular is justified by the following proposition which matches our Euclidean intuition that the perpendiculars can be obtained by intersecting the ambient space  $A$  with the affine space which passes through  $q$  and is orthogonal to  $A_0$ . It also shows that the perpendicular corresponds to the set of prices that satisfy conditions (a) and (c) with the convex hull relaxed to the affine hull (when  $A_0$  is the affine hull of face  $X$ , point  $a_1$  coincides with  $\mu$  and  $q$  is the initial state). Recall that for an arbitrary set  $X \subseteq \mathbb{R}^n$ , its orthogonal complement is defined as  $X^\perp := \{u : u \cdot (x' - x) = 0 \text{ for all } x, x' \in X\}$ .

**Proposition 4.2.** *Let  $\gamma$  be the  $a_1$ -perpendicular to  $A_0$  at  $q$ , and let  $A = \text{aff}(A_0 \cup \{a_1\})$ . The following two statements are equivalent for any  $\nu' \in \mathbb{R}^n$ :*

- (i)  $\nu' \in \text{im } \gamma$
- (ii)  $\nu' \in A \cap (\text{ri dom } C^*), p^{-1}(\nu') \cap (q + A_0^\perp) \neq \emptyset$

Proposition 4.2 is proved in Appendix F of the full version. The perpendiculars have the following closure property which is useful for showing budget additivity (also proved in Appendix F of the full version):

**Proposition 4.3.** *Under the assumptions of Proposition 4.2,  $\gamma$  is also the  $a_1$ -perpendicular to  $A_0$  at any  $q' \in p^{-1}(\text{im } \gamma) \cap (q + A_0^\perp)$ .*

## 5 BUDGET ADDITIVITY

We now state the *acute angles* property which links the Bregman perpendicular and Corollary 3.5, and is sufficient for budget additivity.

**Definition 5.1.** We say that the *acute angles* hold for a face  $X$ , if for every  $\mu$ -perpendicular  $\gamma$  to  $X$  at  $q$ , such that  $\mu \in \tilde{\mathcal{M}}$  and  $q \in p^{-1}(\tilde{\mathcal{M}})$ , the following holds: If  $\nu' \in \text{im } \gamma$  and  $\nu' \succeq p(q)$ , then  $p^{-1}(\nu') \cap [q + \mathcal{K}(X)] \neq \emptyset$ .

The motivation for the name ‘‘acute angles’’ comes from the Euclidean distance case, where this assumption is equivalent to Definition 3.8 (see Proposition G.1 in the full version). The acute angles property is non-trivial and we have seen that without this property, budget additivity need not hold; we conjecture that it is also a necessary condition. After stating the main theorem, we analyze in more detail when the acute angles are satisfied by the quadratic and log-partition costs.

We now state the main result, that the acute angles are sufficient for budget additivity:

**Theorem 5.2** (Sufficient conditions for budget additivity). *If acute angles hold for every face  $X \subseteq \Omega$ , then the prediction market is budget additive on  $\tilde{\mathcal{M}}$ .*

**Sufficient conditions for acute angles.** We next give the sufficient conditions when the acute angles hold for the quadratic and log-partition cost functions. We also show that the acute angles hold for all one-dimensional outcome spaces, and that they are preserved by taking *direct sums* of markets. Recall that a set  $\mathcal{K} \in \mathbb{R}^n$  is called a cone if it is closed under multiplication by positive scalars. A cone is called *acute*, if  $x \cdot y \geq 0$  for all  $x, y \in \mathcal{K}$ . An *affine cone* with the vertex  $a_0$  is a set  $\mathcal{K}'$  of the form  $a_0 + \mathcal{K}$  where  $\mathcal{K}$  is a cone.

**Theorem 5.3** (Sufficient condition for quadratic cost). *Let  $X$  be a face and  $A'$  be the affine space  $a_0 + X^\perp$  for an arbitrary  $a_0 \in \text{aff}(X)$ . Acute angles hold for the face  $X$  and the quadratic cost if and only if the projection of  $\Omega$  (or, equivalently,  $\mathcal{M}$ ) on  $A'$  is contained in an affine acute cone with the vertex  $a_0$ .*

**Corollary 5.4.** *Acute angles hold for the quadratic cost and a hypercube  $\Omega = \{0, 1\}^n$ .*

**Corollary 5.5.** *Acute angles hold for the quadratic cost and simplex  $\Omega = \{e_i : i \in [n]\}$  where  $[n] = \{1, 2, \dots, n\}$  and  $e_i$  is the  $i$ -th vector of the standard basis in  $\mathbb{R}^n$ .*

**Theorem 5.6** (Log-partition over affinely independent outcomes). *If the set  $\Omega$  is affinely independent then acute angles assumption is satisfied for the log-partition cost.*

**Theorem 5.7** (One-dimensional outcome spaces). *Acute angles hold for any cost function if  $\mathcal{M}$  is a line segment.*

Let  $\Omega_1 \subseteq \mathbb{R}^{n_1}$  and  $\Omega_2 \subseteq \mathbb{R}^{n_2}$  be outcome spaces with costs  $C_1$  and  $C_2$ . We define the *direct sum* of  $\Omega_1$  and  $\Omega_2$  to be the outcome space  $\Omega = \Omega_1 \times \Omega_2$  with the cost  $C : \mathbb{R}^{n_1+n_2} \rightarrow \mathbb{R}$  defined as  $C(q_1, q_2) = C_1(q_1) + C_2(q_2)$ .

**Theorem 5.8** (Acute angles for direct sums). *If acute angles hold for  $\Omega_1$  with cost  $C_1$ , and  $\Omega_2$  with cost  $C_2$ , then they also hold for their direct sum.*

As a direct consequence of this theorem, we obtain that the log-partition cost function satisfies the acute angles assumption on a hypercube. More generally, any direct sum of costs on line segments satisfies the acute angles. This means that all cost-based prediction markets consisting of independent binary questions are budget additive, regardless of costs used to price individual questions.

As mentioned in the introduction, a vast number of deployed cost-based prediction markets consists of independent questions (not necessarily binary), each priced according to an LMSR (i.e., a log-partition cost on a simplex). Theorems 5.6 and 5.8 imply that this industry standard is budget additive.

### 5.1 Proof of Theorem 5.2

In this section we sketch the proof of Theorem 5.2 (for a complete proof see Appendix H of the full version). We proceed in several steps. Let  $\nu_0 = p(q_0)$ . Assuming acute

angles, we begin by constructing an oriented curve  $L$  joining  $\nu_0$  with  $\mu$ , by sequentially choosing portions of perpendiculars for monotonically decreasing active sets. We then show that budget additivity holds for any solutions with prices in  $L$ , and finally show that the curve  $L$  is the locus of the optimal prices of solutions  $\hat{Q}(q_0)$ , as well as optimal prices of solutions  $\hat{Q}(q)$  for any  $q \in \hat{Q}(q_0)$ .

**Part 1: Construction of the solution path  $L$ .** In this part, we construct:

- a sequence of prices  $\nu_0, \nu_1, \dots, \nu_k$  with  $\nu_0 = p(q_0)$  and  $\nu_k = \mu$
- a sequence of oriented curves  $\ell_0, \dots, \ell_{k-1}$  where each  $\ell_i$  goes from  $\nu_i$  to  $\nu_{i+1}$
- a monotone sequence of sets  $\Omega \supseteq X_0 \supset X_1 \supset \dots \supset X_k = \emptyset$ , such that the following *minimality* property holds:  $X_i$  is the minimal face for all  $\nu \in (\text{im } \ell_i) \setminus \{\nu_{i+1}\}$  for  $i \leq k-1$ , and  $X_k$  is the minimal face for  $\nu_k$ .
- a sequence of states  $q_1, \dots, q_{k-1}$  such that  $q_i \in p^{-1}(\nu_i) \cap [q_{i-1} + \mathcal{K}(X_{i-1})]$

The curves  $\ell_i$  will be referred to as *segments*. The curve obtained by concatenating the segments  $\ell_0$  through  $\ell_{k-1}$  will be called the *solution path* and denoted  $L$ . In the special case that  $\nu_0 = \mu$ , we have  $k = 0$ ,  $X_0 = \emptyset$  and  $L$  is a degenerate curve with  $\text{im } L = \{\mu\}$ .

If  $\nu_0 \neq \mu$ , we construct the sequence of segments iteratively. Let  $X_0 \neq \emptyset$  be the minimal face such that  $\nu_0 \in \text{conv}(X_0 \cup \{\mu\})$ . By the minimality,  $\mu \notin \text{aff}(X_0)$ . Let  $\gamma$  be the  $\mu$ -perpendicular to  $\text{aff}(X_0)$  at  $q_0$ . The curve  $\gamma$  passes through  $\nu_0$  and eventually reaches the boundary of  $\text{conv}(X_0 \cup \{\mu\})$  at some  $\nu_1$  by continuity of  $\gamma$  (see Theorem F.3). Let segment  $\ell_0$  be the portion of  $\gamma$  going from  $\nu_0$  to  $\nu_1$ .

This construction gives us the first segment  $\ell_0$ . There are two possibilities:

1.  $\nu_1 = \mu$ ; in this case we are done;
2.  $\nu_1$  lies on a lower-dimensional face of  $\text{conv}(X_0 \cup \{\mu\})$ ; in this case, we pick some  $q_1 \in p^{-1}(\nu_1) \cap [q_0 + \mathcal{K}(X_0)]$ , which can be done by the acute angles assumption, and use the above construction again, starting with  $q_1$ , and obtaining a new set  $X_1 \subset X_0$  and a new segment  $\ell_1$ ; and iterate.

The above process eventually ends, because with each iteration, the size of the active set decreases. This construction yields monotonicity of  $X_i$  and the minimality property.

The above construction yields a specific sequence of  $q_i \in p^{-1}(\nu_i) \cap [q_{i-1} + \mathcal{K}(X_{i-1})]$ . We show in Appendix H of the full version that actually  $q_i \in p^{-1}(\nu_i) \cap (q_0 + X_{i-1}^\perp)$  and that the construction of  $L$  is independent of the choice of  $q_1, q_2, \dots, q_{k-1}$ .

**Part 2: Budget additivity for points on  $L$ .** Let  $\nu, \nu' \in$

$\text{im } L$  such that  $\nu \preceq \nu'$ . Let  $q \in \hat{Q}(\nu; q_0)$  and  $q' \in \hat{Q}(\nu'; q)$  such that  $q \in \hat{Q}(B; q_0)$  and  $q' \in \hat{Q}(B'; q)$ . In this part we show that  $q' \in \hat{Q}(B + B'; q_0)$ .

First, consider the case that  $\nu' = \mu$ . To see that  $q' \in \hat{Q}(B + B'; q_0)$ , first note that the constraints of Convex Program (2.1) hold, because  $U(q', \omega; q_0) = U(q', \omega; q) + U(q, \omega; q_0) \geq -B' - B$  for all  $\omega$  by path independence of the utility function. As noted in the introduction, in the absence of constraints, the utility  $U(\bar{q}, \mu; q_0)$  is maximized at any  $\bar{q}$  with  $p(\bar{q}) = \mu$ . Thus,  $q'$  is a global maximizer of the utility and satisfies the constraints, so  $q' \in \hat{Q}(B + B'; q_0)$ . If  $\nu = \mu$ , we must also have  $\nu' = \mu$  and the statement holds by previous reasoning.

In the remainder, we only analyze the case  $\nu \preceq \nu' \prec \mu$ . This means that  $\nu \in (\text{im } \ell_i) \setminus \{\nu_{i+1}\}$  and  $\nu' \in (\text{im } \ell_j) \setminus \{\nu_{j+1}\}$  for  $i \leq j$ . By Theorem 3.4, we therefore must have  $q \in [q_0 + \mathcal{K}(X_i)]$  and  $q' \in [q + \mathcal{K}(X_j)]$ . By anti-monotonicity of witness cones,  $\mathcal{K}(X_j) \supseteq \mathcal{K}(X_i)$  and hence,  $q' \in [q_0 + \mathcal{K}(X_j)]$ , yielding  $q' \in \hat{Q}(\nu'; q_0)$ .

We now argue that the budgets add up. Let  $x \in X_j \subseteq X_i$ . By Lemma 3.1, we obtain that  $q \in \hat{Q}(B; q_0)$  for  $B = -U(q, x; q_0)$ , and  $q' \in \hat{Q}(B'; q)$  for  $B' = -U(q', x; q)$ , and finally  $q' \in \hat{Q}(\bar{B}; q_0)$  for  $\bar{B} = -U(q', x; q_0)$ . However, by path independence of the utility function

$$\bar{B} = -U(q', x; q_0) = -U(q', x; q) - U(q, x; q_0) = B' + B.$$

**Part 3:  $L$  as the locus of all solutions.** See Appendix H of the full version for the proof that

$$\hat{Q}(q_0) = \bigcup_{\nu \in \text{im } L} \hat{Q}(\nu; q_0) .$$

**Part 3':  $L$  as the locus of solutions starting at a midpoint.** Let  $\nu \in \text{im } L$  and  $q \in \hat{Q}(\nu; q_0)$ . Since  $\hat{Q}(\nu; q_0) \subseteq p^{-1}(\nu) \cap (q_0 + X_\nu^\perp)$ , Part 1' (Appendix H of the full version) yields that the solution path  $L'$  for  $q$  coincides with the portion of  $L$  starting at  $\nu$ . Applying the proof of Part 3 to  $L'$ , we obtain

$$\hat{Q}(q) = \bigcup_{\nu' \in \text{im } L: \nu' \succeq \nu} \hat{Q}(\nu'; q) .$$

**Part 4: Proof of the theorem.** Let  $B, B' \geq 0$  and  $q \in \hat{Q}(B; q_0)$  and  $q' \in \hat{Q}(B'; q)$ . From Parts 3 and 3', we know that  $q \in \hat{Q}(\nu; q_0)$  and  $q' \in \hat{Q}(\nu'; q)$  for some  $\nu, \nu' \in \text{im } L$  such that  $\nu \preceq \nu'$ . By Part 2, we therefore obtain that  $q' \in \hat{Q}(B + B'; q_0)$ , proving the theorem.

## Abstract

The main goal of this work is to present the proof-theoretical and model-theoretical approach to a probabilistic logic which allows reasoning about temporal information. We extend both the language of linear time logic and the language of probabilistic logic, allowing statements like “A will always hold” and “the probability that A will hold in next moment is at least the probability that B will always hold,” where A and B are arbitrary statements. We axiomatize this logic, provide corresponding semantics and prove that the axiomatization is sound and strongly complete. We show that the problem of deciding decidability is PSPACE-complete, no worse than that of linear time logic.

## 1 INTRODUCTION

The study of temporal logics started with the seminal work of Arthur Prior [Prior, 1957]. Temporal logics are designed in order to analyze and reason about the way that systems change over time, and have been shown to be a useful tool in describing behavior of an agent’s knowledge base, for specification and verification of programs, hardware, protocols in distributed systems etc. [Emerson, 1990, Emerson, 1995]. In many practical situations the temporal information is not known with certainty. A typical example is formal representation of information about tracking moving objects with GPS systems, in the case in which the locations or the identities of the objects are not certainly known [Grant et al., 2010].

Many different tools are developed for representing, and reasoning with, uncertain knowledge. One particular line of research concerns the formalization in terms of probabilistic logic. After Nilsson [Nilsson, 1986] gave a procedure for probabilistic entailment which, given probabilities of premises, calculates bounds on the probabilities of the

derived sentences, researchers from the field started investigation about formal systems for probabilistic reasoning. [Fagin et al., 1990] provided a finitary axiomatization for reasoning about linear combinations of probabilities, and they proved weak completeness (every consistent formula is satisfiable). Their formulas are Boolean combinations of the expressions of the form  $r_1w(\alpha_1) + \dots + r_nw(\alpha_n) \geq r_{n+1}$ , where  $w$  is the probability operator and  $\alpha_i$ ’s are propositional formulas. The semantics of the logic use finitely additive probabilities, since  $\sigma$ -additivity cannot be expressed by a formula of their language.

In this paper, we extend the approach from [Fagin et al., 1990]. We start with the propositional linear time logic (LTL) [Gabbay et al., 1980] with the “next” operator  $\bigcirc$  and “until” operator  $U$ . The meaning of the formula  $\bigcirc\alpha$  is “ $\alpha$  holds in the next time instance”, and  $\alpha U\beta$  we read “ $\alpha$  holds in every time instance until  $\beta$  holds”. We apply the probabilistic operator  $w$  to the formulas of LTL and define probabilistic formulas using the linear combinations, like in [Fagin et al., 1990]. In our logic there are two types of formulas, LTL formulas and probabilistic formulas, with the requirement that if an LTL formula is true, then its probability is equal to 1.

The main technical challenge in axiomatizing such a logic lies in the fact that the set of models of the formula  $\alpha U\beta$  can be represented as a countable union of models of temporal formulas which are pairwise disjoint. As a consequence, finitely additive semantics is obviously not appropriate for such a logic, and we propose  $\sigma$ -additive semantics for the logic. On the other hand, expressing  $\sigma$ -additivity with an axiom would require infinite disjunctions, and the resulting logic would be undecidable. We shown in Section 3.1 that any finitary axiomatic system wouldn’t be complete for the  $\sigma$ -additive semantics.

In order to overcome this problem, we axiomatize our language using infinitary rules of inference. Thus, in this work the term “infinitary” concerns the meta language only, i.e., the object language is countable and the formulas are finite, while only proofs are allowed to be infinite. We prove that our axiomatization is sound and strongly complete (every

consistent set of formulas is satisfiable). We also prove that the logic is decidable, and we show that the satisfiability problem is *PSPACE*-complete, no harder than satisfiability for LTL.

There are several logics which combine time and probability in different ways [Guelev, 2000, Haddawy, 1996, Halpern and Pucella, 2006, Hansson and Jonsson, 1994, Ognjanovic, 2006, Shakarian et al., 2011]. However, to the best of our knowledge, this is the first complete axiomatization for the  $\sigma$ -additive probabilistic semantics.

## 2 THE LOGIC $PL_{LTL}$ : SYNTAX AND SEMANTICS

We present the syntax and semantics of the logic for probabilistic reasoning about linear time formulas, that we denote by  $PL_{LTL}$ . The logic contains two types of formulas: formulas of LTL without probabilities, and the linear weight formulas in the style of [Fagin et al., 1990], with weights applied to temporal formulas.

In order to give semantics to the formulas, we first briefly review some probability theory [Ash and Doléans-Dade, 1999]. If  $W \neq \emptyset$ , then  $H$  is an algebra of subsets of  $W$ , if it is a set of subsets of  $W$  such that:

- (a)  $W \in H$ ,
- (b) if  $A, B \in H$ , then  $W \setminus A \in H$  and  $A \cup B \in H$ .

A function  $\mu : H \rightarrow [0, 1]$  is a ( $\sigma$ -additive) probability measure, if the following conditions hold:

- (1)  $\mu(W) = 1$ ,
- (2)  $\mu(\bigcup_{i \in \omega} A_i) = \sum_{i \in \omega} \mu(A_i)$ , whenever  $A, A_i \in H$  and  $A_i \cap A_j = \emptyset$  for all  $i \neq j$ .

For  $W, H$  and  $\mu$  described above, the triple  $\langle W, H, \mu \rangle$  is called a probability space. A function  $\mu : H \rightarrow [0, 1]$  is a finitely additive probability measure, if the condition

- (3)  $\mu(A \cup B) = \mu(A) + \mu(B)$ , whenever  $A \cap B = \emptyset$ .

holds, instead of (2). We also say that an algebra  $H$  is a  $\sigma$ -algebra, if  $\bigcup_{i \in \omega} A_i \in H$  whenever  $A_i \in H$  for every  $i \in \omega$ .

For a finitely additive  $\mu$ , the condition (2) is equivalent to the condition

- (2')  $\mu(\bigcup_{i \in \omega} A_i) = \lim_{n \rightarrow +\infty} \mu(\bigcup_{i=0}^n A_i)$ .

We will actually use (2') in the axiomatization of our logic (see the inference rule R6).

### 2.1 SYNTAX

First we introduce LTL formulas. Suppose that  $\mathcal{P}$  is a nonempty finite set of propositional letters. We denote the

elements of  $\mathcal{P}$  with  $p$  and  $q$ , possibly with subscripts.

**Definition 1 (LTL formula)** An LTL formula is any formula built from propositional letters from  $\mathcal{P}$ , using the Boolean connectives  $\neg$  and  $\wedge$ , and the temporal operators  $\bigcirc$  and  $U$ .

We use  $For_{LTL}$  for the set of all state formulas and denote arbitrary LTL formulas by  $\alpha, \beta$  and  $\gamma$ , possibly with subscripts.

We use  $\neg$  and  $\wedge$  as the primitive connectives, while other Boolean connectives ( $\rightarrow, \vee, \leftrightarrow$ ) can be introduced as usual. We also define other LTL operators  $F$  (sometime) and  $G$  (always) as abbreviations:  $F\alpha$  is  $\bigvee U\alpha$ , and  $G\alpha$  is  $\neg F\neg\alpha$ . Note that we use the strong version of  $U$ , which means that if  $\alpha U \beta$  holds in a path, then  $\beta$  must hold eventually.

**Example 1** The expression

$$\bigcirc(p \wedge q) \rightarrow (pU\neg q)$$

is an example of LTL formula. Its meaning is “if both  $p$  and  $q$  hold in the next moment, then  $p$  will hold until  $q$  becomes false”.

Semantics for LTL formulas consists of the set of paths, where a path is a  $\omega$ -structure in  $\mathcal{P}$ , of the form  $\sigma = s_0, s_1, s_2, \dots$ . Here  $s_i$ , called the  $i$ -th time instance of  $\sigma$ , is a subset of  $\mathcal{P}$ , and  $p \in s_i$  represent the propositional letter  $p$  being true at time  $i$  in  $\sigma$ . We denote the set of all paths with  $\bar{\Sigma}$ . In the rest of the paper, we use the following abbreviations:

- $\sigma_{\geq i}$  is the path  $s_i, s_{i+1}, s_{i+2}, \dots$
- $\sigma_i$  is the state  $s_i$ .

The evaluation function<sup>1</sup>  $v : \bar{\Sigma} \times For_{LTL} \rightarrow \{0, 1\}$  is defined recursively as follows:

- if  $p \in \mathcal{P}$ , then  $v(\sigma, p) = 1$  iff  $p \in \sigma_0$ ,
- $v(\sigma, \neg\alpha) = 1$  iff  $v(\sigma, \alpha) = 0$ ,
- $v(\sigma, \alpha \wedge \beta) = 1$  iff  $v(\sigma, \alpha) = 1$  and  $v(\sigma, \beta) = 1$ ,
- $v(\sigma, \bigcirc\alpha) = 1$  iff  $v(\sigma_{\geq 1}, \alpha) = 1$ ,
- $v(\sigma, \alpha U \beta) = 1$  iff there is some  $i \in \omega$  such that  $v(\sigma_{\geq i}, \beta) = 1$ , and for each  $j \in \omega$ , if  $0 \leq j < i$  then  $v(\sigma_{\geq j}, \alpha) = 1$ .

<sup>1</sup>In the literature, the evaluation of LTL formulas in paths is usually given in terms of satisfiability relation  $\models$ . We do not follow this notation, because in this paper we use  $\models$  to denote satisfiability of formulas in  $PL_{LTL}$ -structures.

We say that  $\alpha$  is true in the path  $\sigma$ , if  $v(\sigma, \alpha) = 1$ .

Now we introduce the probabilistic formulas. By  $\mathcal{Q}$  we denote the set of rational numbers. First we define the probabilistic terms.

**Definition 2 (Probabilistic term)** A probabilistic term is any expression of the form

$$r_1 w(\alpha_1) + \dots + r_k w(\alpha_k) + r_{k+1},$$

where  $k$  is a positive integer, and for all  $i \leq k + 1$ ,  $\alpha_i \in For_{LTL}$  and  $r_i \in \mathcal{Q}$ .<sup>2</sup>

We use  $f$  and  $g$ , possibly subscripted, to denote probabilistic terms.

**Definition 3 (Probabilistic formula)** A basic probabilistic formula is any formula of the form  $f \geq r$ , where  $f$  is a probabilistic term and  $r \in \mathcal{Q}$ . The set  $For_P$  of probabilistic formulas is the smallest set containing all basic probabilistic formulas, closed under Boolean connectives.

We denote by  $\phi, \psi$  and  $\theta$  (possibly with indices) the elements of  $For_P$ . To simplify notation, we define the following abbreviations:  $f \geq g$  is  $f - g \geq 0$ ,  $f \leq g$  is  $g \geq f$ ,  $f < g$  is  $\neg f \geq g$ ,  $f > g$  is  $\neg f \leq g$  and  $f = g$  is  $f \geq g \wedge f \leq g$ .

**Example 2** The expression

$$w(p \vee q) = w(\bigcirc p) \rightarrow w(Gq) \leq \frac{1}{2}$$

is a probabilistic formula. Its meaning is “if the probability that either  $p$  or  $q$  hold in this moment is equal to the probability that  $p$  will hold in the next moment, then the probability that  $q$  will always hold is at most one half”.

**Definition 4 (Formula)** The set  $For$  of all formulas of the logic  $PL_{LTL}$  is  $For = For_{LTL} \cup For_P$ .

We denote arbitrary formulas by  $\Phi$  and  $\Psi$  (possibly with subscripts). We denote by  $\perp$  both  $\phi \wedge \neg\phi$  and  $\alpha \wedge \neg\alpha$ , letting the context determines the meaning. Similarly, we use  $\top$  for both LTL and probabilistic formulas.

**Example 3** The expression

$$(p \vee \bigcirc q) \rightarrow w(p \vee \bigcirc q) = 1$$

is not a formula, since mixing LTL formulas and probabilistic formulas is not allowed, by Definition 4.

<sup>2</sup>In [Fagin et al., 1990],  $r_{k+1}$  does not appear in the definition of terms. We introduce it for the simpler presentation, when we introduce other formulas as abbreviations.

## 2.2 SEMANTICS

The semantics of the logic  $PL_{LTL}$  is based on the possible-world approach.

**Definition 5 ( $PL_{LTL}$  structure)** A  $PL_{LTL}$  structure is a tuple  $M = \langle W, H, \mu, \pi \rangle$  where:

- $W$  is a nonempty set of worlds,
- $\langle W, H, \mu \rangle$  is a probability space, and
- $\pi : W \rightarrow \bar{\Sigma}$  provides for each world  $w \in W$  a path  $\pi(w)$ .

For a  $PL_{LTL}$  structure  $M = \langle W, H, \mu, \pi \rangle$ , we define

$$[\alpha]_M = \{w \in W \mid v(\pi(w), \alpha) = 1\}.$$

We say that  $M$  is measurable, if  $[\alpha]_M \in H$  for every  $\alpha \in For_{LTL}$ . We denote the class of all measurable  $PL_{LTL}$  structures with  $PL_{LTL}^{Meas}$ .

Now we define the satisfiability of a formula from  $For$  in a structure from  $PL_{LTL}^{Meas}$ .

**Definition 6 (Satisfiability)** Let  $M = \langle W, H, \mu, \pi \rangle$  be a  $PL_{LTL}$  structure. We define the satisfiability relation  $\models_{\subseteq} PL_{LTL}^{Meas} \times For$  recursively as follows:

- $M \models \alpha$  iff  $v(\pi(w), \alpha) = 1$  for every  $w \in W$ ,
- $M \models r_1 w(\alpha_1) + \dots + r_k w(\alpha_k) \geq r$  iff  $r_1 \mu([\alpha_1]_M) + \dots + r_k \mu([\alpha_k]_M) \geq r$ ,
- $M \models \neg\phi$  iff  $M \not\models \phi$ ,
- $M \models \phi \wedge \psi$  iff  $M \models \phi$  and  $M \models \psi$ .

**Definition 7 (Model)** We say that  $M \in PL_{LTL}^{Meas}$  is a model of  $\Phi$ , if  $M \models \Phi$ . A formula  $\Phi$  is valid, if  $M \models \Phi$  holds for every  $M \in PL_{LTL}^{Meas}$ . We say that  $M$  is a model of a set of formulas  $T$ , and we write  $M \models T$ , iff  $M \models \Phi$  for every  $\Phi \in T$ . A set of formulas  $T$  is satisfiable if there is  $M$  such that  $M \models T$ .

**Definition 8 (Entailment)** We say that the set of formulas  $T$  entails a formula  $\Phi$ , and we write  $T \models \Phi$ , if all  $M \in PL_{LTL}^{Meas}$ ,  $M \models T$  implies  $M \models \Phi$ .

For every  $\alpha, \beta \in For_{LTL}$ , let us denote by  $\alpha \bar{U}_n \beta$  the formula

$$\bigwedge_{k=0}^{n-1} \bigcirc^k \alpha \wedge \bigcirc^n \beta,$$

and by  $\alpha U_n \beta$  the formula  $\bigvee_{k=0}^n \alpha \bar{U}_k \beta$ .

Those formulas will play the important role in our axiomatization. Obviously,  $v(\sigma, \alpha U \beta) = 1$  iff there is some  $n \in \omega$  such that  $v(\sigma, \alpha \bar{U}_n \beta) = 1$ , and

$$[\alpha U \beta]_M = \bigcup_{n \in \omega} [\alpha \bar{U}_n \beta]_M. \quad (1)$$

Similarly,

$$[\alpha U \beta]_M = \bigcup_{n \in \omega} [\alpha U_n \beta]_M. \quad (2)$$

Since (1) follows directly from the definition of the evaluation function  $v$ , we will use it to properly axiomatize LTL part of our logic. On the other hand, (2) is more convenient for capturing  $\sigma$ -additivity.

### 3 The axiomatization of $PL_{LTL}$

In this section we provide an axiomatization for  $PL_{LTL}$ , which we denote by  $AX_{PL_{LTL}}$ . Let us first discuss some axiomatization issues. By (2) and  $\sigma$ -additivity, we obtain  $\mu([\alpha U \beta]_M) = \mu(\bigcup_{n \in \omega} [\alpha U_n \beta]_M)$ . Then we can see that the set

$$T = \{w(\alpha U \beta) > r\} \cup \{w(\alpha U_n \beta) \leq r \mid n \in \omega\}$$

is an unsatisfiable set of formulas. On the other hand, it is easy to check that every finite subset of  $T$  is satisfiable. In other words, the logic is not compact. It is known that, in this case, any finitary axiomatization would be incomplete [van der Hoek, 1997]. Here we use an infinitary rule (R6) to obtain completeness, and, in particular, to make the set  $T$  inconsistent. It turns that it is necessary (see the proof of Theorem 4) to introduce another infinitary rule (R4) to properly axiomatize LTL part of the logic, since the set of LTL formulas  $\{\alpha U \beta\} \cap \{\neg(\alpha \bar{U}_n \beta) \mid n \in \omega\}$  is also an example of non-compactness.

#### 3.1 THE AXIOMATIC SYSTEM $AX_{PL_{LTL}}$

the axiomatization  $AX_{PL_{LTL}}$  contains 8 axioms and 6 rules of inference. We divide the axioms into 3 groups as given below.

Tautologies

A1. All instances of classical propositional tautologies for both LTL and probabilistic formulas.

Temporal axioms

A2.  $\bigcirc(\alpha \rightarrow \beta) \rightarrow (\bigcirc\alpha \rightarrow \bigcirc\beta)$ .

A3.  $\neg \bigcirc \alpha \leftrightarrow \bigcirc \neg \alpha$ .

A4.  $\alpha U \beta \leftrightarrow \beta \vee (\alpha \wedge \bigcirc(\alpha U \beta))$ .

Axioms for reasoning about linear inequalities

A5. All instances of valid formulas about linear inequalities.

Probabilistic axioms

A6.  $w(\alpha) \geq 0$ .

A7.  $w(\alpha \wedge \beta) + w(\alpha \wedge \neg \beta) = w(\alpha)$ .

A8.  $w(\alpha \rightarrow \beta) = 1 \rightarrow w(\alpha) \leq w(\beta)$ .

Inference rules

R1. From  $\Phi$  and  $\Phi \rightarrow \Psi$  infer  $\Psi$  (where either  $\Phi, \Psi \in For_{LTL}$  or  $\Phi, \Psi \in For_P$ ).

R2. From  $\alpha$  infer  $\bigcirc\alpha$ .

R3. From  $\alpha$  infer  $w(\alpha) = 1$ .

R4. From the set of premises

$$\{\gamma \rightarrow \neg(\alpha \bar{U}_n \beta) \mid n \in \omega\}$$

infer  $\gamma \rightarrow \neg(\alpha U \beta)$ .

R5. From the set of premises

$$\{\phi \rightarrow f \geq r - \frac{1}{n} \mid n \in \omega \setminus \{0\}\}$$

infer  $\phi \rightarrow f \geq r$ .

R6. From the set of premises

$$\{\phi \rightarrow w(\alpha U_n \beta) \leq r \mid n \in \omega\}$$

infer  $\phi \rightarrow w(\alpha U \beta) \leq r$ .

Let us briefly discuss the axiomatic system.

A1 and R1 allow propositional reasoning with all formulas from  $For$ .

The axioms A2–A4 are some standard axioms in various axiomatization of LTL. Although all the axiomatizations contain some additional axioms, we show in Lemma 1(1) that all the valid temporal formulas can be deduced in  $AX_{PL_{LTL}}$ . Moreover, by Lemma 2, A1–A4 together with R1, R2 and R4 make a strongly complete system for LTL. Note that we use the temporal necessitation R2 with the next operator, while the standard generalization can be derived, as it is shown in the proof of Lemma 1(1). The rule R4 is an infinitary rule that characterizes the until operator. It is similar to a rule from [Marinkovic et al., 2014], and it is necessary for the proof of  $\sigma$ -additivity.

The axiom A5 includes all valid formulas about linear inequalities. For example,  $f + 1 \leq f + 2$  and  $f + g =$

$g + f$  are instances of A5. A particular sound and complete axiomatization for Boolean combination is given in [Fagin et al., 1990], but, as it is pointed out there, any other axiomatization can be used.

The probabilistic axioms A6 and A7 correspond to non-negativity and finite additivity, respectively. They are two of the four axioms presented in [Fagin et al., 1990]. Other two axioms are theorems of  $AX_{PLTL}$  (see Lemma 1). The rule R3 states that if we know that  $\alpha$  holds, then we believe that it is true with probability 1. The rules R4–R6 are infinitary rules of inference. R4 and R6 are crucial for the proof of  $\sigma$ -additivity, while R5, ensures that the values of probability measures belong to the set of reals. R5 is a variant of a rule introduced in [Perovic et al., 2008].

**Definition 9 (Proof)** A formula  $\Phi$  is a theorem of the logic  $PLTL$ , ( $\vdash \Phi$ ), if there is an at most countable sequence of formulas  $\Phi_0, \Phi_1, \dots, \Phi$ , such that every  $\Phi_i$  is an axiom, or it is derived from the preceding formulas by an inference rule.

A formula  $\Phi$  is deducible from a set of formulas  $T$  ( $T \vdash \Phi$ ) if there is an at most countable sequence of formulas  $\Phi_0, \Phi_1, \dots, \Phi$ , such that every  $\Phi_i$  is a theorem or a formula from  $T$ , or it is derived from the preceding formulas by one of the inference rules, excluding R2. The corresponding sequence  $\Phi_0, \Phi_1, \dots, \Phi$  is the proof of  $\Phi$  from  $T$ .

By the previous definition, application of the rule R2 is restricted to theorems only. Otherwise, any change during the time would be impossible. Note that the length of a proof (the number of formulas in the corresponding sequence) is any countable successor ordinal.

**Definition 10 (Consistency)** A set of formulas  $T$  is consistent if there is no  $\phi \in For_P$  such that  $T \vdash \phi \wedge \neg\phi$ , otherwise it is inconsistent.  $T$  is maximal consistent if it is consistent and for all  $\Phi \notin T$ ,  $T \cup \{\Phi\}$  is inconsistent.

Next we make several observations about the notions of consistency and maximal consistency:

- If  $T$  is consistent, then there is no  $\alpha \in For_{LTL}$  such that  $T \vdash \alpha \wedge \neg\alpha$ , since otherwise  $T \vdash w(\alpha) = 1 \wedge w(\neg\alpha) = 1$  by R3, and  $T \vdash w(\alpha) = 1 \wedge \neg w(\alpha) = 1$  by probabilistic axioms.

- Maximal consistency of  $T$  doesn't imply that for every  $\alpha \in For_{LTL}$  either  $T \vdash \alpha$  or  $T \vdash \neg\alpha$ . Indeed, suppose that  $w(\alpha) = \frac{1}{2} \in T$  for some  $\alpha$ . If  $T \vdash \alpha$  or  $T \vdash \neg\alpha$ , then by R3 (and some probabilistic reasoning) we have  $T \vdash w(\alpha) = 1$  or  $T \vdash w(\alpha) = 0$ , which would make  $T$  inconsistent. On the other hand, for a  $\phi \in For_P$  we have either  $T \vdash \phi$  or  $T \vdash \neg\phi$  (see Lemma 1(4)).

- If  $T$  is consistent, then  $T$  is *deductively closed*, i.e., if  $T \vdash \Phi$  then  $\Phi \in T$ .

### 3.2 SOME THEOREMS ABOUT $AX_{PLTL}$

It is straightforward to check that all the axioms of  $AX_{PLTL}$  are valid, and that the rules of inference maintain the validity of formulas. Thus, we omit the proof of the following result.

**Theorem 1 (Soundness)** The axiomatization  $AX_{PLTL}$  is sound with respect to the class of models  $PL_{LTL}^{Meas}$ .

**Theorem 2 (Deduction theorem)** Let  $T$  be a set of formulas and let  $\Phi$  and  $\Psi$  be two formulas such that either  $\Phi, \Psi \in For_{LTL}$  or  $\Phi, \Psi \in For_{LTL}$ . Then  $T \cup \{\Phi\} \vdash \Psi$  iff  $T \vdash \Phi \rightarrow \Psi$ .

*Proof. (sketch)* We will prove the direction from right to left because the other direction is immediate from R1. We will use induction on the length of the inference. We will only consider the case when R6 is applied. Suppose that  $T \cup \{\phi\} \vdash \psi \rightarrow w(\alpha U \beta) \leq r$  is obtained by R6. Then  $T \cup \{\phi\} \vdash \psi \rightarrow w(\alpha U_n \beta) \leq r$  holds, by assumption, for every  $n \in \omega$ . Using induction hypothesis and reasoning as above, we have:

$T \vdash \phi \rightarrow (\psi \rightarrow w(\alpha U_n \beta) \leq r)$ , for every  $n \in \omega$ ;

$T \vdash (\phi \wedge \psi) \rightarrow w(\alpha U_n \beta) \leq r$ , for every  $n \in \omega$ ;

$T \vdash (\phi \wedge \psi) \rightarrow w(\alpha U \beta) \leq r$ , by R6;

$T \vdash \phi \rightarrow (\psi \rightarrow w(\alpha U \beta) \leq r)$ .

#### Lemma 1

1. If  $v(\sigma, \alpha) = 1$  for all  $\sigma \in \bar{\Sigma}$ , then  $\vdash \alpha$ .
2.  $\vdash w(\top) = 1$
3. If  $T \vdash \alpha \leftrightarrow \beta$ , then  $T \vdash w(\alpha) = w(\beta)$
4. If  $T$  is maximal consistent then either  $\phi \in T$  or  $\neg\phi \in T$ , for every  $\phi \in For_P$ .

*Proof.* (1) It is sufficient to prove that all the axioms of any complete axiomatization of LTL (for example C1–C8 form [Reynolds, 2001]) are theorems of our logic, and that the standard Generalization rule “if  $\alpha$  is a theorem, from  $\alpha$  infer  $G\alpha$ ” is derived rule in  $AX_{PLTL}$ . As an illustration, let us derive Generalization. If  $\vdash \alpha$ , applying rule R2 we obtain  $\vdash \bigcirc^n \alpha$  for every  $n \in \omega$ . Using A3, we conclude  $\vdash \neg \bigcirc^n \neg \alpha$  for every  $n \in \omega$ . Note that  $\neg \bigcirc^n \neg \alpha$  can be written as  $\neg(\top U_n \neg \alpha)$ . Finally, applying R4 we obtain  $\vdash \neg(\top U \neg \alpha)$ , or, equivalently,  $\vdash G\alpha$ .

(2) Follows directly from R3.

(3) Apply R3, then A8.

(4) If  $\phi \notin T$ , then  $T \cup \{\phi\} \vdash \perp$ , by the maximality of  $T$ . By Theorem 2, we have  $T \vdash \phi \rightarrow \perp$ , so  $T \vdash \neg\phi$ . Similarly, if  $\phi \in T$ , then  $T \vdash \phi$ , which contradicts the assumption that  $T$  is consistent.

Let us comment the lemma. By (1), we can use all the standard theorems of LTL in our reasoning in  $PL_{LTL}$ . (2) is an

axiom for probabilistic reasoning from [Fagin et al., 1990]. (3) plays the crucial role in the construction of the canonical model in the next section. If we choose  $\alpha$  and  $\beta$  to be propositional formulas and  $T = \emptyset$ , we obtain another axiom from [Fagin et al., 1990]. Thus, by (1)–(3),  $AX_{PLTL}$  extends both temporal and probabilistic logic.

We use (4) in the proof of Theorem 5. We already pointed out that the same property doesn't hold for the LTL formulas. Note that we cannot copy the proof of (4) in LTL case, since we distinguish between the probabilistic contradiction and LTL contradiction (although we use  $\perp$  in both cases).

## 4 THE COMPLETENESS OF $PL_{LTL}$

In this section we prove strong version of completeness theorem: “every consistent set of formulas has a model”. We use a Henkin-like construction. First we extend a consistent set  $T$  of formulas to a maximal consistent set  $T^*$ , then we use  $T^*$  to define the corresponding structure  $M_{T^*}$ , and finally we prove that  $M_{T^*}$  is a model of  $T$ . For given  $T^*$ , we say that  $M_{T^*}$  is its canonical model.

### 4.1 LINDENBAUM'S LEMMA

**Theorem 3 (Lindenbaum's lemma)** *Every consistent set of formulas can be extended to a maximal consistent set.*

*Proof.(sketch)* Let  $T$  be a consistent set and let  $\Phi_0, \Phi_1, \dots$  be an enumeration of all formulas from  $For$ . We define the sequence of sets  $T_i$ ,  $i = 0, 1, 2, \dots$  and the set  $T^*$  recursively as follows:

1.  $T_0 = T$ ,
2. for every  $i \geq 0$ ,
  - (a) if  $T_i \cup \{\Phi_i\}$  is consistent, then  $T_{i+1} = T_i \cup \{\Phi_i\}$ , otherwise
  - (b) if  $\Phi_i$  is of the form  $\gamma \rightarrow \neg(\alpha U \beta)$ , then  $T_{i+1} = T_i \cup \{\gamma \rightarrow (\alpha \bar{U}_n \beta)\}$ , where  $n$  is the smallest nonnegative integer such that  $T_{i+1}$  is consistent, otherwise
  - (c) if  $\Phi_i$  is of the form  $\phi \rightarrow f \geq r$ , then  $T_{i+1} = T_i \cup \{\phi \rightarrow f < r - \frac{1}{n}\}$ , where  $n$  is the smallest positive integer such that  $T_{i+1}$  is consistent, otherwise
  - (d) if  $\Phi_i$  is of the form  $\phi \rightarrow w(\alpha U \beta) \leq r$ , then  $T_{i+1} = T_i \cup \{\phi \rightarrow w(\alpha U_n \beta) > r\}$ , where  $n$  is the smallest nonnegative integer such that  $T_{i+1}$  is consistent, otherwise
  - (e)  $T_{i+1} = T_i$ .
3.  $T^* = \bigcup_{i=0}^{\infty} T_i$ .

First, using Theorem 2 one can prove that the set  $T^*$  is correctly defined, i.e., there exist  $n$  from the parts 2(b)–2(d) of the construction. Each  $T_i$ ,  $i > 0$  is consistent. The steps (1) and (2) of the construction ensure that  $T^*$  is maximal. Also,  $T^*$  obviously doesn't contain all formulas. Finally, one can show that  $T^*$  is deductively closed set, and as a consequence we obtain that  $T^*$  is consistent (otherwise it would contain  $\perp$ ).

### 4.2 CANONICAL MODEL

**Definition 11 (Canonical model)** *For a maximal consistent set  $T^*$ , we define a  $PL_{LTL}$  structure as a tuple  $M_{T^*} = \langle W, H, \mu, \pi \rangle$ , such that:*

1.  $W = \{\sigma \in \bar{\Sigma} \mid v(\sigma, \alpha) = 1 \text{ for all } \alpha \in T^* \cap For_{LTL}\}$ ,
2.  $H = \{[\alpha] \mid \alpha \in For_{LTL}\}$ , where  $[\alpha] = \{w \in W \mid v(w, \alpha) = 1\}$ ,
3.  $\mu([\alpha]) = \sup\{r \in \mathcal{Q} \mid T^* \vdash w(\alpha) \geq r\}$ , for every  $\alpha \in For_{LTL}$ ,
4.  $\pi(w) = w$  for every  $w \in W$ .

Now we show that  $M_{T^*}$  is a measurable  $PL_{LTL}$  structure. In the proof, we will use the following result.

**Lemma 2** *The axioms A1–A4 and the inference rules R1, R2 and R4 form a strongly complete axiomatization for LTL.*

*Proof.* We need to show that every consistent set  $T$  of LTL formulas has a model, i.e., that there is  $\sigma$  such that  $v(\sigma, \alpha) = 1$  for every  $\alpha \in T$ . Reasoning similarly as above, we can prove that Deduction theorem holds and that  $T$  can be extended to a maximal consistent set  $T^*$ . Now we work with LTL formulas only, and we can prove that for each  $\alpha$  either  $\alpha \in T^*$  or  $\neg\alpha \in T^*$ . Also, using the axiomatization it is straightforward to show that if  $T^*$  is maximal consistent set, then the set  $T_n^* = \{\alpha \mid \bigcirc \alpha \in T^*\}$  is also maximal consistent.

For given  $T^*$ , we define the path  $\sigma = s_0, s_1, \dots$  by  $s_i = \{p \in \mathcal{P} \mid T_i^* \vdash p\}$ .

It is sufficient to prove that  $v(\sigma, \gamma) = 1$  iff  $T^* \vdash \gamma$ , for every LTL formula  $\gamma$ . We use induction on the complexity of the formula. The only interesting case is when  $\gamma$  is of the form  $\alpha U \beta$ .

$v(\sigma, \gamma) = 0$  iff  $v(\sigma, \neg(\alpha U \beta)) = 1$

iff for all  $n \in \omega$ , it is not the case that  $v(\sigma_{\geq n}, \beta) = 1$  and

for all  $k < n$ ,  $v(\sigma_{\geq k}, \alpha) = 1$

iff for all  $n \in \omega$ , it is not the case that  $T_n^* \vdash \beta$  and for all  $k < n$ ,  $T_k^* \vdash \alpha$  (by induction hypothesis)

iff for all  $n \in \omega$ , it is not the case that  $T^* \vdash \bigcirc^n \beta$  and for all  $k < n$ ,  $T^* \vdash \bigcirc^k \alpha$

iff for all  $n \in \omega$ ,  $T^* \vdash \neg(\alpha \bar{U}_n \beta)$  (by the maximal consistency of  $T^*$ )  
iff  $T^* \vdash \neg(\alpha U \beta)$  (by R4).

**Theorem 4** For every maximal consistent set  $T^*$ ,  $M_{T^*} \in PL_{LTL}^{Meas}$ .

*Proof.* First we need to show that the definition is correct. The set  $\{[\alpha] \mid \alpha \in For_{LTL}\}$  is an algebra of subsets of  $W$ , since  $W = [\top]$ ,  $W \setminus [\alpha] = [\neg\alpha]$  and  $[\alpha] \cup [\beta] = [\alpha \vee \beta]$ . We also need to check that  $\mu$  is correctly defined, i.e., that if  $[\alpha] = [\beta]$  then  $\mu([\alpha]) = \mu([\beta])$ . From  $[\alpha] = [\beta]$  we conclude that if  $\sigma$  is a path such that  $v(\sigma, \gamma) = 1$  for all  $\gamma \in T^* \cap For_{LTL}$ , then  $v(\sigma, \alpha \leftrightarrow \beta) = 1$ . From Lemma 2 we obtain  $T^* \vdash \alpha \leftrightarrow \beta$ . Consequently,  $T^* \vdash w(\alpha) = w(\beta)$  by Lemma 1(3), so  $\mu([\alpha]) = \mu([\beta])$ . Obviously  $\mu(W) = \mu([\top]) = 1$  by Lemma 1(2). Similarly, using A6 we conclude that  $\mu$  is nonnegative, and using A7 we conclude that  $\mu$  is a finitely additive probability measure on  $A$ . We need to prove that  $\mu$  is  $\sigma$ -additive.

Let  $H_{\bar{\Sigma}} = \{[\alpha]_{\bar{\Sigma}} \mid \alpha \in For_{LTL}\}$ , where  $[\alpha]_{\bar{\Sigma}} = \{\sigma \in \bar{\Sigma} \mid v(w, \alpha) = 1\}$ . By  $For_{LTL}^{\circ}$  we denote the set of all LTL formulas in which  $\circ$  is the only temporal operator (i.e. there are no appearances of  $U$ ). We also introduce the set  $A = \{[\alpha] \mid \alpha \in For_{LTL}^{\circ}\}$ . Using the same argument as above, we can show that the sets  $H_{\bar{\Sigma}}$  and  $A$  are two algebras of subsets of  $\bar{\Sigma}$ . Similarly as in the definition of  $M_{T^*}$ , we define  $\mu^*$  on  $H_{\bar{\Sigma}}$  by

$$\mu^*([\alpha]_{\bar{\Sigma}}) = \sup\{r \in \mathcal{Q} \mid T^* \vdash w(\alpha) \geq r\}.$$

Reasoning as above, we conclude that  $\mu^*$  is a finitely additive measure. We also use the same symbol  $\mu^*$  to denote the restriction of  $\mu^*$  to  $A$ . We actually want to show that  $\mu^*$  is  $\sigma$ -additive on  $A$ . It is sufficient to show that if  $B = \bigcup_{n \in \omega} B_n$ , where  $B, B_n \in A$ , then there is  $n$  such that  $B = \bigcup_{n=0}^n B_n$ .

If  $2^{\mathcal{P}}$  denotes the set of subsets of  $\mathcal{P}$ , note that  $\bar{\Sigma} = 2^{\mathcal{P}} \times 2^{\mathcal{P}} \times 2^{\mathcal{P}} \times \dots$ . If we assume discrete topology on the finite set  $2^{\mathcal{P}}$  and the induced product topology on  $\bar{\Sigma}$ , then  $\bar{\Sigma}$  is a compact space as a product of compact spaces.<sup>3</sup> By definition of evaluation function  $v$ , we obtain that for every  $\alpha \in For_{LTL}^{\circ}$  there exist  $n \in \omega$  (for example  $n$  is the number of appearances of  $\circ$ ) and  $S \subseteq (2^{\mathcal{P}})^n$  such that  $[\alpha]_{\bar{\Sigma}} = S \times 2^{\mathcal{P}} \times 2^{\mathcal{P}} \times \dots$ . Note that the sets of the form  $S \times 2^{\mathcal{P}} \times 2^{\mathcal{P}} \times \dots$ , where  $S \subseteq (2^{\mathcal{P}})^n$  for some  $n \in \omega$ , are clopen (both closed and open) sets in product topology. Thus, each  $[\alpha]_{\bar{\Sigma}} \in A$  is a clopen set in  $\bar{\Sigma}$ . Now assume that  $[\alpha]_{\bar{\Sigma}} = \bigcup_{n \in \omega} [\alpha_n]_{\bar{\Sigma}}$ , where  $\alpha \in For_{LTL}^{\circ}$  and  $\alpha_n \in For_{LTL}^{\circ}$  for every  $n \in \omega$ . The set  $\{[\alpha_n]_{\bar{\Sigma}} \mid n \in \omega\}$  is an open cover of the closed subset  $[\alpha]_{\bar{\Sigma}}$  of the compact space  $\bar{\Sigma}$ , so there is a finite subcover  $\{[\alpha_{n_1}]_{\bar{\Sigma}}, \dots, [\alpha_{n_1}]_{\bar{\Sigma}}\}$  of  $[\alpha]_{\bar{\Sigma}}$ . Thus,  $\mu^*$  is  $\sigma$ -additive on  $A$ .

<sup>3</sup>For the basic notions and results about the topology used here we refer the reader to [Kechris, 1995]

Let  $F$  be the  $\sigma$ -algebra generated by  $A$ . Since  $[\alpha U \beta]_{\bar{\Sigma}} = \bigcup_{n \in \omega} [\alpha U_n \beta]_{\bar{\Sigma}}$ , we can show that  $[\alpha]_{\bar{\Sigma}} \in F$  for every  $\alpha \in For_{LTL}$ , using the induction on the number of appearances of  $U$  in  $\alpha$ . Thus,  $H_{\bar{\Sigma}} \subseteq F$ . By Caratheodory's extension theorem (see [Ash and Doléans-Dade, 1999]), there is a unique  $\sigma$ -additive probability measure  $\nu$  on  $F$  which coincide with  $\mu^*$  on  $A$ . We will actually show that  $\mu^*$  is the restriction of  $\nu$  to  $H_{\bar{\Sigma}}$ , i.e., that  $\mu^*([\alpha]_{\bar{\Sigma}}) = \nu([\alpha]_{\bar{\Sigma}})$  for all  $\alpha \in For_{LTL}$ , using the induction on the number of appearances of  $U$  in  $\alpha$ . Indeed,  $\nu([\alpha]_{\bar{\Sigma}}) = \nu(\bigcup_{n \in \omega} [\alpha U_n \beta]_{\bar{\Sigma}}) = \lim_{k \rightarrow +\infty} \nu(\bigcup_{n=1}^k [\alpha U_n \beta]_{\bar{\Sigma}}) = \lim_{k \rightarrow +\infty} \mu^*(\bigcup_{n=1}^k [\alpha U_n \beta]_{\bar{\Sigma}}) = \mu^*([\alpha U \beta]_{\bar{\Sigma}})$ . Here we used  $\sigma$ -additivity of  $\nu$ , the induction hypothesis and, in the last step, the definition of  $\mu^*$  and R6.

Thus,  $\mu^*$  is a  $\sigma$ -additive probability measure on  $H_{\bar{\Sigma}}$ . Note that we have that  $\mu^*([\alpha]_{\bar{\Sigma}}) = 1$  whenever  $T^* \vdash \alpha$ , by R3. Thus,  $\mu^*(W) = \mu^*(\bigcap_{\alpha: T^* \vdash \alpha} [\alpha]_{\bar{\Sigma}}) = 1$ , by  $\sigma$ -additivity of  $\mu^*$ .

Note that  $[\alpha] = [\alpha]_{\bar{\Sigma}} \cap W$ , so  $H \subseteq F$ . Let  $\bar{\mu}$  be the  $\sigma$ -additive probability measure on  $H$  induced by  $\mu^*$  by

$$\bar{\mu}([\alpha]) = \bar{\mu}([\alpha]_{\bar{\Sigma}} \cap W) = \mu^*([\alpha]_{\bar{\Sigma}}).$$

Note that  $\mu^*(W) = 1$  implies  $\mu^*([\alpha]_{\bar{\Sigma}}) = \mu^*([\alpha]_{\bar{\Sigma}} \cap W)$ , so  $\mu^*([\alpha]) = \nu([\alpha])$ . By definitions of  $\mu$  and  $\mu^*$  it follows that  $\mu$  and  $\nu$  coincide. Thus,  $\mu$  is  $\sigma$ -additive.

We showed that  $M_{T^*}$  is a  $PL_{LTL}$  structure. Finally, note that  $[\alpha] = [\alpha]_{M_{T^*}}$ , by the choice of  $\pi$ , so  $M_{T^*} \in PL_{LTL}^{Meas}$ .

Now we can prove the main result of this section.

### 4.3 COMPLETENESS THEOREM

**Theorem 5 (Strong completeness)** A set of formulas  $T \subseteq For$  is consistent iff it is satisfiable.

*Proof.* The direction from right to left follows from the soundness of the axiomatization  $AX_{PL_{LTL}}$ . For the other direction, we need to show that a consistent set of formulas  $T$  has a model. First we extend  $T$  to a maximal consistent set  $T^*$ , and we construct the canonical model  $M_{T^*}$ . We will show that  $M_{T^*}$  is a model of  $T^*$ , and, consequently, a model of  $T$ . It is sufficient to prove that for all  $\Phi \in For$ ,  $T^* \vdash \Phi$  iff  $M_{T^*} \models \Phi$ .

If  $\Phi = \alpha \in For_{LTL}$ . If  $\alpha \in T^*$ , then by the definition of  $W$  from  $M_{T^*}$ ,  $M_{T^*} \models \alpha$ . Conversely, if  $M_{T^*} \models \alpha$ , by Lemma 2,  $\alpha \in T^*$ .

If  $\Phi \in For_P$ , we proceed by induction on the complexity of  $\Phi$ .

Let  $\Phi = f \geq r$ . If  $f = r_1 w(\alpha_1) + \dots + r_k w(\alpha_k) + r_{k+1}$ , we can show, using the properties of supremum, that

$$r_1 \mu([\alpha_1]) + \dots + r_k \mu([\alpha_k]) + r_{k+1} = \sup\{s \mid T^* \vdash f \geq s\}.$$

If we suppose that  $f \geq r \in T^*$ , then  $r \leq \sup\{s \mid T^* \vdash f \geq s\}$ , so  $M_{T^*} \models f \geq r$ . For the other direction, assume that  $M_{T^*} \models f \geq r$ . Then  $M_{T^*} \not\models f < r$ . If  $f < r \in T^*$ ,

then, reasoning as above, we conclude  $M_{T^*} \models f < r$ , a contradiction. By Maximality of  $T^*$ , we obtain  $f \geq r \in T^*$ .

If  $\Phi = \neg\phi$ , then  $M_{T^*} \models \neg\phi$  iff  $M_{T^*} \not\models \phi$  iff  $\phi \notin T^*$  iff  $\neg\phi \in T^*$ , by maximality of  $T^*$ .

If  $\Phi = \phi \wedge \psi$ , then  $M_{T^*} \models \phi \wedge \psi$  iff  $M_{T^*} \models \phi$  and  $M_{T^*} \models \psi$  iff  $\phi, \psi \in T^*$  iff  $\phi \wedge \psi \in T^*$ , by maximality of  $T^*$ .

As it is well known, the alternative formulation of Completeness theorem, stated below, follows directly from the previous result.

**Theorem 6** *If  $T \subseteq For$  and  $\Phi \in For$ , then  $T \models \Phi$  iff  $T \vdash \Phi$ .*

## 5 THE DECIDABILITY OF $PL_{LTL}$

[Sistla and Clarke, 1985] proved that the logic LTL is decidable, and they showed that the problem of deciding whether an LTL formula is satisfiable in a path is  $PSPACE$ -complete. Note that if  $\alpha$  is not satisfiable in any path, then by Definition 6 it is not satisfiable in the logic  $PL_{LTL}$ . On the other hand, if there is a path  $\sigma$  such that  $v(\sigma, \alpha) = 1$ , then we can define a measurable structure  $M = \langle W, H, \mu, \pi \rangle$ , such that  $W = \{w\}$  is a singleton and  $\pi(w) = \sigma$  (note that in that case the range of  $\mu$  is  $\{0, 1\}$ ). Obviously,  $v(\pi(w), \alpha) = 1$  for every  $w \in W$ , so  $M \models \alpha$ . Thus, we proved that the satisfiability problem of LTL formulas for the logic  $PL_{LTL}$  is  $PSPACE$ -complete.

Now let us consider the satisfiability of a formula  $\varphi \in For_P$ . Let  $For_B(\varphi)$  denote the set of all basic probabilistic formulas which appear in  $\varphi$ . Suppose that the formula  $\varphi \in For_P$  is given in the complete disjunctive normal form (CDNF), i.e.,  $\varphi = \bigvee_{i=1}^m \varphi_i$ , where each  $\varphi_i$  is a conjunction of the formulas from  $For_B(\varphi)$  or their negations, using all elements of  $For_B(\varphi)$ , i.e. the number of conjuncts of each  $\varphi_i$  is  $|For_B(\varphi)|$ . Note that the disjunction  $\varphi$  is satisfiable iff at least one of its disjuncts  $\varphi_i$  is satisfiable.

Thus, we focus on satisfiability of the formulas of the form

$$\bigwedge_{k=1}^{|For_B(\varphi)|} \psi_k, \quad (3)$$

where each  $\psi_k$  is a basic formula or its negation. In the following, we assume that a formula of the form (3) is given, and we denote by  $F$  the set of its conjuncts  $\{\psi_k \mid k = 1, \dots, |For_B(\varphi)|\}$ .

For a LTL formula  $\alpha$ , by  $Subfor(\alpha)$  we denote the set of its subformulas. If  $For_{LTL}(F)$  is the set of all LTL formulas which appear in at least one element of  $F$  (under the scope of probability operator  $w$ ), let  $Subfor = \bigcup_{\alpha \in For_{LTL}(F)} Subfor(\alpha)$ . Let us consider the formulas

of the form

$$\bigwedge_{k=1}^{|Subfor|} \beta_k, \quad (4)$$

where each  $\beta_k$  belongs to  $Subfor \cup \{\neg\beta \mid \beta \in Subfor\}$ , and each subformula of  $\alpha$  appears exactly once (negated or not). Obviously the conjunction of any two different formulas of the form (4) is a contradiction, while the disjunction of all such formulas is a tautology. This enables us to translate the satisfiability problem to the problem of finding a solution of a system of inequalities. First, note that there are  $2^{|Subfor|}$  formulas of the form (4). First we eliminate the formulas which are not satisfiable in LTL, using the procedure from [Sistla and Clarke, 1985]. Suppose that there are  $\ell$  formulas which are satisfiable ( $\ell \leq 2^{|Subfor|}$ ). We denote those formulas by  $\alpha_1, \dots, \alpha_\ell$ .

For any formula  $\alpha \in For_{LTL}(F)$  we have that  $\alpha \in Subfor$ . Consequently,  $\alpha$  appears in each conjunction  $\alpha_k$ , negated or not. Since  $\bigvee_{k=1}^{\ell} \alpha_k$  is a tautology, there is a unique set of indices  $I_\alpha \subseteq \{1, \dots, \ell\}$  such that  $\alpha \leftrightarrow \bigvee_{i \in I_\alpha} \alpha_i$  is a tautology. Let  $\Gamma_\alpha$  be the corresponding set  $\{\alpha_i \mid i \in I_\alpha\}$ . Using the probabilistic axioms and Lemma 1(3), we obtain

$$\vdash w(\alpha) = \sum_{\alpha_i \in \Gamma_\alpha} w(\alpha_i). \quad (5)$$

Now, we can transform every formula  $\psi \in F$  of the form  $r_1 w(\gamma_1) + \dots + r_k w(\gamma_k) \geq r_{k+1}$  to the equivalent formula

$$r_1 \sum_{\alpha_i \in \Gamma_{\gamma_1}} w(\alpha_i) + \dots + r_k \sum_{\alpha_i \in \Gamma_{\gamma_k}} w(\alpha_i) \geq r_{k+1}. \quad (6)$$

Thus, we obtain that a measurable structure  $M = \langle W, H, \mu, \pi \rangle$  satisfies  $\psi$  if and only if

$$r_1 \sum_{\alpha_i \in \Gamma_{\gamma_1}} \mu([\alpha_i]) + \dots + r_k \sum_{\alpha_i \in \Gamma_{\gamma_k}} \mu([\alpha_i]) \geq r_{k+1}. \quad (7)$$

Similarly, if  $\psi$  from  $F$  is a negation of a basic probabilistic formula, then it is of the form  $r_1 w(\gamma_1) + \dots + r_k w(\gamma_k) < r_{k+1}$ , which give us the similar condition for satisfiability of  $\psi$  under  $M$ :

$$r_1 \sum_{\alpha_i \in \Gamma_{\gamma_1}} \mu([\alpha_i]) + \dots + r_k \sum_{\alpha_i \in \Gamma_{\gamma_k}} \mu([\alpha_i]) < r_{k+1}. \quad (8)$$

Let denote by  $x_i$  the probability of the formula  $\alpha_i$  in a potential model  $M = \langle W, H, \mu, \pi \rangle$  of the formula (3), i.e.,  $x_i = \mu([\alpha_i])$  each  $i \in \{1, \dots, \ell\}$ .

Let  $F_{pos}$  be the set of basic probabilistic formulas from  $F$ , and let  $F_{neg}$  be the set of formulas from  $F$  which are negations of basic probabilistic formulas. For given  $\psi \in F_{pos}$  of the form  $r_1 w(\gamma_1) + \dots + r_k w(\gamma_k) \geq r_{k+1}$  we define the inequality  $Ineq(\psi)$ , obtained by (7), as

$$Ineq(\psi) : r_1 \left( \sum_{i: \alpha_i \in \Gamma_{\gamma_1}} x_i \right) + \dots + r_k \left( \sum_{i: \alpha_i \in \Gamma_{\gamma_k}} x_i \right) \geq r_{k+1}.$$

In the same way we define  $Ineq(\psi)$  for  $\psi \in F_{neg}$  of the form  $r_1 w(\gamma_1) + \dots + r_k w(\gamma_k) < r_{k+1}$  as

$$Ineq(\psi) : r_1 \left( \sum_{i:\alpha_i \in \Gamma_{\gamma_1}} x_i \right) + \dots + r_k \left( \sum_{i:\alpha_i \in \Gamma_{\gamma_k}} x_i \right) < r_{k+1}.$$

Then the formula (3) is satisfiable iff the following sentence of the language of real closed fields is satisfiable:

$$\begin{aligned} \exists x_1 \dots \exists x_\ell \quad & \left( \bigwedge_{k=1}^{\ell} (x_k \geq 0) \right) \\ & \wedge \sum_{k=1}^{\ell} x_k = 1 \\ & \wedge \bigwedge_{\psi \in F} Ineq(\psi). \end{aligned}$$

The sentence represents a nonlinear system of linear inequalities: the first line represents non-negativity of probability measures; the second line represents the condition  $\mu(W) = \mu([\top]) = \sum_{k=1}^{\ell} \mu([\alpha_k]) = 1$ . The third line represent the conditions (7) and (8). Obviously, if the system doesn't have a solution, there is no  $\mu$  which satisfies (3). If the system has the solution  $(x_1, \dots, x_\ell) = (c_1, \dots, c_\ell)$ , then we can construct  $M = \langle W, H, \mu, \pi \rangle$  which satisfies (3) in the following way:  $W = \{w_1, \dots, w_\ell\}$ ,  $\pi(w_i)$  is any path  $\sigma$  such that  $v(\sigma, \alpha_i) = 1$ ,  $H$  is the set of all subsets of  $W$  and  $\mu$  is determined by the condition  $\mu(\{w_i\}) = c_i$ .

Since the theory of real closed fields is decidable, our logic is decidable as well. Moreover, note that the above sentence is an existential sentence. Thus, we can use Canny's decision procedure from [Canny, 1988]. Since the procedure decides satisfiability of the formula in  $PSPACE$ , we conclude that satisfiability of probabilistic formulas is in  $PSPACE$  as well.

Thus, in both probabilistic and LTL case there is a procedure which decides satisfiability of the formula in  $PSPACE$ . Since  $PSPACE$  is also a lower bound in the case of LTL formulas, we proved the following result.

**Theorem 7** *The problem of deciding whether a formula of the logic  $PL_{LTL}$  is satisfiable in a measurable structure from  $PL_{LTL}^{Meas}$  is  $PSPACE$ -complete.*

## 6 CONCLUSION

In this paper, we introduced the logic  $PL_{LTL}$  for probabilistic reasoning about temporal information. The language contains both LTL formulas and probabilistic formulas in the style of [Fagin et al., 1990], with the difference that the probabilistic operator  $w$  is now applied to LTL formulas. We propose an axiomatization for the logic and prove strong completeness. Since the semantical relationship between the operators “next” and “until” explicitly requires  $\sigma$ -additive semantics, the axiomatization contains infinitary rules of inference. We show that the satisfiability

problem is  $PSPACE$ -complete, no harder than satisfiability for LTL.

It seems that combining any standard finitary axiomatization of LTL with the axiomatization from [Fagin et al., 1990] could be extended to a weakly (but not strongly) complete axiomatization for a finitely additive restriction of our logic, which would be convenient for possible applications. On the other hand, we believe that our infinitary rules of inference can be represented using schemes (similarly as quantifiers in the first order logic are abbreviations for the infinite conjunctions and disjunctions), so that some of infinitary proofs might be finitary represented and used in automated reasoning.

Some probabilistic LTL's were motivated by the need to analyze probabilistic programs and stochastic systems [Donaldson and Gilbert, 2008, Feldman, 1984, Hansson and Jonsson, 1994, Kozen, 1985, Lehmann and Shelah, 1982]. In some of them, probabilistic operators are not explicitly mentioned in the formulas, while in the others it is possible to directly express probabilities. Our logic allows one to quantify runs satisfying some properties. In this paper we restrict our attention to theoretical issues (e.g., worst case complexity), while the possible applications (e.g., heuristic procedures for satisfiability checking) are left for the future work.

## Abstract

We consider training a deep neural network to generate samples from an unknown distribution given i.i.d. data. We frame learning as an optimization minimizing a two-sample test statistic—informally speaking, a good generator network produces samples that cause a two-sample test to fail to reject the null hypothesis. As our two-sample test statistic, we use an unbiased estimate of the maximum mean discrepancy, which is the centerpiece of the nonparametric kernel two-sample test proposed by Gretton et al. [2]. We compare to the *adversarial nets* framework introduced by Goodfellow et al. [1], in which learning is a two-player game between a generator network and an adversarial discriminator network, both trained to outwit the other. From this perspective, the MMD statistic plays the role of the discriminator. In addition to empirical comparisons, we prove bounds on the generalization error incurred by optimizing the empirical MMD.

## 1 INTRODUCTION

In this paper, we consider the problem of learning generative models from i.i.d. data with unknown distribution  $\mathcal{P}$ . We formulate the learning problem as one of finding a function  $G$ , called the *generator*, such that, given an input  $Z$  drawn from some fixed *noise* distribution  $\mathcal{N}$ , the distribution of the output  $G(Z)$  is close to the data's distribution  $\mathcal{P}$ . Note that, given  $G$  and  $\mathcal{N}$ , we can easily generate new samples despite not having an explicit representation for the underlying density.

We are particularly interested in the case where the generator is a deep neural network whose parameters we must learn. Rather than being used to classify or predict, these networks transport input randomness to output random-

ness, thus inducing a distribution. The first direct instantiation of this idea is due to MacKay [7], although MacKay draws connections even further back to the work of Saund [11] and others on autoencoders, suggesting that generators can be understood as decoders. MacKay's proposal, called *density networks*, uses multi-layer perceptrons (MLP) as generators and learns the parameters by approximating Bayesian inference.

Since MacKay's proposal, there has been a great deal of progress on learning generative models, especially over high-dimensional spaces like images. Some of the most successful approaches have been based on restricted Boltzmann machines [10] and deep Boltzmann networks [3]. A recent example is the Neural Autoregressive Density Estimator due to Uria, Murray, and Larochelle [15]. An indepth survey, however, is beyond the scope of this article.

This work builds on a proposal due to Goodfellow et al. [1]. Their *adversarial nets* framework takes an indirect approach to learning deep generative neural networks: a discriminator network is trained to recognize the difference between training data and generated samples, while the generator is trained to confuse the discriminator. The resulting two-player game is cast as a minimax optimization of a differentiable objective and solved greedily by iteratively performing gradient descent steps to improve the generator and then the discriminator.

Given the greedy nature of the algorithm, Goodfellow et al. [1] give a careful prescription for balancing the training of the generator and the discriminator. In particular, two gradient steps on the discriminator's parameters are taken for every iteration of the generator's parameters. It is not clear at this point how sensitive this balance is as the data set and network vary. In this paper, we describe an approximation to adversarial learning that replaces the adversary with a closed-form nonparametric two-sample test statistic based on the Maximum Mean Discrepancy (MMD), which we adopted from the kernel two sample test [2]. We call our proposal *MMD nets*.<sup>1</sup> We give bounds on the estimation

<sup>1</sup>In independent work reported in a recent preprint, Li, Swer-

error incurred by optimizing an empirical estimator rather than the true population MMD and give some illustrations on synthetic and real data.

## 2 LEARNING TO SAMPLE AS OPTIMIZATION

It is well known that, for any distribution  $\mathcal{P}$  and any continuous distribution  $\mathcal{N}$  on sufficiently regular spaces  $\mathbb{X}$  and  $\mathbb{W}$ , respectively, there is a function  $G : \mathbb{W} \rightarrow \mathbb{X}$ , such that  $G(W) \sim \mathcal{P}$  when  $W \sim \mathcal{N}$ . (See, e.g., [4, Lem. 3.22].) In other words, we can transform an input from a fixed input distribution  $\mathcal{N}$  through a deterministic function, producing an output whose distribution is  $\mathcal{P}$ . For a given family  $\{G_\theta\}$  of functions  $\mathbb{W} \rightarrow \mathbb{X}$ , called *generators*, we can cast the problem of learning a generative model as an optimization

$$\arg \min_{\theta} \delta(\mathcal{P}, G_\theta(\mathcal{N})), \quad (1)$$

where  $\delta$  is some measure of discrepancy and  $G_\theta(\mathcal{N})$  is the distribution of  $G_\theta(W)$  when  $W \sim \mathcal{N}$ . In practice, we only have i.i.d. samples  $X_1, X_2, \dots$  from  $\mathcal{P}$ , and so we optimize an empirical estimate of  $\delta(\mathcal{P}, G_\theta(\mathcal{N}))$ .

### 2.1 ADVERSARIAL NETS

Adversarial nets [1] can be cast within this framework: Let  $\{D_\phi\}$  be a family of functions  $\mathbb{X} \rightarrow [0, 1]$ , called *discriminators*. We recover the adversarial nets objective with the discrepancy

$$\delta_{\text{AN}}(\mathcal{P}, G_\theta(\mathcal{N})) = \max_{\phi} E[\log D_\phi(X) + \log(1 - D_\phi(Y))],$$

where  $X \sim \mathcal{P}$  and  $Y \sim G_\theta(\mathcal{N})$ . In this case, Eq. (1) becomes

$$\min_{\theta} \max_{\phi} V(G_\theta, D_\phi)$$

where

$$V(G_\theta, D_\phi) = E[\log D_\phi(X) + \log(1 - D_\phi(G_\theta(W)))]$$

for  $X \sim \mathcal{P}$  and  $W \sim \mathcal{N}$ . The output of the discriminator  $D_\phi$  can be interpreted as the probability it assigns to its input being drawn from  $\mathcal{P}$ , and so  $V(G_\theta, D_\phi)$  is the expected log loss incurred when classifying the origin of a point equally likely to have been drawn from  $\mathcal{P}$  or  $G_\theta(\mathcal{N})$ . Therefore, optimizing  $\phi$  maximizes the probability of distinguishing samples from  $\mathcal{P}$  and  $G_\theta(\mathcal{N})$ . Assuming that the optimal discriminator exists for every  $\theta$ , the optimal generator  $G$  is that whose output distribution is closest to  $\mathcal{P}$ , as measured by the Jensen–Shannon divergence, which is minimized when  $G_\theta(\mathcal{N}) = \mathcal{P}$ .

sky, and Zemel [6] also propose to use MMD as a training objective for generative neural networks. We leave a comparison to future work.

In [1], the generators  $G_\theta$  and discriminators  $D_\phi$  are chosen to be multilayer perceptrons (MLP). In order to find a minimax solution, they propose taking alternating gradient steps along  $D_\phi$  and  $G_\theta$ . Note that the composition  $D_\phi(G_\theta(\cdot))$  that appears in the value function is yet another (larger) MLP. This fact permits the use of the back-propagation algorithm to take gradient steps.

### 2.2 MMD AS AN ADVERSARY

In their paper introducing adversarial nets, Goodfellow et al. [1] remark that a balance must be struck between optimizing the generator and optimizing the discriminator. In particular, the authors suggest  $k$  maximization steps for every one minimization step to ensure that  $D_\phi$  is well synchronized with  $G_\theta$  during training. A large value for  $k$ , however, can lead to overfitting. In their experiments, for every step taken along the gradient with respect to  $G_\theta$ , they take two gradient steps with respect to  $D_\phi$  to bring  $D_\phi$  closer to the desired optimum (Goodfellow, pers. comm.).

It is unclear how sensitive this balance is. Regardless, while adversarial networks deliver impressive sampling performance, the optimization takes approximately 7.5 hours to train on the MNIST dataset running on a GeForce GTX TITAN GPU from nVidia with 6GB RAM. Can we potentially speed up the process with a more tractable choice of adversary?

Our proposal is to replace the adversary with the kernel two-sample test introduced by Gretton et al. [2]. In particular, we replace the family of discriminators with a family  $\mathcal{H}$  of test functions  $\mathbb{X} \rightarrow \mathbb{R}$ , closed under negation, and use the maximum mean discrepancy between  $\mathcal{P}$  and  $G_\theta(\mathcal{N})$  over  $\mathcal{H}$ , given by

$$\delta_{\text{MMD}_{\mathcal{H}}}(\mathcal{P}, G_\theta(\mathcal{N})) = \sup_{f \in \mathcal{H}} E[f(X)] - E[f(Y)], \quad (2)$$

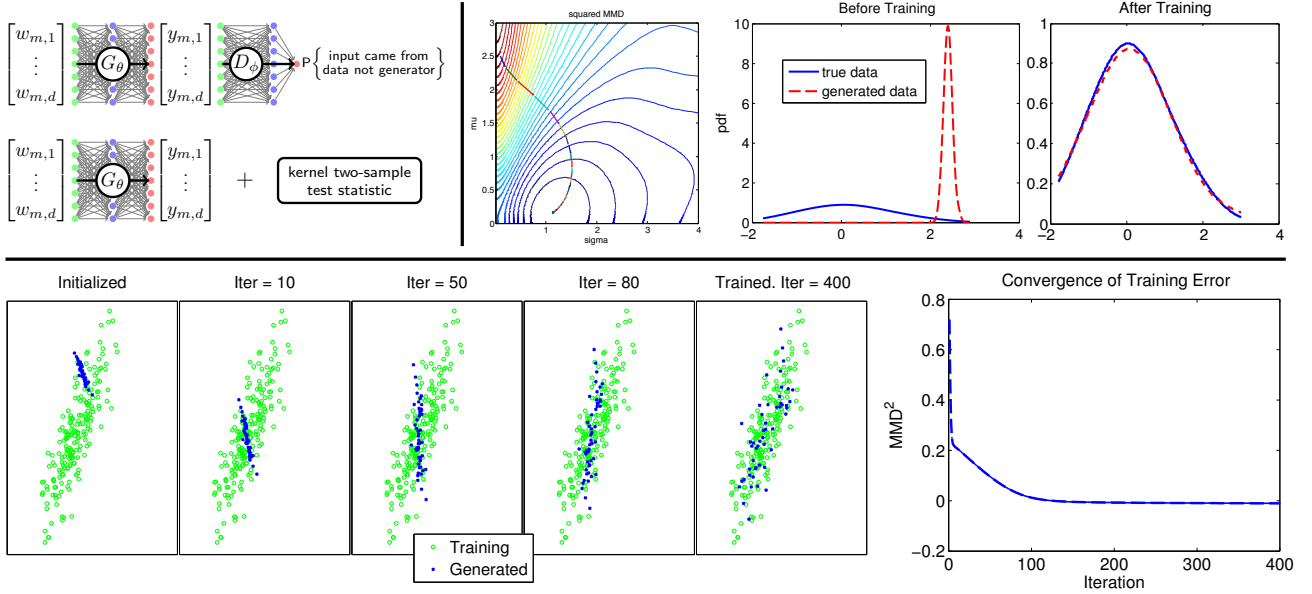

where  $X \sim \mathcal{P}$  and  $Y \sim G_\theta(\mathcal{N})$ . See Fig. 1 for a comparison of the architectures of adversarial and MMD nets.

While Eq. (2) involves a maximization over a family of functions, Gretton et al. [2] show that it can be solved in closed form when  $\mathcal{H}$  is a reproducing kernel Hilbert space (RKHS).

More carefully, let  $\mathcal{H}$  be a reproducing kernel Hilbert space (RKHS) of real-valued functions on  $\Omega$  and let  $\langle \cdot, \cdot \rangle_{\mathcal{H}}$  denote its inner product. By the reproducing property it follows that there exists a *reproducing kernel*  $k \in \mathcal{H}$  such that every  $f \in \mathcal{H}$  can be expressed as

$$f(x) = \langle f, k(\cdot, x) \rangle_{\mathcal{H}} = \sum \alpha_i k(x, x_i) \quad (3)$$

The functions *induced by a kernel*  $k$  are those functions in the closure of the span of the set  $\{k(\cdot, x) : x \in \Omega\}$ , which is necessarily an RKHS. Note, that for every positive definite kernel there is a unique RKHS  $\mathcal{H}$  such that every function in  $\mathcal{H}$  satisfies Eq. (3).

**Figure 1:** (top left) Comparison of adversarial nets and MMD nets. (top right) Here we present a simple one-dimensional illustration of optimizing a generator via MMD. Both the training data and noise data are Gaussian distributed and we consider the class of generators given by  $G_{(\mu, \sigma)}(w) = \mu + \sigma w$ . The plot on the left shows the isocontours of the MMD-based cost function and the path taken by gradient descent. On right, we show the distribution of the generator before and after a number of training iterations, as compared with the data generating distribution. Here we did not resample the generated points and so we do not expect to be able to drive the MMD to zero and match the distribution exactly. (bottom) The same procedure is repeated here for a two-dimensional dataset. On the left, we see the gradual alignment of the Gaussian-distributed input data to the Gaussian-distributed output data as the parameters of the generator  $G_\theta$  are optimized. The learning curve on the right shows the decrease in MMD obtained via gradient descent.

Assume that  $\mathbb{X}$  is a nonempty compact metric space and  $\mathcal{F}$  a class of functions  $f : \mathbb{X} \rightarrow \mathbb{R}$ . Let  $p$  and  $q$  be Borel probability measures on  $\mathbb{X}$ , and let  $X$  and  $Y$  be random variables with distribution  $p$  and  $q$ , respectively. The *maximum mean discrepancy* (MMD) between  $p$  and  $q$  is

$$\text{MMD}(\mathcal{F}, p, q) = \sup_{f \in \mathcal{F}} E[f(X)] - E[f(Y)]$$

If  $\mathcal{F}$  is chosen to be an RKHS  $\mathcal{H}$ , then

$$\text{MMD}^2(\mathcal{F}, p, q) = \|\mu_p - \mu_q\|_{\mathcal{H}}^2$$

where  $\mu_p \in \mathcal{H}$  is the *mean embedding* of  $p$ , given by

$$\mu_p = \int_{\mathbb{X}} k(x, \cdot) p(dx) \in \mathcal{H}$$

and satisfying, for all  $f \in \mathcal{H}$ ,

$$E[f(X)] = \langle f, \mu_p \rangle_{\mathcal{H}}.$$

The properties of  $\text{MMD}(\mathcal{H}, \cdot, \cdot)$  depend on the underlying RKHS  $\mathcal{H}$ . For our purposes, it suffices to say that if we take  $\mathbb{X}$  to be  $\mathbb{R}^D$  and consider the RKHS  $\mathcal{H}$  induced by Gaussian or Laplace kernels, then MMD is a metric, and so the minimum of our learning objective is achieved uniquely by  $\mathcal{P}$ , as desired. (For more details, see Sriperumbudur et al. [12].)

In practice, we often do not have access to  $p$  or  $q$ . Instead, we are given independent i.i.d. data  $X, X', X_1, \dots, X_N$  and  $Y, Y', Y_1, \dots, Y_M$  from  $p$  and  $q$ , respectively, and would like to estimate the MMD. Gretton et al. [2] showed that

$$\text{MMD}^2[\mathcal{H}, p, q] = E[k(X, X') - 2k(X, Y) + k(Y, Y')]$$

and then proposed an unbiased estimator

$$\begin{aligned} \text{MMD}_u^2[\mathcal{H}, X, Y] &= \frac{1}{N(N-1)} \sum_{n \neq n'} k(x_n, x_{n'}) \\ &+ \frac{1}{M(M-1)} \sum_{m \neq m'} k(y_m, y_{m'}) \\ &- \frac{2}{MN} \sum_{m=1}^M \sum_{n=1}^N k(x_n, y_m). \end{aligned} \quad (4)$$

### 3 MMD NETS

With an unbiased estimator of the MMD objective in hand, we can now define our proposal, *MMD nets*: Fix a neural network  $G_\theta$ , where  $\theta$  represents the parameters of the network. Let  $W = (w_1, \dots, w_M)$  denote noise inputs drawn from  $\mathcal{N}$ , let  $Y_\theta = (y_1, \dots, y_m)$  with  $y_j = G_\theta(w_j)$  denote

---

**end for**

---

the noise inputs transformed by the network  $G_\theta$ , and let  $X = (x_1, \dots, x_N)$  denote the training data in  $\mathbb{R}^D$ . Given a positive definite kernel  $k$  on  $\mathbb{R}^D$ , we minimize  $C(Y_\theta, X)$  as a function of  $\theta$ , where

$$C(Y_\theta, X) = \frac{1}{M(M-1)} \sum_{m \neq m'} k(y_m, y_{m'}) - \frac{2}{MN} \sum_{m=1}^M \sum_{n=1}^N k(y_m, x_n).$$

Note that  $C(Y_\theta, X)$  is composed of only those parts of the unbiased estimator (Eq. (4)) that depend on  $\theta$ .

In practice, the minimization is solved by gradient descent, possibly on subsets of the data. More carefully, the chain rule gives us

$$\nabla C(Y_\theta, X) = \frac{1}{N} \sum_{n=1}^N \sum_{m=1}^M \frac{\partial C_n(Y_\theta, X_n)}{\partial y_m} \frac{\partial G_\theta(w_m)}{\partial \theta},$$

where

$$C_n(Y_\theta, X_n) = \frac{1}{M(M-1)} \sum_{m \neq m'} k(y_m, y_{m'}) - \frac{2}{M} \sum_{m=1}^M k(y_m, x_n).$$

Each derivative  $\frac{\partial C_n(Y_\theta, X_n)}{\partial y_m}$  is easily computed for standard kernels like the RBF kernel. Our gradient  $\nabla C(Y_\theta, X_n)$  depends on the partial derivatives of the generator with respect to its parameters, which we can compute using back propagation.

## 4 MMD GENERALIZATION BOUNDS

MMD nets operate by minimizing an empirical estimate of the MMD. This estimate is subject to Monte Carlo error and so the network weights (parameters)  $\hat{\theta}$  that are found to

minimize the empirical MMD may do a poor job at minimizing the exact population MMD. We show that, for sufficiently large data sets, this estimation error is bounded, despite the space of parameters  $\theta$  being continuous and high dimensional.

Let  $\Theta$  denote the space of possible parameters for the generator  $G_\theta$ , let  $\mathcal{N}$  be the distribution on  $\mathcal{W}$  for the noisy inputs, and let  $p_\theta = G_\theta(\mathcal{N})$  be the distribution of  $G_\theta(W)$  when  $W \sim \mathcal{N}$  for  $\theta \in \Theta$ . Let  $\hat{\theta}$  be the value optimizing the unbiased empirical MMD estimate, i.e.,

$$\text{MMD}_u^2(\mathcal{H}, X, Y_{\hat{\theta}}) = \inf_{\theta} \text{MMD}_u^2(\mathcal{H}, X, Y_\theta), \quad (5)$$

and let  $\theta^*$  be the value optimizing the population MMD, i.e.,

$$\text{MMD}^2(\mathcal{H}, p_{\text{data}}, p_{\theta^*}) = \inf_{\theta} \text{MMD}^2(\mathcal{H}, p_{\text{data}}, p_\theta).$$

We are interested in bounding the difference

$$\text{MMD}^2(\mathcal{H}, p_{\text{data}}, p_{\hat{\theta}}) - \text{MMD}^2(\mathcal{H}, p_{\text{data}}, p_{\theta^*}).$$

To that end, for a measured space  $\mathcal{X}$ , write  $L_\infty(\mathcal{X})$  for the space of essentially bounded functions on  $\mathcal{X}$  and write  $B(L_\infty(\mathcal{X}))$  for the unit ball under the sup norm, i.e.,

$$B(L_\infty(\mathcal{X})) = \{f: \mathcal{X} \rightarrow \mathbb{R} : (\forall x \in \mathcal{X}) f(x) \in [-1, 1]\}.$$

The bounds we obtain will depend on a notion of complexity captured by the fat-shattering dimension:

**Definition 1** (Fat-shattering [8]). Let  $\mathcal{X}_N = \{x_1, \dots, x_N\} \subset \mathcal{X}$  and  $\mathcal{F} \subset B(L_\infty(\mathcal{X}))$ . For every  $\varepsilon > 0$ ,  $\mathcal{X}_N$  is said to be  $\varepsilon$ -shattered by  $\mathcal{F}$  if there is some function  $h: \mathcal{X} \rightarrow \mathbb{R}$ , such that for every  $I \subset \{1, \dots, N\}$  there is some  $f_I \in \mathcal{F}$  for which

$$\begin{aligned} f_I(x_n) &\geq h(x_n) + \varepsilon \text{ if } n \in I, \\ f_I(x_n) &\leq h(x_n) - \varepsilon \text{ if } n \notin I. \end{aligned}$$

For every  $\varepsilon$ , the *fat-shattering dimension* of  $\mathcal{F}$ , written  $\text{fat}_\varepsilon(\mathcal{F})$ , is defined as

$$\text{fat}_\varepsilon(\mathcal{F}) = \sup \{|\mathcal{X}_N| : \mathcal{X}_N \subset \mathcal{X}, \mathcal{X}_N \text{ is } \varepsilon\text{-shattered by } \mathcal{F}\}.$$

Consider the class

$$\mathcal{G}_{k+}^{\mathbb{X}} = \{g = k(x, G_\theta(\cdot)) : x \in \mathbb{X}, \theta \in \Theta\}$$

of functions from  $\mathcal{W}$  to  $\mathbb{R}$  that are compositions of some generator and the kernel with some fixed input, and the (sub)class

$$\mathcal{G}_{k+} = \{g = k(G_\theta(w), G_\theta(\cdot)) : w \in \mathcal{W}, \theta \in \Theta\}.$$

We then have the following bound on the estimation error:

**Theorem 1** (estimation error). *Assume the kernel is bounded by one and that there exists  $\gamma_1, \gamma_2 > 1$  and  $p_1, p_2 \in \mathbb{N}$  such that, for all  $\varepsilon > 0$ , it holds that  $\text{fat}_\varepsilon(\mathcal{G}_{k+}) \leq \gamma_1 \varepsilon^{-p_1}$  and  $\text{fat}_\varepsilon(\mathcal{G}_{k+}^X) \leq \gamma_2 \varepsilon^{-p_2}$ . Then with probability at least  $1 - \delta$ ,*

$$\text{MMD}^2(\mathcal{H}, p_{\text{data}}, p_{\hat{\theta}}) < \text{MMD}^2(\mathcal{H}, p_{\text{data}}, p_{\theta^*}) + \varepsilon,$$

with

$$\varepsilon = r(p_1, \gamma_1, M) + r(p_2, \gamma_2, M - 1) + 12M^{-\frac{1}{2}} \sqrt{\log \frac{2}{\delta}},$$

where the rate  $r(p, \gamma, M)$  is

$$r(p, \gamma, M) = C_p \sqrt{\gamma} \begin{cases} M^{-\frac{1}{2}} & \text{if } p < 2, \\ M^{-\frac{1}{2}} \log^{\frac{3}{2}}(M) & \text{if } p = 2, \\ M^{-\frac{1}{p}} & \text{if } p > 2, \end{cases}$$

for constants  $C_{p_1}$  and  $C_{p_2}$  depending on  $p_1$  and  $p_2$  alone.

The proof appears in the appendix. We can obtain simpler, but slightly more restrictive, hypotheses if we bound the fat-shattering dimension of the class of generators  $\{G_\theta : \theta \in \Theta\}$  alone: Take the observation space  $\mathbb{X}$  to be a bounded subset of a finite-dimensional Euclidean space and the kernel to be Lipschitz continuous and translation invariant. For the RBF kernel, the Lipschitz constant is proportional to the inverse of the length-scale: the resulting bound loosens as the length scale shrinks.

## 5 EMPIRICAL EVALUATION

In this section, we demonstrate the approach on an illustrative synthetic example as well as the standard MNIST digits and Toronto Face Dataset (TFD) benchmarks. We show that MMD-based optimization of the generator rapidly delivers a generator that produces recognizable samples, but these samples are inferior to those produced by adversarial networks, both visually and as measured by an estimate of the mean log density on a held-out test set.

### 5.1 GAUSSIAN DATA, KERNEL, AND GENERATOR

Under an RBF kernel and Gaussian generator with parameters  $\theta = \{\mu, \sigma\}$ , it is straightforward to find the gradient of  $C(Y_\theta, X)$  by applying the chain rule. Using fixed random standard normal numbers  $\{w_1, \dots, w_M\}$ , we have  $y_m = \mu + \sigma w_m$  for  $m \in \{1, \dots, M\}$ . The result of these illustrative synthetic experiments can be found in Fig. 1. The dataset consisted of  $N = 200$  samples from a standard normal and  $M = 50$  noise input samples were generated from a standard normal with a fixed random seed. The algorithm was initialized at values  $\{\mu, \sigma\} = \{2.5, 0.1\}$ . We fixed the learning rate to 0.5 and ran gradient descent steps for  $K = 250$  iterations.

### 5.2 MNIST DIGITS

We evaluated MMD nets on MNIST digits [5]. The generator was chosen to be a fully connected, 3 hidden layer neural network with sigmoidal activation functions. Following Gretton et al. [2], we used a radial basis function (RBF) kernel, but also evaluated the rational quadratic (RQ) kernel [9] and Laplacian kernel, but found that the RBF performed best in the parameter ranges we evaluated. We used Bayesian optimization (WHETLab) to set the bandwidth of the RBF and the number of neurons in each layer on initial test runs of 50,000 iterations. However, one can get a similar-quality generator simply using the median heuristic [2] to set the kernel bandwidth. The learning rate was adjusting during optimization by RMSPROP [14].

Fig. 2 presents the digits learned after 1,000,000 iterations. (Doubling the number of iterations produced similar images.) We performed minibatch stochastic gradient descent, resampling the generated digits every 300 iterations, with minibatches of 500 training and generated points. It is clear that the digits produced have many artifacts not appearing in the MNIST data set. Indeed, the mean log density of held-out test data was estimated to be only  $113 \pm 2$ , as compared with the reported  $225 \pm 2$  achieved by adversarial nets. On the other hand, most of the gain is achieved by MMD nets in the first 100-200k iterations, and so perhaps MMD nets could be used to initialize a network further optimized by other means.

### 5.3 TORONTO FACE DATASET

We also evaluated MMD nets on the Toronto face dataset (TFD) [13]. We used a 3-hidden-layer sigmoidal MLP with similar architecture (1000, 600, and 1000 units) and RBF kernel for the cost function with the same hyper parameter. We used 500 training and generated points per batch. The generated points were resampled every 500 iterations. The network was optimized for 500,000 iterations. Samples from the resulting network are plotted in Fig. 3. Again, the samples produced by MMD nets are clearly distinguishable from the training samples and this is reflected in a much lower mean log density than adversarial nets.

## 6 CONCLUSION

MMD offers a closed-form surrogate for the discriminator in the adversarial nets framework. After using Bayesian optimization for the parameters, we found that the network produced samples that were visually similar, but far from indistinguishable from those used to train the network. On one hand, adversarial nets handily outperformed MMD nets in terms of mean log density. On the other, MMD nets achieve most of their gain quickly and so it seems promising to combine MMD nets with another technique, perhaps using MMD nets to initialize a more costly procedure.

**Figure 2:** (top-left) MNIST digits from the training set. (top-right) Newly generated digits produced after 1,000,000 iterations (approximately 5 hours). Despite the remaining artifacts, the resulting kernel-density estimate of the test data is state of the art. (top-center) Newly generated digits after 300 further iterations optimizing the associated empirical MMD. (bottom-left) MMD learning curves for first 2000 iterations. (bottom-right) MMD learning curves from 2000 to 500,000 iterations. Note the difference in y-axis scale. No appreciable change is seen in later iterations.

**Figure 3:** (left) TFD. (right) Faces generated by network trained for 500,000 iterations. (center) After an additional 500 iterations.

## A PROOFS

We begin with some preliminaries and known results:

**Definition 2** ([8]). A random variable  $\sigma$  is said to be a *Rademacher random variable* if it takes values in  $\{-1, 1\}$ , each with probability  $1/2$ .

**Definition 3** ([8]). Let  $\mu$  be a probability measure on  $\mathcal{X}$ , and let  $\mathcal{F}$  be a class of uniformly bounded functions on  $\mathcal{X}$ . Then the *Rademacher complexity* of  $\mathcal{F}$  (with respect to  $\mu$ ) is

$$R_N(\mathcal{F}) = E_{\mu} E_{\sigma_1, \dots, \sigma_N} \left[ \frac{1}{\sqrt{N}} \sup_{f \in \mathcal{F}} \left| \sum_{n=1}^N \sigma_n f(X_n) \right| \right],$$

where  $\sigma = (\sigma_1, \sigma_2, \dots)$  is a sequence of independent Rademacher random variables, and  $X_1, X_2, \dots$  are independent,  $\mu$ -distributed random variables, independent also from  $\sigma$ .

**Theorem 2** (McDiarmids Inequality [8]). *Let  $f : \mathcal{X}_1 \times \dots \times \mathcal{X}_N \rightarrow \mathbb{R}$  and assume there exists  $c_1, \dots, c_N \geq 0$  such that, for all  $k \in \{1, \dots, N\}$ , we have*

$$\sup_{x_1, \dots, x_k, x'_k, \dots, x_N} |f(x_1, \dots, x_k, \dots, x_N) - f(x_1, \dots, x'_k, \dots, x_N)| \leq c_k.$$

*Then, for all  $\varepsilon > 0$  and independent random variables  $\xi_1, \dots, \xi_N$  in  $\mathcal{X}$ ,*

$$\Pr \{f(\xi_1, \dots, \xi_N) - E(f(\xi_1, \dots, \xi_N)) \geq \varepsilon\} < \exp \left( \frac{-2\varepsilon^2}{\sum_{n=1}^N c_n^2} \right).$$

**Theorem 3** ([8, Thm. 2.35]). *Let  $\mathcal{F} \subset B(L_{\infty}(\mathcal{X}))$ . Assume there exists  $\gamma > 1$ , such that for all  $\varepsilon > 0$ ,  $\text{fat}_{\varepsilon}(\mathcal{F}) \leq \gamma \varepsilon^{-p}$  for some  $p \in \mathbb{N}$ . Then there exists constants  $C_p$  depending on  $p$  only, such that  $R_N(\mathcal{F}) \leq C_p \Psi(p, N, \gamma)$  where*

$$\Psi(p, N, \gamma) = \gamma^{\frac{1}{2}} \begin{cases} 1 & \text{if } 0 < p < 2 \\ \log^{\frac{3}{2}} N & \text{if } p = 2 \\ N^{\frac{1}{2} - \frac{1}{p}} & \text{if } p > 2. \end{cases}$$

**Theorem 4** ([2]). *Assume  $0 \leq k(x_i, x_j) \leq K$ ,  $M = N$ . Then*

$$\Pr [|\text{MMD}_u^2(\mathcal{H}, X, Y_{\theta}) - \text{MMD}^2(\mathcal{H}, p_{\text{data}}, p_{\theta})| > \varepsilon] \leq \delta_{\varepsilon}$$

where

$$\delta_{\varepsilon} = 2 \exp \left( -\frac{\varepsilon^2 M}{16K^2} \right).$$

The case where  $\Theta$  is a finite set is elementary:

**Theorem 5** (estimation error for finite parameter set). *Let  $p_{\theta}$  be the distribution of  $G_{\theta}(W)$ , with  $\theta$  taking values in some finite set  $\Theta = \{\theta_1, \dots, \theta_T\}$ ,  $T < \infty$ . Then, with probability at least  $1 - (T + 1)\delta_{\varepsilon}$ , where  $\delta_{\varepsilon}$  is defined as in Theorem 4, we have*

$$\text{MMD}^2(\mathcal{H}, p_{\text{data}}, p_{\hat{\theta}}) < \text{MMD}^2(\mathcal{H}, p_{\text{data}}, p_{\theta^*}) + 2\varepsilon.$$

*Proof.* Let  $\mathcal{E}(\theta) = \text{MMD}_u^2(\mathcal{H}, X, Y_{\theta})$  and let  $\mathcal{T}(\theta) = \text{MMD}^2(\mathcal{H}, p_{\text{data}}, p_{\theta})$ .

Note, that the upper bound stated in Theorem 4 holds for the parameter value  $\theta^*$ , i.e.,

$$\Pr [|\mathcal{E}(\theta^*) - \mathcal{T}(\theta^*)| > \varepsilon] \leq \delta_{\varepsilon}. \quad (6)$$

Because  $\hat{\theta}$  depends on the training data  $X$  and generator data  $Y$ , we use a uniform bound that holds over all  $\theta$ . Specifically,

$$\begin{aligned} \Pr \left[ |\mathcal{E}(\hat{\theta}) - \mathcal{T}(\hat{\theta})| > \varepsilon \right] &\leq \Pr \left[ \sup_{\theta} |\mathcal{E}(\theta) - \mathcal{T}(\theta)| > \varepsilon \right] \\ &\leq \sum_{t=1}^T \Pr \left[ |\mathcal{E}(\hat{\theta}) - \mathcal{T}(\hat{\theta})| > \varepsilon \right] \leq T\delta_\varepsilon. \end{aligned} \quad (7)$$

This yields that with probability at least  $1 - T\delta_\varepsilon$ ,

$$\begin{aligned} 2\varepsilon &\geq |\mathcal{E}(\hat{\theta}) - \mathcal{T}(\hat{\theta})| + |\mathcal{E}(\theta^*) - \mathcal{T}(\theta^*)| \\ &\geq |\mathcal{E}(\theta^*) - \mathcal{E}(\hat{\theta}) + \mathcal{T}(\hat{\theta}) - \mathcal{T}(\theta^*)|. \end{aligned} \quad (8)$$

Since  $\theta^*$  was chosen to minimize  $\mathcal{T}(\theta)$ , we know that  $\mathcal{T}(\hat{\theta}) \geq \mathcal{T}(\theta^*)$ . Similarly, by Eq. (5),  $\mathcal{E}(\theta^*) \geq \mathcal{E}(\hat{\theta})$ . Therefore it follows that

$$\begin{aligned} 2\varepsilon &\geq \mathcal{T}(\hat{\theta}) - \mathcal{T}(\theta^*) \\ &= \text{MMD}^2(\mathcal{H}, p_{\text{data}}, p_{\theta^*}) - \text{MMD}^2(\mathcal{H}, p_{\text{data}}, p_{\hat{\theta}}) \end{aligned}$$

proving the theorem.  $\square$

**Corollary 1.** *With probability at least  $1 - \delta$ ,*

$$\text{MMD}^2(\mathcal{H}, p_{\text{data}}, p_{\hat{\theta}}) < \text{MMD}^2(\mathcal{H}, p_{\text{data}}, p_{\theta^*}) + 2\varepsilon_\delta,$$

where

$$\varepsilon_\delta = 8K \sqrt{\frac{1}{M} \log [2(T+1)\delta]}.$$

In order to prove the general result, we begin with some technical lemmas. The development here owes much to Gretton et al. [2].

**Lemma 1.** *Let  $\mathcal{F} = \{f : \mathcal{Y} \times \mathcal{Y} \rightarrow \mathbb{R}\}$  and*

$$\mathcal{F}_+ = \{h = f(y, \cdot) : f \in \mathcal{F}, y \in \mathcal{Y}\} \cap B(L_\infty(\mathcal{Y})).$$

*Let  $\{Y_n\}_{n=1}^N$  be  $\mu$ -distributed independent random variables in  $\mathcal{Y}$ . Assume for some  $\gamma > 1$  and some  $p \in \mathbb{N}$ , we have  $\text{fat}_\varepsilon(\mathcal{F}_+) \leq \gamma\varepsilon^{-p}$ , for all  $\varepsilon > 0$ . For  $y_n \in \mathcal{Y} \quad \forall n = 1, \dots, N$ , define  $\rho(y_1, \dots, y_N)$  to be*

$$\sup_{f \in \mathcal{F}} \left| E(f(Y, Y')) - \frac{1}{N(N-1)} \sum_{n \neq n'} f(y_n, y_{n'}) \right|.$$

*Then there exists a constant  $C$  that depends on  $p$ , such that*

$$E(\rho(Y_1, \dots, Y_N)) \leq \frac{C}{\sqrt{N-1}} \Psi(\gamma, N-1, p).$$

*Proof.* Let us introduce  $\{\zeta_n\}_{n=1}^N$ , where  $\zeta_n$  and  $Y_{n'}$  have the same distribution and are independent for all  $n, n' \in \{1, \dots, N\}$ . Then the following is true:

$$E(f(Y, Y')) = E\left(\frac{1}{N(N-1)} \sum_{n, n': n \neq n'} f(\zeta_n, \zeta_{n'})\right)$$

Using Jensen's inequality and the independence of  $Y, Y'$  and  $Y_n, Y_{n'}$ , we have

$$\begin{aligned} &E(\rho(Y_1, \dots, Y_N)) \\ &= E\left(\sup_{f \in \mathcal{F}} \left| E(f(Y, Y')) \right. \right. \\ &\quad \left. \left. - \frac{1}{N(N-1)} \sum_{n \neq n'} f(Y_n, Y_{n'}) \right| \right) \\ &\leq E\left(\sup_{f \in \mathcal{F}} \left| \frac{1}{N(N-1)} \sum_{n \neq n'} f(\zeta_n, \zeta_{n'}) \right. \right. \\ &\quad \left. \left. - \frac{1}{N(N-1)} \sum_{n \neq n'} f(Y_n, Y_{n'}) \right| \right). \end{aligned} \quad (9)$$

Introducing conditional expectations allows us to rewrite the equation with the sum over  $n$  outside the expectations. I.e., Eq. (9) equals

$$\begin{aligned} &\frac{1}{N} \sum_n E E^{(Y_n, \zeta_n)} \left( \sup_{f \in \mathcal{F}} \left| \frac{1}{N-1} \sum_{n \neq n'} \Phi(\zeta_n, \zeta_{n'}, Y_n, Y_{n'}) \right| \right) \\ &= E E^{(Y, \zeta)} \left( \sup_{f \in \mathcal{F}} \left| \frac{1}{N-1} \sum_{n=1}^{N-1} \sigma_n \Phi(\zeta, \zeta_n, Y, Y_n) \right| \right), \end{aligned} \quad (10)$$

where  $\Phi(x, x', y, y') = f(x, x') - f(y, y')$ . The second equality follows by symmetry of random variables  $\{\zeta_n\}_{n=1}^{N-1}$ . Note that we also added Rademacher random variables  $\{\sigma_n\}_{n=1}^{N-1}$  before each term in the sum since  $(f(\zeta_n, \zeta_{n'}) - f(Y_n, Y_{n'}))$  has the same distribution as  $-(f(\zeta_n, \zeta_{n'}) - f(Y_n, Y_{n'}))$  for all  $n, n'$  and therefore the  $\sigma$ 's do not affect the expectation of the sum.

Note that  $\zeta_m$  and  $Y_m$  are identically distributed. Thus the triangle inequality implies that Eq. (10) is less than or equal to

$$\begin{aligned} &\frac{2}{N-1} E \left( E^{(Y)} \left( \sup_{f \in \mathcal{F}} \left| \sum_{n=1}^{N-1} \sigma_n f(Y, Y_n) \right| \right) \right) \\ &\leq \frac{2}{\sqrt{N-1}} R_{N-1}(\mathcal{F}_+), \end{aligned}$$

where  $R_{N-1}(\mathcal{F}_+)$  is the Rademacher's complexity of  $\mathcal{F}_+$ . Then by Theorem 3, we have

$$E(\rho(Y_1, \dots, Y_N)) \leq \frac{C}{\sqrt{N-1}} \Psi(\gamma, N-1, p).$$

$\square$

**Lemma 2.** *Let  $\mathcal{F} = \{f : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}\}$  and  $\mathcal{F}_+ = \{f : x \times \mathcal{Y} \rightarrow \mathbb{R}, x \in \mathcal{X}\}$  and assume  $\mathcal{F}_+ \subset B(L_\infty(\mathcal{Y}))$ . Let  $\{X_n\}_{n=1}^N$  and  $\{Y_m\}_{m=1}^M$  be  $\nu$ - and  $\mu$ -distributed independent random variables in  $\mathcal{X}$  and  $\mathcal{Y}$ , respectively. Assume for some  $\gamma > 1$ , such that for all  $\varepsilon > 0$ ,  $\text{fat}_\varepsilon(\mathcal{F}_+) \leq \gamma\varepsilon^{-p}$ ,*

for some  $p \in \mathbb{N}$ . For all  $x_n \in \mathcal{X}$ ,  $n \leq N$ , and all  $y_m \in \mathcal{Y}$ ,  $m \leq M$ , define

$$\rho(x_1, \dots, x_N, y_1, \dots, y_M) = \sup_{f \in \mathcal{F}} \left| E(f(X, Y)) - \frac{1}{NM} \sum_{n,m} f(x_n, y_m) \right|.$$

Then there exists  $C$  that depends on  $p$ , such that

$$E(\rho(X_1, \dots, X_N, Y_1, \dots, Y_M)) \leq \frac{C}{\sqrt{M}} \Psi(\gamma, M, p).$$

*Proof.* The proof is very similar to that of Lemma 1.  $\square$

*Proof of Theorem 1.* The proof follows the same steps as the proof of Theorem 5 apart from a stronger uniform bound stated in Eq. (7). I.e., we need to show:

$$\Pr \left[ \sup_{\theta \in \Theta} |\mathcal{E}(\theta) - \mathcal{T}(\theta)| \geq \varepsilon \right] \leq \delta.$$

Expanding MMD as defined by Eq. (4), and substituting  $Y = G_\theta(W)$ , yields

$$\begin{aligned} & \sup_{\theta \in \Theta} |\mathcal{E}(\theta) - \mathcal{T}(\theta)| \\ &= \sup_{\theta \in \Theta} \left| E(k(X, X')) \right. \\ & \quad - \frac{1}{N(N-1)} \sum_{n' \neq n} k(X_n, X_{n'}) \\ & \quad + E(k(G_\theta(W), G_\theta(W'))) \\ & \quad - \frac{1}{M(M-1)} \sum_{m \neq m'} k(G_\theta(W_m), G_\theta(W_{m'})) \\ & \quad - 2E(k(X, G_\theta(W))) \\ & \quad \left. + \frac{2}{MN} \sum_{m,n} k(X_n, G_\theta(W_m)) \right|. \end{aligned} \quad (11)$$

For all  $n \in \{1, \dots, N\}$ ,  $k(X_n, X_{n'})$  does not depend on  $\theta$  and therefore the first two terms of the equation above can be taken out of the supremum. Also, note that since  $|k(\cdot, \cdot)| \leq K$ , we have

$$\left| \zeta(x_1, \dots, x_n, \dots, x_N) - \zeta(x_1, \dots, x'_n, \dots, x_N) \right| \leq \frac{2K}{N},$$

where

$$\zeta(x_1, \dots, x_N) = \frac{1}{N(N-1)} \sum_{n, n': n' \neq n} k(x_n, x_{n'}),$$

and  $\zeta$  is an unbiased estimate of  $E(k(X, X'))$ . Then from McDiarmid's inequality on  $\zeta$ , we have

$$\begin{aligned} & \Pr \left( \left| E(k(X, X')) - \frac{1}{N(N-1)} \sum_{n' \neq n} k(X_n, X_{n'}) \right| \geq \varepsilon \right) \\ & \leq \exp \left( -\frac{\varepsilon^2}{2K^2} N \right). \end{aligned} \quad (12)$$

Therefore Eq. (11) is bounded by the sum of the bound on Eq. (12) and the following:

$$\begin{aligned} & \sup_{\theta \in \Theta} \left| E(k(G_\theta(W), G_\theta(W'))) \right. \\ & \quad - \frac{1}{M(M-1)} \sum_{m \neq m'} k(G_\theta(W_m), G_\theta(W_{m'})) \\ & \quad - 2E(k(X, G_\theta(W))) \\ & \quad \left. + \frac{2}{MN} \sum_{m,n} k(X_n, G_\theta(W_m)) \right|. \end{aligned} \quad (13)$$

Thus the next step is to find the bound for the supremum above.

Define

$$\begin{aligned} & f(W_1, \dots, W_M; p_{\text{noise}}) = f(\underline{W}_M) \\ &= \sup_{\theta \in \Theta} \left| E(k(G_\theta(W), G_\theta(W'))) \right. \\ & \quad \left. - \frac{1}{M(M-1)} \sum_{m \neq m'} k(G_\theta(W_m), G_\theta(W_{m'})) \right| \end{aligned}$$

and

$$\begin{aligned} & h(X_1, \dots, X_N, W_1, \dots, W_M; p_{\text{data}}, p_{\text{noise}}) \\ &= h(\underline{X}_N, \underline{W}_M) \\ &= \sup_{\theta \in \Theta} \left| \frac{1}{MN} \sum_{m,n} k(X_n, G_\theta(W_m)) - E(k(X, G_\theta(W))) \right|. \end{aligned}$$

Then by triangle inequality, the supremum in Eq. (13) is bounded by

$$f(\underline{W}_M) + 2h(\underline{X}_N, \underline{W}_M).$$

We will first find the upper bound on  $f(\underline{W}_M)$ , i.e., for every  $\varepsilon > 0$ , we will show that there exists  $\delta_f$ , such that

$$\Pr(f(\underline{W}_M) > \varepsilon) \leq \delta_f \quad (14)$$

For each  $m \in \{1, \dots, M\}$ ,

$$\begin{aligned} & \left| f(W_1, \dots, W_m, \dots, W_M) \right. \\ & \quad \left. - f(W_1, \dots, W'_m, \dots, W_M) \right| \leq \frac{2K}{M} \end{aligned}$$

since the kernel is bounded by  $K$ , and therefore  $k(G_\theta(W_m), G_\theta(W_{m'}))$  is bounded by  $K$  for all  $m$ . The conditions of Theorem 2 are satisfied and thus we can use McDiarmid's Inequality on  $f$ :

$$\Pr(f(\underline{W}_M) - E(f(\underline{W}_M)) \geq \varepsilon) \leq \exp \left( -\frac{\varepsilon^2 M}{2K^2} \right).$$

Define

$$\mathcal{G}_k = \{k(G_\theta(\cdot), G_\theta(\cdot)) : \theta \in \Theta\}$$

To show Eq. (14), we need to bound the expectation of  $f$ . We can apply Lemma 1 on the function classes  $\mathcal{G}_k$  and  $\mathcal{G}_{k+}$ . The resulting bound is

$$E(f(\underline{W}_M)) \leq \varepsilon_{p_1} = \frac{C_f}{\sqrt{M-1}} \Psi(\gamma_1, M-1, p_1), \quad (15)$$

where  $p_1$  and  $\gamma_1$  are parameters associated with fat shattering dimension of  $\mathcal{G}_{k+}$  as stated in the assumptions of the theorem, and  $C_f$  is a constant depending on  $p_1$ .

Now we can write down the bound on  $f$ :

$$\Pr(f(\underline{W}_M) \geq \varepsilon_{p_1} + \epsilon) \leq \exp\left(-\frac{\varepsilon^2 M}{2K^2}\right) = \delta_f. \quad (16)$$

Similarly,  $h(\underline{X}_N, \underline{W}_M)$  has bounded differences:

$$\left| h(X_1, \dots, X_n, \dots, X_N, W_1, \dots, W_M) - h(X_1, \dots, X_{n'}, \dots, X_N, W_1, \dots, W_M) \right| \leq \frac{2K}{N}$$

and

$$\left| h(X_1, \dots, X_N, W_1, \dots, W_m, \dots, W_M) - h(X_1, \dots, X_N, W_1, \dots, W_{m'}, \dots, W_M) \right| \leq \frac{2K}{M}.$$

McDiarmid's inequality then implies

$$\Pr(h(\underline{X}_N, \underline{W}_M) - E(h(\underline{X}_N, \underline{W}_M)) \geq \varepsilon) \leq \exp\left(-\frac{\varepsilon^2}{2K^2} \frac{NM}{N+M}\right). \quad (17)$$

We can bound expectation of  $h(\underline{X}_N, \underline{W}_M)$  using Lemma 2 applied on  $\mathcal{G}_k^{\mathbb{X}}$  and  $\mathcal{G}_{k+}^{\mathbb{X}}$ , where

$$\mathcal{G}_k^{\mathbb{X}} = \{k(\cdot, G_\theta(\cdot)) : \theta \in \Theta\}.$$

Then

$$E(h(\underline{X}_N, \underline{W}_M)) \leq \varepsilon_{p_2} = \frac{C_h}{\sqrt{M}} \Psi(\gamma_2, M, p_2). \quad (18)$$

for some constant  $C_h$  that depends on  $p_{\otimes}$ . The final bound on  $h$  is then

$$\Pr(h(\underline{X}_N, \underline{W}_M) \geq \varepsilon_{p_2} + \varepsilon) \leq \exp\left(-\frac{\varepsilon^2}{2K^2} \frac{NM}{N+M}\right) = \delta_h.$$

Summing up the bounds from Eq. (16) and Eq. (17), it follows that

$$\Pr(f(\underline{W}_M) + 2h(\underline{X}_N, \underline{W}_M) \geq \varepsilon_{p_1} + 2\varepsilon_{p_2} + 3\varepsilon) \leq \max(\delta_f, \delta_h) = \delta_h.$$

Using the bound in Eq. (12), we have obtain the uniform bound we were looking for:

$$\Pr\left[\sup_{\theta \in \Theta} |\mathcal{E}(\theta) - \mathcal{T}(\theta)| > \varepsilon_{p_1} + 2\varepsilon_{p_2} + 4\varepsilon\right] \leq \delta_h,$$

which by Eq. (7) yields

$$\Pr\left[|\mathcal{E}(\hat{\theta}) - \mathcal{T}(\hat{\theta})| > \varepsilon_{p_1} + 2\varepsilon_{p_2} + 4\varepsilon\right] \leq \delta_h.$$

Since it was assumed that  $K = 1$  and  $N = M$ , we get  $\delta_h = \exp(-\varepsilon^2 M/4)$ .

To finish, we proceed as in the proof of Theorem 5. We can rearrange some of the terms to get a different form of Eq. (6):

$$\Pr[|\mathcal{E}(\theta^*) - \mathcal{T}(\theta^*)| > 2\varepsilon] \leq 2 \exp\left(-\frac{\varepsilon^2 M}{4}\right) = 2\delta_h.$$

All of the above implies that for any  $\varepsilon > 0$ , there exists  $\delta$ , such that

$$\Pr(\text{MMD}^2(\mathcal{H}, p_{\text{data}}, p_{\hat{\theta}}) - \text{MMD}^2(\mathcal{H}, p_{\text{data}}, p_{\theta^*}) \geq \varepsilon) \leq \delta,$$

where

$$\varepsilon = \varepsilon_{p_1} + 2\varepsilon_{p_2} + \frac{12}{\sqrt{M}} \sqrt{\log \frac{2}{\delta}}.$$

We can rewrite  $\varepsilon$  as:

$$\varepsilon = r(p_1, \gamma_1, M) + r(p_2, \gamma_2, M-1) + 12M^{-\frac{1}{2}} \sqrt{\log \frac{2}{\delta}},$$

The rate  $r(p, \gamma, N)$  is given by Eq. (15) and Eq. (18):

$$r(p, \gamma, M) = C_p \sqrt{\gamma} \begin{cases} M^{-\frac{1}{2}} & \text{if } p < 2, \\ M^{-\frac{1}{2}} \log^{\frac{3}{2}}(M) & \text{if } p = 2, \\ M^{-\frac{1}{p}} & \text{if } p > 2, \end{cases}$$

where  $C_{p_1}$  and  $C_{p_2}$  depend on  $p_1$  and  $p_2$  alone.  $\square$

We close by noting that the approximation error is zero in the nonparametric limit.

**Theorem 6** (Gretton et al. [2]). *Let  $F$  be the unit ball in a universal RKHS  $\mathcal{H}$ , defined on the compact metric space  $\mathbb{X}$ , with associated continuous kernel  $k(\cdot, \cdot)$ . Then  $\text{MMD}[\mathcal{H}, p, q] = 0$  if and only if  $p = q$ .*

**Corollary 2** (approximation error). *Assume  $p_{\text{data}}$  is in the family  $\{p_\theta\}$  and that  $\mathcal{H}$  is an RKHS induced by a characteristic kernel. Then*

$$\inf_{\theta} \text{MMD}(\mathcal{H}, p_{\text{data}}, p_\theta) = 0$$

and the infimum is achieved at  $\theta$  satisfying  $p_\theta = p_{\text{data}}$ .

*Proof.* By Theorem 6, it follows that  $\text{MMD}^2(\mathcal{H}, \cdot, \cdot)$  is a metric. The result is then immediate.  $\square$

## Abstract

Region choice is a key issue for many approximate inference bounds. Mini-bucket elimination avoids the space and time complexity of exact inference by using a top-down partitioning approach that mimics the construction of a junction tree and aims to minimize the number of regions subject to a bound on their size; however, these methods rarely take into account functions' values. In contrast, message passing algorithms often use "cluster pursuit" methods to select regions, a bottom-up approach in which a pre-defined set of clusters (such as triplets) is scored and incrementally added. In this work, we develop a hybrid approach that balances the advantages of both perspectives, providing larger regions chosen in an intelligent, energy-based way. Our method is applicable to bounds on a variety of inference tasks, and we demonstrate its power empirically on a broad array of problem types.

## 1 INTRODUCTION

Mini-bucket elimination (MBE) (Dechter and Rish, 2003) is a popular bounding technique for reasoning tasks defined over graphical models. MBE is often used to develop heuristic functions for search and optimization tasks (Dechter and Rish, 2003; Kask and Dechter, 2001; Marinescu and Dechter, 2007; Choi et al., 2007; Marinescu et al., 2014), although it has also been used to provide bounds on weighted counting problems such as computing the probability of evidence in Bayesian networks (Rollon and Dechter, 2010; Liu and Ihler, 2011).

MBE obtains its bounds by approximating the variable or "bucket" elimination process. Rather than exactly eliminating each variable, MBE partitions the functions into smaller sets of bounded complexity; eliminating within each partition separately gives an upper or lower bound. A sin-

gle control variable allows the user to easily trade off between accuracy and computation (memory and time). A recent extension called weighted mini-bucket (WMB) also serves to connect mini-bucket to the framework of variational bounds, allowing iterative reparameterization updates to improve the WMB bound.

The partitioning of a bucket into mini-buckets of bounded size can be accomplished in many ways, each resulting in a different accuracy. Viewed from a variational perspective, this corresponds to the critical choice of *regions* in the approximations, defining which sets of variables will be reasoned about jointly.

Traditionally, MBE is guided only by the graph structure, using a *scope-based* heuristic (Dechter and Rish, 2003) to minimize the number of buckets. However, this ignores the influence of the functions themselves on the bound. More recent extensions such as Rollon and Dechter (2010) have suggested ways of incorporating the function values into the partitioning process, with mixed success. A more bottom-up construction technique is the *relax-compensate-recover* (RCR) method of Choi and Darwiche (2010), which constructs a sequence of mini-bucket-like bounds of increasing complexity.

Variational approaches typically use a greedy, bottom-up approach termed *cluster pursuit*. Starting with the smallest possible regions, the bounds are optimized using message passing, and then new regions are added greedily from an enumerated list of clusters such as triplets (e.g., Sontag et al., 2008; Komodakis and Paragios, 2008). This technique is often very effective if only a few regions can be added, but the sheer number of regions considered often creates a computational bottleneck and prevents adopting large regions (e.g., Batra et al., 2011).

We propose a hybrid approach that is guided by the graph structure and connects to the mini-bucket construction, but takes advantage of the iterative optimization and scoring techniques of cluster pursuit. In practice, we find that our methods work significantly better than either the partitioning heuristics of Rollon and Dechter (2010), or a pure re-

gion pursuit approach. We also discuss the connections of our work to RCR (Choi and Darwiche, 2010). We validate our approach with experiments on a wide variety of problems drawn from recent UAI approximate inference competitions (Elidan et al., 2012).

## 2 PRELIMINARIES

Graphical models capture the dependencies among large numbers of random variables by explicitly representing the independence structure of the joint probability distribution. Consider a distribution

$$p(x) = \frac{1}{Z} \prod_{\alpha \in \mathcal{I}} f_{\alpha}(x_{\alpha}) \quad Z = \sum_x \prod_{\alpha} f_{\alpha}(x_{\alpha})$$

where  $x_{\alpha}$  indicates a subset of variables and  $Z$  is the normalizing constant called the *partition function*. We associate  $p(x)$  with a graph  $G = (V, E)$  where each variable  $x_i$  is associated with a node  $i \in V$  and is connected to  $x_j$  if both variables  $x_i$  and  $x_j$  are arguments of some function  $f_{\alpha}$ .  $\mathcal{I}$  is then a set of all cliques in  $G$ .

Common inference tasks include finding the most likely or MAP configuration of  $p(x)$ , a combinatorial optimization problem, or computing the partition function  $Z$ , a combinatorial summation problem. Computing  $Z$ , which corresponds to the probability of evidence in Bayesian networks, or the marginal probabilities of  $p(x)$ , are central problems in many learning and inference tasks.

### 2.1 MINI-BUCKET ELIMINATION

Unfortunately, inference tasks such as computing the partition function are often computationally intractable for many real-world problems. Exact inference, such as variable or “bucket” elimination (Dechter, 1999) is exponential in the tree-width of the model, leading to a spectrum of approximations and bounds subject to computational limits. In this section, we briefly describe bucket elimination and mini-bucket approximations.

**Bucket Elimination** (Dechter, 1999) is an exact algorithm that directly eliminates variables in sequence. Given an elimination order, BE collects all factors that include variable  $x_i$  as their earliest-eliminated argument in a *bucket*  $B_i$ , then takes their product and eliminates  $x_i$  to produce a new factor over later variables, which is placed in the bucket of its “parent”  $\pi_i$ , the earliest uneliminated variable:

$$\lambda_{i \rightarrow \pi_i}(x_{i \rightarrow \pi_i}) = \sum_{x_i} \prod_{f_{\alpha} \in B_i} f_{\alpha}(x_{\alpha}) \prod_{\lambda_{j \rightarrow i} \in B_i} \lambda_{j \rightarrow i}(x_{j \rightarrow i})$$

The functions  $\lambda_{j \rightarrow i}$  constructed during this process can be interpreted as *messages* that are passed downward in a join-tree representation of the model (Ihler et al., 2012); see Figure 1(a)-(b).

The space and time complexity of BE are exponential in the *induced width* of the graph given the elimination order. While good elimination orders can be identified using various heuristics (see e.g., Kask et al., 2011), this exponential dependence often makes direct application of BE intractable for many problems of interest.

**Minibucket Elimination.** To avoid the complexity of bucket elimination, Dechter and Rish (1997) proposed an approximation in which the factors in bucket  $B_i$  are grouped into partitions  $Q_i = \{q_i^1, \dots, q_i^p\}$ , where each partition  $q_i^j \in Q_i$ , also called a *mini-bucket*, includes no more than *ibound*+1 variables. The bounding parameter *ibound* then serves as a way to control the complexity of elimination, as the elimination operator is applied to each mini-bucket separately. Using the inequality

$$\sum_{x_i} \prod_{f_{\alpha} \in B_i} f_{\alpha} \leq \left[ \sum_{x_i} \prod_{f_{\alpha} \in q_i^1} f_{\alpha} \right] \cdot \left[ \max_{x_i} \prod_{f_{\alpha} \in q_i^2} f_{\alpha} \right],$$

MBE gives an upper bound on the true partition function, and its time and space complexity are exponential in the user-controlled *ibound*. Smaller *ibound* values result in lower computational cost, but are typically less accurate. See Figure 1(c) for an illustration.

The resulting bound depends significantly on the partitionings  $\{Q_i\}$ ; we discuss strategies for partitioning in Section 2.2.

**Weighted Mini-bucket.** A recent improvement to mini-bucket (Liu and Ihler, 2011) generalizes the MBE bound with a “weighted” elimination,

$$\sum_{x_i} \prod_{f_{\alpha} \in B_i} f_{\alpha} \leq \left[ \sum_{x_i} \prod_{f_{\alpha} \in q_i^1} f_{\alpha}^{w_1} \right]^{w_1} \cdot \left[ \sum_{x_i} \prod_{f_{\alpha} \in q_i^2} f_{\alpha}^{w_2} \right]^{w_2},$$

where  $w_i > 0$  and  $w_1 + w_2 = 1$ .

Liu and Ihler (2011) also show that the resulting bound is equivalent to a class of bounds based on tree reweighted (TRW) belief propagation (Wainwright et al., 2005), or more generally conditional entropy decompositions (CED) (Globerson and Jaakkola, 2007), on a join-graph defined by the mini-bucket procedure (see Figure 1(d)). This connection is used to derive fixed point reparameterization updates, which change the relative values of the factors  $f_{\alpha}$  while keeping their product constant in order to tighten the bound.

### 2.2 PARTITIONING METHODS

As discussed above, mini-bucket elimination and its weighted variant compute a partitioning over each bucket  $B_i$  to bound the complexity of inference and compute an upper bound on the partition function  $Z$ . However, different partitioning strategies will result in different upper

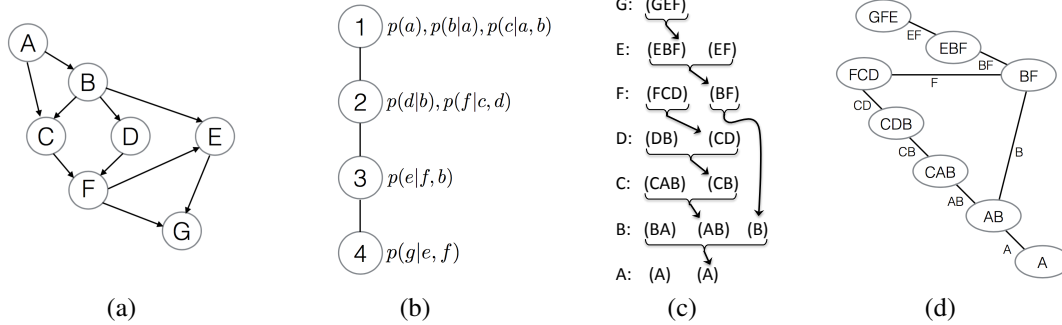

Figure 1: (a) A belief network  $P(A, B, C, D, E, F, G) = P(A) \cdot P(B|A) \cdot P(C|A, B) \cdot P(D|B) \cdot P(F|C, D) \cdot P(E|B, F) \cdot P(G|E, F)$ ; (b) a join-tree decomposition for exact inference; (c) a mini-bucket approximation ( $ibound = 2$ ), with  $F$  eliminated approximately; (d) the region or join-graph associated with (c).

bounds. Rollon and Dechter (2010) proposed a framework to study different partitioning heuristics, and compared them with the original scope based heuristic proposed by Dechter and Rish (1997). Here we summarize several approaches.

**Scope-based Partitions.** Proposed in Dechter and Rish (1997), scope-based partitioning is a top-down approach that tries to minimize the number of mini-buckets in  $B_i$  by including as many functions as possible in each mini-bucket  $q_i^k$ . To this end, it first orders the factors in  $B_i$  by decreasing number of arguments. Starting from the largest, each factor  $f_\alpha$  is then merged with the first available mini-bucket that satisfies the computational limits, i.e., where  $|\text{var}(f) \cup \text{var}(q_i^j)| \leq ibound + 1$ . If there are no mini-buckets available that can include the factor, a new mini-bucket is created and the scheme continues until all factors are assigned to a mini-bucket.

**Content-based Partitions.** Rollon and Dechter (2010), on the other hand, seeks to find a partitioning that is closest to the true bucket function,  $g_i = \sum_{X_i} \prod_{\alpha \in B_i} f_\alpha$ . This requires solving an optimization problem

$$Q^* = \arg \min_Q \text{dist}(g_i^Q, g_i)$$

where  $Q$  is a partitioning of  $B_i$  with bounding parameter  $ibound$  and

$$g_i^Q = \prod_{j=1}^p \sum_{X_i} \prod_{\alpha \in q_i^j} f_\alpha$$

is the function represented by the partitioning  $Q$ . The distance is minimized in a greedy fashion, and Rollon and Dechter (2010) studied the effectiveness of several different distance functions across multiple problem instances; however, no one distance was found to consistently outperform scope-based partitioning.

**Relax-Compensate-Recover.** Choi and Darwiche (2010) indirectly addresses the problem of partition selection within their *Relax, Compensate and Recover* framework,

in which certain equality constraints in the graph are first relaxed in order to reduce complexity of inference. New auxiliary factors are then introduced to compensate for the relaxation and enforce a weaker notion of equivalence. The recovery process then aims to identify those equivalence constraints whose relaxation were most damaging and recover them. Choi and Darwiche (2010) proposed a number of recovery heuristics, including mutual information and residual recovery.

### 2.3 VARIATIONAL BOUNDS.

The variational viewpoint of inference corresponds to optimizing an objective function over a collection of *beliefs* constrained to lie within the marginal polytope, or set of marginal probabilities that can be achieved by some joint distribution. Efficient approximations are developed by relaxing these constraints to enforce only a subset of the constraints – that the beliefs be consistent between overlapping cliques. In the case of the log partition function, we also approximate the entropy term in the objective; for example, the CED bound is:

$$\log Z \leq \max_{b_\alpha \in \mathbb{L}} \sum_{\alpha} \mathbb{E}_{b_\alpha} [\log f_\alpha] + \sum_{i,\alpha} w_{i\alpha} H(x_i | x_{\alpha \setminus i}; b_\alpha)$$

where  $\sum_{\alpha} w_{i\alpha} = 1$  for all  $i$ .

Like mini-bucket bounds, the quality of variational bounds depends significantly on the choice of regions, which determine what constraints will be enforced by the local polytope  $\mathbb{L}$  as well as the form of the entropy approximation. Traditionally, variational approximations have focused more on the optimization of the bound through message passing than the region selection aspect. Often regions are chosen to match the original model factors, and then improved using methods like cluster pursuit, described next.

**Cluster Pursuit.** Sontag et al. (2008) studied the problem of region selection for MAP inference in the context of *cluster-based* dual decomposition relaxations. They developed a bottom-up approach in which regions (typically

cycles or triplets) are added incrementally: First, the dual decomposition bound is optimized through message passing. Then, a pre-defined set of clusters, such as triplets or faces of a grid, are scored by computing a lower bound on their potential improvement of the bound; the scoring function used measures the difference between independently maximizing each pairwise factor, versus jointly maximizing over the triplet. After adding the best-scoring cluster, the procedure repeats. Similar cycle repair processes were also proposed by Komodakis and Paragios (2008) and Werner (2008), and related cluster pursuit methods have also been applied to summation problems (Welling, 2004; Hazan et al., 2012). However, scoring all possible clusters often becomes a computational bottleneck; for example, Batra et al. (2011) proposed pre-selection heuristics to reduce the number of clusters considered. In practice, cluster pursuit is usually applied to add only a few, small regions; scoring sets of larger regions is typically considered prohibitive.

### 3 A HYBRID APPROACH

Mini-bucket elimination avoids the space and time complexity of exact inference by using a top-down partitioning approach that mimics the construction of a junction tree. In contrast, message passing algorithms often use “cluster pursuit” methods to select regions, a bottom-up approach in which a predefined set of clusters (such as triplets) is scored and incrementally added.

To balance the effectiveness of both approaches, our hybrid scheme, like mini-bucket, uses the graph structure to guide region selection, while also taking advantage of the iterative optimization and scoring techniques of cluster pursuit.

Cluster pursuit algorithms use the function values, and more concretely the bound produced by them, in order to select regions that tighten the upper bound more effectively. However, there are often prohibitively many clusters to consider: for example, in a fully connected pairwise model, there are  $O(n^3)$  triplets,  $O(n^4)$  possible 4-cliques, etc., to score at each step. For this reason, cluster pursuit methods typically restrict their search to a predefined set of clusters, such as triplets Sontag et al. (2008). Our proposed approach uses the graph structure to guide the search for regions, restricting the search to merges of existing clusters, within one bucket at a time. This allows us to restrain the complexity of the search and add larger regions more effectively.

In contrast, the content-based heuristics for region selection of Rollon and Dechter (2010) use the graph structure as a guide, but their scoring scheme only takes into account the messages from the earlier buckets in the elimination order. Our proposed hybrid approach uses iterative optimization on the junction tree in order to make more effective partitioning decisions.

    **end for**  
**until** no more merges possible  
**end for**

---

Algorithm 1 describes the overall scheme of our hybrid approach, which is explained in detail next.

#### 3.1 INITIALIZING A JOIN TREE

Given a factor graph  $G$  and a bounding parameter  $ibound$ , we start by initializing a join graph, using a min-fill elimination ordering (Dechter, 2003)  $\mathbf{o} = \{x_1, \dots, x_n\}$  and  $ibound = 1$ . For any given bucket  $B_i$ , this results in each mini-bucket  $k \in B_i$  containing a single factor  $f_\alpha$ . We denote the result of the elimination as  $\lambda_{k \rightarrow l}$  which is sent to the bucket  $B_j$  of its first-eliminated argument in  $\mathbf{o}$ . Here,  $l = \text{pa}(k)$  denotes the parent region of  $k$  which can be one of the initial mini-buckets in  $B_j$  if  $\text{var}(\lambda_{k \rightarrow l}) \subseteq \text{var}(l)$ , or be a new mini-bucket with  $f_l = 1$ . In our implementation we choose  $l \in B_j$  to be the mini-bucket with the largest number of arguments,  $|\text{var}(l)|$ , such that  $\text{var}(\lambda_{k \rightarrow l}) \subseteq \text{var}(l)$ .

Using weighted mini-bucket for our elimination scheme, we initialize the mini-bucket weights  $w_r$  uniformly within each bucket  $B_i$ , so that for  $r \in Q_i$ ,  $w_r = \frac{1}{|Q_i|}$ , which ensures  $\sum_{r \in Q_i} w_r = 1$ .

#### 3.2 MESSAGE PASSING

We use iterative message passing on the join graph to guide the region selection decision. Having built an initial join graph, we use the weighted mini-bucket messages (Liu and Ihler, 2011) to compute forward and backward messages, and perform reparameterization of the functions  $f_\alpha$  to tighten the bound.

Let  $r$  be a region of the mini-bucket join graph, and  $s$  its parent,  $s = \text{pa}(r)$ , with weights  $w_r$  and  $w_s$ , and  $f_r(x_r)$  the product of factors assigned to region  $r$ . Then we compute

the forward messages as,

**Forward Messages:**

$$\lambda_{r \rightarrow s}(x_s) = \left[ \sum_{x_r \setminus x_s} [f_r(x_r) \prod_{t:s=\text{pa}(t)} \lambda_{t \rightarrow s}(x_s)]^{\frac{1}{w_s}} \right]^{w_s} \quad (1)$$

and compute the upper bound using the product of forward messages computed at roots of the join graph,

**Upper bound on Z:**

$$Z \leq \prod_{r:\text{pa}(r)=\emptyset} \lambda_{r \rightarrow \emptyset} \quad (2)$$

In order to tighten the bound, we compute backward messages in the join graph,

**Backward Messages:**

$$\lambda_{s \rightarrow r}(x_r) = \left[ \sum_{x_s \setminus x_r} [f_s(\cdot) \prod_t \lambda_{t \rightarrow s}(\cdot)]^{\frac{1}{w_s}} [\lambda_{r \rightarrow s}(\cdot)]^{-\frac{1}{w_r}} \right]^{w_r}$$

where  $t$  indexes all neighbors (parent and children) of region  $s$ . We then use these incoming messages to compute a weighted belief at region  $r$ , and reparameterize the factors  $f_r$  for each region  $r$  in a given bucket  $B_i$  (e.g.,  $r \in Q_i$ ) to enforce a weighted moment matching condition:

**Reparameterization:**

$$\begin{aligned} b_r(x_i) &= \sum_{x_r \setminus x_i} [f_r(x_r) \prod_t \lambda_{t \rightarrow r}(x_r)]^{\frac{1}{w_r}} \\ \bar{b}(x_i) &= \left[ \prod_{r \in Q_i} b_r(x_i) \right]^{1/\sum_r w_r} \\ f_r(x_r) &\leftarrow f_r(x_r) [\bar{b}(x_i)/b_r(x_i)]^{w_r} \end{aligned}$$

In practice, we usually match on the variables present in all mini-buckets  $r$ , e.g.,  $\cap_{r \in Q_i} x_r$ , rather than just  $x_i$ ; this gives a tighter bound for the same amount of computation.

**3.3 ADDING NEW REGIONS**

New regions are added to the initial join tree after one or more rounds of iterative optimization. To contain the complexity of the search over clusters, we restrict our attention to pairs of mini-buckets to merge within each bucket. To do so, we also use the elimination order  $o$  to guide our search, processing each bucket  $B_i$  one at a time in order.

Given bucket  $B_i$  and current partitioning  $Q_i = \{q_i^1, \dots, q_i^k\}$ , we score the merge for each allowed pair of mini-buckets  $(q_i^m, q_i^n)$ , e.g., those with  $|\text{var}(q_i^m) \cup \text{var}(q_i^n)| \leq \text{ibound} + 1$ , using an estimate of the benefit to the bound that may arise from merging the pair:

$$S(q_i^m, q_i^n) = \max_x [\lambda_{m \rightarrow \pi_m}(x_{\pi_m}) \times \lambda_{n \rightarrow \pi_n}(x_{\pi_n}) \div \lambda_{r \rightarrow \pi_r}(x_r)]$$

This score can be justified as a lower bound on the decrease in  $\log Z$ , since it corresponds to adding region  $\pi_r$  with weight  $w_{\pi_r} = 0$ , while reparameterizing the parents  $\pi_m, \pi_n$  to preserve their previous beliefs. This procedure leaves the bound unchanged except for the contribution of  $\pi_r$ ; eliminating with  $w_{\pi_r} = 0$  is equivalent to the max operation. For convenience, we set  $S(q_i^m, q_i^n) = 0$  for pairs which violate the *ibound* constraint. Then, having computed the score between all pairs, we choose the pair with maximum score to be merged into a new clique. In Algorithm 1, the function `SelectMerge( $\cdot$ )` denotes this scoring and selection process.

**3.4 UPDATING GRAPH STRUCTURE**

Having found which mini-buckets to merge, we update the join graph to include the new clique  $r = q_i^m \cup q_i^n$ . Our goal is to add the new region such that it affects the scope of the existing regions in the join tree as little as possible. Adding the new clique is done in two steps:

First we initialize a new mini-bucket in  $B_i$  with its scope matching  $\text{var}(r)$ . Eliminating variable  $x_i$  from this new mini-bucket results in the message  $\lambda_{r \rightarrow \pi_r}$ . The earliest argument of  $\lambda_{r \rightarrow \pi_r}$  in the elimination order determines the bucket  $B_j$  containing mini-buckets that can potentially be the parent,  $\pi_r$ , of the new region. To find  $\pi_r$  in  $B_j$  we seek a mini-bucket  $q_j^k$  that can contain  $r$ , i.e.,  $\text{var}(\lambda_{r \rightarrow \pi_r}) \subseteq \text{var}(q_j^k)$ . If such a mini-bucket exists, we set  $\pi_r$  to  $q_j^k$ ; otherwise, we create a new mini-bucket  $q_j^{|Q_j|+1}$  and add it to  $Q_j$ , with a scope that matches  $\text{var}(\lambda_{r \rightarrow \pi_r})$ . The same procedure is repeated after eliminating  $x_j$  from  $q_j^{|Q_j|+1}$  until we either find a mini-bucket already in the join tree that can serve as the parent, or  $\text{var}(\lambda_{r \rightarrow \pi_r}) = \emptyset$  in which case the newly added mini-bucket is a root. Algorithm 2 describes these initial structural modifications.

Having added the new regions, we then try to remove any unnecessary mini-buckets, and update both the join tree and the function values of the newly added regions to ensure that the bound is improved. To this end, we update every new mini-bucket  $r$  that was added to the join tree in the previous step as follows. For mini-bucket  $r \in Q_i$ , we first find any mini-buckets  $s \in Q_i$  that can be subsumed by  $r$ , i.e.,  $\text{var}(s) \subseteq \text{var}(r)$ . For each of these mini-buckets  $s$ , we connect all of  $s$ 's children (mini-buckets  $t$  such that  $\text{pa}(t) = s$ ) to  $r$ , e.g., set  $\text{pa}(t) = r$ . We also merge the factors associated with  $r$  and  $s$ , so that  $f_r \leftarrow f_r \times f_s$ .

Next, we reparameterize several other functions in the join graph in order to preserve or improve the current bound

---

**Algorithm 2** AddRegions: find regions to add for merge

---

**Input:** The join graph  $wmb$ , elimination order  $o$ , and mini-buckets  $q_i^m$  and  $q_i^n$  to be merged

**Output:** a list of newly added mini-buckets  $\mathcal{R}$

**Initialize** new region  $q^r$  with  $\text{var}(q^r) = \text{var}(q_i^m \cup q_i^n)$  and add it to  $Q_i$

**repeat**

**Update**  $\mathcal{R} = \mathcal{R} \cup q^r$

**Set** new clique  $C = \text{var}(q^r) \setminus x_i$

**if**  $C = \emptyset$  **then**

$done \leftarrow True$

**else**

**Find**  $B_j$  corresponding to the first un-eliminated variable in  $C$  based on elimination order  $o$

**for** each mini-bucket region  $q_j^k \in Q_j$  **do**

**if**  $C \subseteq \text{var}(q_j^k)$  **then**

        //forward message fits in existing mini-bucket:

$done \leftarrow True$

**end if**

**end for**

**end if**

**if** not  $done$  **then**

    // Create a new region to contain forward message:

**Initialize** new region  $q^r$  with  $\text{var}(q^r) = C$  and add it to  $Q_j$

**end if**

**until** done

---

value. Specifically, removing  $s$  changes the incoming, forward messages to its parent,  $\pi_s = \text{pa}(s)$ , which changes the bound. By reparameterizing the factor at  $\pi_s$ ,

$$f_{\pi_s} \leftarrow f_{\pi_s} \times \lambda_{s \rightarrow \pi_s} \quad f_{\pi_r} \leftarrow f_{\pi_r} \div \lambda_{s \rightarrow \pi_s}$$

we keep the overall distribution unchanged, but ensure that the bound is strictly decreased.

Finally we remove  $s$  from  $Q_i$ , completing the merge of mini-buckets  $s$  and  $r$ . This process is given in Algorithm 3 and depicted in Figure 2 for a small portion of join-graph.

Every merge decision is followed by one or more iterations of message passing, followed by rescaling the mini-buckets in  $B_i$ . The process of message passing and merging continues until no more mini-buckets of  $B_i$  can be merged, while satisfying the bounding parameter  $ibound$ .

Continuing along the elimination order, the same procedure is repeated for the mini-buckets in each bucket  $B_i$ , and the final upper bound to the partition function is computed using Eq. (2).

## 4 DISCUSSION

Our method is similar to context-based mini-buckets, with the main difference being that message passing performed

---

**Algorithm 3** MergeRegions: merge and parameterize newly added regions to improve bound

---

**Input:** The join graph  $wmb$  and a list of newly added mini-buckets  $\mathcal{R}$

**for all**  $r \in \mathcal{R}$  **do**

**Initialize** new region  $r$  in  $B_i$  with  $f_r(x_r) = 1$

**Find** regions  $\{s \mid s \in Q_i \ \& \ \text{var}(s) \subseteq \text{var}(r)\}$

  // Remove / merge contained regions  $s$ :

**for all** found regions  $s$  **do**

    Connect all children of  $s$  to  $r$

$f_r = f_r \cdot f_s$  // merge factors and

    // preserve belief at parent  $\pi_s$ :

$f_{\pi_s} = f_{\pi_s} \times \lambda_{s \rightarrow \pi_s}$

$f_{\pi_r} = f_{\pi_r} \div \lambda_{s \rightarrow \pi_s}$

    Remove  $s$  from  $Q_i$

**end for**

**end for**

---

Figure 2: Merge and post-merge reparameterization operations. (a) A portion of a join-graph corresponding to the elimination of  $x_2$  and  $x_3$ , each with two mini-buckets. (b) Merging cliques  $(2, 3, 4)$  and  $(2, 3, 5)$  produces a new clique  $(3, 4, 5)$ , which subsumes and removes clique  $(3, 4)$ . Having removed parent  $(2, 3, 5)$ , we reparameterize the new clique functions by the original message  $\lambda_{3,5}$  (red) to preserve the original belief at  $(3, 5, 6)$  and ensure that the bound is tightened. See text for more detail.

on the simpler graph is used to reparameterize the functions before the merge scores are computed.

Our method can also be viewed as a cluster pursuit approach, in which we restrict the clusters considered, to unions of the current minibuckets at the earliest bucket  $B_i$ , and merge up to our computational limit before moving on to later buckets. These restrictions serve to reduce the number of clusters considered, but in addition, appear to lead to better regions than a purely greedy region choice – in the experiments (Section 5), we compare our approach to a more “cluster pursuit-like” method, in which pairs of regions in *any* bucket  $B_i$  are considered and scored. Perhaps surprisingly, we find that this greedy approach actually gives significantly worse regions overall, suggesting

that processing the buckets in order can help by avoiding creating unnecessary regions.

Finally, our method is also closely related to RCR (Choi and Darwiche, 2010). From this perspective, we “relax” to a low-*ibound* minibucket, “compensate” by variational message passing, and “recover” by selecting regions that will tighten the variational bound defined by the join graph. Compared to RCR, we find a number of differences in our approach: (1) RCR selects constraints to recover anywhere in the graph, similar to a greedy cluster pursuit; as noted, this appears to work significantly less well than an ordered recovery process. (2) RCR makes its recovery updates to the relaxed graph, then (re)builds a (new) join tree over the relaxed graph; in contrast, we incrementally alter the join graph directly, which avoids starting from scratch after each merge. (3) Our method is solidly grounded in the theory of variational bounds and message passing, ensuring that both the message passing and region merging steps are explicitly tightening the same bound. From this perspective, for example, it becomes clear that RCR’s “residual recovery” heuristic is unlikely to be effective, since after message passing, the reparameterization updates should ensure that all mini-buckets containing a variable  $x_i$  will match on their marginal beliefs. In other words, residual recovery is making its structure (region) choices using a criterion that actually measures mismatches that can be resolved by message passing.

## 5 EMPIRICAL EVALUATION

To show our method’s effectiveness compared to previous region selection strategies for MBE, we tested our incremental approach on a number of real world problems drawn from past UAI approximate inference challenges, including linkage analysis, protein side chain prediction, and segmentation problems. We compare our hybrid region selection method against the scope-based heuristic of Dechter and Rish (1997) and the content-based heuristic of Rollon and Dechter (2010).

**Experimental Setup.** For each set of experiments, we initialize a join tree using WMB elimination with  $ibound = 1$ . We use an elimination ordering found using the min-fill heuristic (Dechter, 2003) and set the weights uniformly in each bucket. As a result, each mini-bucket  $q_i^k$  contains a single factor  $f_\alpha$  as described in section 3.1.

From this initial setup, we then use Algorithm 1 to merge mini-buckets incrementally and compute the upper bound as in Eq. (2).

**Segmentation.** To evaluate the different methods on pairwise binary problems we used a set of segmentation models from the UAI08 approximate inference challenge. These models have  $\approx 230$  binary variables and  $\approx 850$  factors. We

used varying *ibounds* for comparison and report the results on two values,  $ibound \in [5, 10]$ . Table 1 compares the upper bound on the log partition function for a representative subset of instances in this category, for two different computational limits,  $ibound = 5$  and  $ibound = 10$ . Different columns show the bound achieved using different partitioning heuristics:

- (1) **Sep** represents naïve scope-based partitioning;
- (2) **Cont** represents the energy based heuristic of Rollon and Dechter (2010); and
- (3) **Hyb** represents our hybrid approach, interleaving iterative optimization with partitioning.

The results show clear improvement in the upper bound using our hybrid approach, indicating the effectiveness of iterative message passing and optimization in guiding region selection. To further study the effectiveness of the merged regions in the context of message passing and optimization, we then fully optimized the join-graphs generated by the three region selection schemes using iterative message passing until convergence. The upper bounds after such optimization are denoted by *inst-opt* for each problem instance, *inst*. As might be expected, this additional optimization step improves the bounds of the scope-based and content-based heuristics more dramatically than our hybrid method; however, even after full optimization of the bounds, we find that the hybrid method’s bounds remain better in all of the 6 instances except one, indicating that our method has identified fundamentally better regions than the previous approaches.

**Linkage Analysis.** To compare the various methods on models with non-pairwise factors and higher cardinalities of variables, we studied pedigree models. The pedigree linkage analysis models from the UAI08 approximate inference challenge have  $\approx 300 - 1000$  variables, whose cardinalities vary in the range of  $[2, \dots, 5]$ ; the induced width of the models are typically  $\approx 20 - 30$ . We used varying *ibounds* for comparison and report the results on two values  $ibound \in [5, 10]$ .

Table 2 shows the upper bounds on a subset of pedigree problems, again showing the effectiveness of the hybrid method: we find that again, the hybrid method consistently outperforms the other two region selection approaches, and results in better fully optimized bounds in all of the 22 instances when  $ibound = 5$  and all but two cases when  $ibound = 10$ .

**Effect of *ibound*.** We further studied the results of the three partitioning methods across a range of *ibounds* to compare the effectiveness of our method when *ibound* is set to a range of values. Figure 3 shows the results for an instance of pedigree dataset. As shown here, our method is more effective on smaller *ibounds*, where there are a large number of possible merges and finding the best one results

Table 1: **UAI Segmentation Instances.** Different columns show the bound achieved using each partitioning heuristic, where “Scp”, “Cont” and “Hyb” represent the naïve scope based partitioning for MBE (Dechter and Rish, 1997), the context (or energy) based heuristic of Rollon and Dechter (2010) and our hybrid approach interleaving iterative optimization with partitioning, respectively. In all but one case, our proposed construction provides tighter bounds.

| Instance   | <i>ibound = 5</i> |          |                 | <i>ibound = 10</i> |          |                 |

in a greater improvement to the upper bound. For larger *ibound*s, the upper bounds produced by all three heuristics are fairly close.

**Protein Side-Chain Prediction.** Finally, to examine models over high-cardinality variables, we look at a subset of the protein side chain prediction models, originally from Yanover and Weiss (2003) and Yanover et al. (2006). These models contain  $\approx 300 - 1000$  variables with cardinalities between 2 and 81, with pairwise potential functions. For these problems, we only ran our experiments

using *ibound = 2*, due to the high number of states for each variable. Table 3 shows the results of the three partitioning methods, which again agrees with the previous experiments: our hybrid method outperforms the other two in all 44 instances in this problem set, both before and after the bound is fully optimized.

**Greedy vs. Elimination Order Based Merging.** As discussed before, we restrict the clusters considered for merges to unions of the current minibuckets at the earliest bucket  $B_i$ , and merge up to our computational limit be-

Figure 3: The upper bound achieved by the three partitioning heuristics for pedigree23 instance over  $ibound$  range between 4 to 20.

Table 3: **Protein side-chain prediction.** Here we show results for only  $ibound = 2$ , due to the high number of states in each variable. Our method often produces dramatically better partitionings than scope- or context-based mini-bucket partitions.

fore moving on to later buckets, which serves to reduce the number of clusters considered. We compare our choice of clusters with a purely greedy region choice in which pairs of regions in *any* bucket  $B_i$  are considered and scored.

Interestingly the upper bounds achieved using the greedy approach was not better than the top down merging based on elimination order. The reason for this behavior is that the top-down approach allows large regions generated by mini-buckets early in the elimination ordering to be processed by buckets later in the order; the greedy approach disrupts this flow and results in extra regions that cannot be merged with any other region while respecting the  $ibound$ .

## 6 CONCLUSION

We presented a new merging heuristic for (weighted) mini-bucket elimination that uses message passing optimization of the bound, and variational interpretations, in order to construct a better heuristic for selecting moderate to large regions in an intelligent, energy-based way. Our approach inherits the advantages of both cluster pursuit in variational

Table 4: **Top-down vs. Greedy Merging.** We examine the effect of using a “fully greedy” merging procedure closer to standard cluster pursuit, in which we merge the best-scoring cluster in any bucket at each step. We find that following the top-down ordering actually results in significantly better bounds. Results shown are for  $ibound = 5$ .

inference, and (weighted) mini-bucket elimination perspectives to produce a tight bound. We validated our approach with experiments on a wide variety of problems drawn from a recent UAI approximate inference competition. In practice, we find that our methods work significantly better than either existing partitioning heuristics for mini-bucket (Rollon and Dechter, 2010), or a pure region pursuit approach. We expect this construction to improve our ability to search and solve large problems. However, our method does involve additional computational overhead compared to, say, scope-based constructions, in order to evaluate and make merge decisions. We did not focus here on any-time performance; a more nuanced balance of time, memory, and bound quality is one direction of potential future study.

## Abstract

Estimating mutual information (MI) from samples is a fundamental problem in statistics, machine learning, and data analysis. Recently it was shown that a popular class of non-parametric MI estimators perform very poorly for strongly dependent variables and have sample complexity that scales exponentially with the true MI. This undesired behavior was attributed to the reliance of those estimators on local uniformity of the underlying (and unknown) probability density function. Here we present a novel semi-parametric estimator of mutual information, where at each sample point, densities are *locally* approximated by a Gaussians distribution. We demonstrate that the estimator is asymptotically unbiased. We also show that the proposed estimator has a superior performance compared to several baselines, and is able to accurately measure relationship strengths over many orders of magnitude.

## 1 Introduction

Mutual information (MI) is a fundamental measure of dependence between two random variables. While it initially arose in the theory of communication as a natural measure of ability to communicate over noisy channels (Shannon, 1948), mutual information has since been used in different disciplines such as machine learning, information retrieval, neuroscience, and computational biology, to name a few. This widespread use is due in part to the generality of the measure, which allows it to characterize dependency strength for both linear and non-linear relationships between arbitrary random variables.

Let us consider the following basic problem, where, given a set of i.i.d. samples from an unknown, absolutely continuous joint distribution, our goal is to estimate the mutual information from these samples. A naive method would

be first to learn the underlying probability distribution using either parametric or non-parametric methods, and then calculate the mutual information from the obtained distribution. Unfortunately, this naive approach often fails, as it requires a very large number of samples, especially in high dimensions. A different approach is to estimate mutual information directly from samples. For instance, rather than estimating the whole probability distribution, one could estimate the density (and its marginals) only at each sample point, and then plug those estimates into the expression for mutual information. This type of direct estimators been shown to be a more feasible method for estimating MI in higher dimensions. An important and very popular class of such estimators is based on k-nearest-neighbor (kNN) graphs and their generalizations (Singh et al., 2003; Kraskov et al., 2004; Pál et al., 2010).

Despite the widespread popularity of the direct estimators, it was recently demonstrated that those methods fail to accurately estimate mutual information for *strongly dependent* variables (Gao et al., 2015). Specifically, it was shown that accurate estimation of mutual information between two strongly dependent variables requires a number of samples that scales *exponentially* with the true mutual information. This undesired behavior was contributed to the assumption of local uniformity of the underlying distribution postulated by those estimators. To address this shortcoming, (Gao et al., 2015) proposed to add a correction term to compensate for non-uniformity, based on local PCA-induced neighborhoods. Although intuitive, the resulting estimator relied on a heuristically tuned threshold parameter and had no theoretical performance guarantees (Gao et al., 2015).

Our main contribution is to propose a novel mutual information estimator based on *local Gaussian approximation*, with provable performance guarantees, and superior empirical performance compared to existing estimators over a wide range of relationship strength. Instead of assuming a uniform distribution in the local neighborhood, our new estimator assumes a Gaussian distribution *locally* around each point. The new estimator leverages previous results on *local likelihood density estimation* (Hjort and Jones, 1996;

Loader, 1996). As our main theoretical result, we demonstrate that the new estimator is asymptotically unbiased. We also demonstrate that the proposed estimator performs as well as existing baseline estimators for weak relationships, but outperforms all of those estimators for stronger relationships.

The paper is organized as follows. In the next section, we review the basic definitions of information-theoretic concepts such as mutual information and formally define our problem. In section 3, we review the limitations of current mutual information estimators as pointed out in (Gao et al., 2015). Section 4 introduces local likelihood density estimation. In Section 5 we use this density estimator to propose a novel entropy and mutual information estimator, and summarize certain theoretical properties of those estimator, which are then proved in Section 6. Section 7 provides numerical experiments demonstrating the superiority of the proposed estimator. We conclude the paper with a brief survey of related work followed by the discussion of our main results and some open problems.

## 2 Formal Problem Definition

In this section we briefly review the formal definition of Shannon entropy and mutual information, before formally defining the objective of our paper.

**Definition 1** Let  $\mathbf{x}$  denote a  $d$ -dimensional absolutely continuous random variable with probability density function  $f : \mathbb{R}^d \rightarrow \mathbb{R}$ . The Shannon differential entropy is defined as

$$H(\mathbf{x}) = - \int_{\mathbb{R}^d} f(\mathbf{x}) \log f(\mathbf{x}) d\mathbf{x} \quad (1)$$

**Definition 2** Let  $\mathbf{x}$  and  $\mathbf{y}$  denote  $d$ -dimensional and  $b$ -dimensional absolutely continuous random variables with probability density function  $f_X : \mathbb{R}^d \rightarrow \mathbb{R}$  and  $f_Y : \mathbb{R}^b \rightarrow \mathbb{R}$ , respectively. Let  $f_{XY}$  denote the joint probability density function of  $\mathbf{x}$  and  $\mathbf{y}$ . The mutual information between  $\mathbf{x}$  and  $\mathbf{y}$  is defined as

$$I(\mathbf{x} : \mathbf{y}) = \int_{\mathbf{y} \in \mathbb{R}^b} \int_{\mathbf{x} \in \mathbb{R}^d} f_{XY}(\mathbf{x}, \mathbf{y}) \log \frac{f_{XY}(\mathbf{x}, \mathbf{y})}{f_X(\mathbf{x}) f_Y(\mathbf{y})} d\mathbf{x} d\mathbf{y} \quad (2)$$

It is easy to show that

$$I(\mathbf{x} : \mathbf{y}) = H(\mathbf{x}) + H(\mathbf{y}) - H(\mathbf{x}, \mathbf{y}), \quad (3)$$

where  $H(\mathbf{x}, \mathbf{y})$  stands for the joint entropy of  $(\mathbf{x}, \mathbf{y})$ , and can be calculated from Eq. 1 using the joint density  $f_{XY}$ . We use the natural logarithms so that information is measured in nats.

It is sometime useful to represent entropy and mutual information as the following expectations:

$$H(\mathbf{x}) = \mathbb{E}_X[-\log f(\mathbf{x})] \quad (4)$$

$$I(\mathbf{x} : \mathbf{y}) = \mathbb{E}_{XY} \left[ \log \frac{f_{XY}(\mathbf{x}, \mathbf{y})}{f_X(\mathbf{x}) f_Y(\mathbf{y})} \right] \quad (5)$$

Assume now we are given  $N$  i.i.d. samples  $(\mathcal{X}, \mathcal{Y}) = \{(\mathbf{x}, \mathbf{y})^{(i)}\}_{i=1}^N$  from the unknown joint distribution  $f_{XY}$ . Our goal is then to construct a mutual information estimator  $\hat{I}(\mathbf{x} : \mathbf{y})$  based on those samples.

## 3 Limitations of Nonparametric MI Estimators

As pointed out in Section 1, one of the most popular class of mutual information estimators is based on  $k$ -nearest neighbor (kNN) graphs and their generalizations (Singh et al., 2003; Kraskov et al., 2004; Pál et al., 2010). However, it was recently shown that for strongly dependent variables, those estimators tend to underestimate the mutual information (Gao et al., 2015). To understand this problem, let us focus on kNN-based estimator as an example. The kNN estimator assumes uniform density within the kNN rectangle (containing  $k$ -nearest neighbors), as shown in Figure 1(a). Generally speaking, this assumption can be made valid for any relationship as long as we have sufficient number of samples. However, for limited sample size, this assumption becomes problematic when the relationship between the two variables becomes sufficiently strong. In fact, as shown in Fig. 1(b), the obtained *local* neighborhood induced by kNN is beyond the support of the probability distribution (shaded area).

This undesired behavior is closely related to the so-called *boundary effect* that occurs in nonparametric density estimation problem. Namely, for strongly dependent random variables, almost all the sample points are close to the boundary of the support (as illustrated in Figure 1(b)), making the density estimation problem difficult.

To relax the local uniformity assumption in kNN-based estimators, (Gao et al., 2015) proposed to replace the axis-aligned rectangle with a PCA-aligned rectangle *locally*, and use the volume of this rectangle for estimating the unknown density at a given point. Mathematically, the above revision was implemented by introducing a novel term that accounted for local non-uniformity. It was shown the the revised estimator significantly outperformed the existing estimators for strongly dependent variables. Nevertheless, the estimator suggested in (Gao et al., 2015) relied on a heuristic for determining when to use the correction term, and did not have any theoretical guarantees. In the remaining of this paper, we suggest a novel estimator based on *local gaussian approximation*, as more general approach to overcome the above limitations. The main idea is that, instead

Figure 1: For a given sample point  $\mathbf{x}^{(i)}$ , we show the max-norm rectangle containing  $k$  nearest neighbors (a) for points drawn from a uniform distribution,  $k = 3$ , (shaded area), and (b) for points drawn from a distribution over two strongly correlated variables,  $k = 4$ , (the area within dotted lines).

of assuming a uniform distribution around the local kNN- or a PCA-aligned rectangle, we approximate the unknown density at each sample point by a local *Gaussian* distribution, which is estimated using the  $k$ -nearest neighborhood of that point. In addition to demonstrating superior empirical performance of the proposed estimator, we also show that it is asymptotically unbiased.

#### 4 Local Gaussian Density Estimation

In this section, we introduce a density estimation method called local Gaussian density estimation, or LGDE (Hjort and Jones, 1996), which serves as the basic building block for the proposed mutual information estimator.

Consider  $N$  i.i.d. samples  $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N$  drawn from an unknown density  $f(\mathbf{x})$ , where  $\mathbf{x}$  is a  $d$ -dimensional continuous random variable. The central idea behind LGDE is to locally approximate the unknown probability density at point  $\mathbf{x}$  using a Gaussian parametric family  $\mathcal{N}_d(\boldsymbol{\mu}(\mathbf{x}), \boldsymbol{\Sigma}(\mathbf{x}))$ , where  $\boldsymbol{\mu}(\mathbf{x})$  and  $\boldsymbol{\Sigma}(\mathbf{x})$  are the ( $\mathbf{x}$ -dependent) mean and covariance matrix of each local approximation. This intuition is formalized in the following definition:

**Definition 3 (Local Gaussian Density Estimator)** Let  $\mathbf{x}$  denote a  $d$ -dimensional absolutely continuous random variable with probability density function  $f(\mathbf{x})$ , and let  $\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N\}$  be  $N$  i.i.d. samples drawn from  $f(\mathbf{x})$ . Furthermore, let  $\mathbf{K}_{\mathbf{H}}(\mathbf{x})$  be a product kernel with diagonal bandwidth matrix  $\mathbf{H} = \text{diag}(h_1, h_2, \dots, h_d)$ , so that  $\mathbf{K}_{\mathbf{H}}(\mathbf{x}) = h_1^{-1}K(h_1^{-1}x_1)h_2^{-1}K(h_2^{-1}x_2)\dots h_d^{-1}K(h_d^{-1}x_d)$ , where  $K(\cdot)$  can be any one-dimensional kernel function. Then the Local Gaussian Density Estimator, or LGDE, of  $f(\mathbf{x})$  is given by

$$\hat{f}(\mathbf{x}) = \mathcal{N}_d(\mathbf{x}; \boldsymbol{\mu}(\mathbf{x}), \boldsymbol{\Sigma}(\mathbf{x})), \quad (6)$$

Here  $\boldsymbol{\mu}, \boldsymbol{\Sigma}$  are different for each point  $\mathbf{x}$ , and are obtained

by solving the following optimization problem,

$$\boldsymbol{\mu}(\mathbf{x}), \boldsymbol{\Sigma}(\mathbf{x}) = \arg \max_{\boldsymbol{\mu}, \boldsymbol{\Sigma}} \mathcal{L}(\mathbf{x}, \boldsymbol{\mu}, \boldsymbol{\Sigma}), \quad (7)$$

where  $\mathcal{L}(\mathbf{x}, \boldsymbol{\mu}, \boldsymbol{\Sigma})$  is the local likelihood function defined as follows:

$$\begin{aligned} \mathcal{L}(\mathbf{x}, \boldsymbol{\mu}, \boldsymbol{\Sigma}) &= \frac{1}{N} \sum_{i=1}^N \mathbf{K}_{\mathbf{H}}(\mathbf{x}_i - \mathbf{x}) \log \mathcal{N}_d(\mathbf{x}_i; \boldsymbol{\mu}, \boldsymbol{\Sigma}) \\ &- \int \mathbf{K}_{\mathbf{H}}(\mathbf{t} - \mathbf{x}) \mathcal{N}_d(\mathbf{t}; \boldsymbol{\mu}, \boldsymbol{\Sigma}) d\mathbf{t} \end{aligned} \quad (8)$$

The first term in the right hand side of Eq. 8 is the localized version of Gaussian log-likelihood. One can see that without the kernel function, Eq. 8 becomes similar to the global log-likelihood function of the Gaussian parametric family. However, since we do not have sufficient information to specify a global distribution, we make a local smoothness assumption by adding this kernel function. The second term of right hand side in Eq. 8 is a penalty term to ensure the consistency of the density estimator.

The key difference between kNN density estimator and LGDE is that the former assumes that the density is locally uniform over the neighborhood of each sample point, whereas the latter method relaxes *local uniformity* to *local linearity*<sup>1</sup>, which allows to compensate for the boundary bias. In fact, any non-uniform parametric probability distribution is suitable for fitting a local distribution under the local likelihood, and the Gaussian distribution used here is simply one realization.

I Theorem 1 below establishes the consistency property of this local Gaussian estimator; for a detailed proof see (Hjort and Jones, 1996).

**Theorem 1 (Hjort and Jones, 1996)** Let  $\mathbf{x}$  denote a  $d$ -dimensional absolutely continuous random variable with probability density function  $f(\mathbf{x})$ , and let  $\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N\}$  be  $N$  i.i.d. samples drawn from  $f(\mathbf{x})$ . Let  $\hat{f}(x)$  be the Local Gaussian Density Estimator with diagonal bandwidth matrix  $\text{diag}(h_1, h_2, \dots, h_d)$ , where the diagonal elements  $h_i$ -s satisfy the following conditions:

$$\lim_{N \rightarrow \infty} h_i = 0, \quad \lim_{N \rightarrow \infty} N h_i = \infty, \quad i = 1, 2, \dots, d. \quad (9)$$

Then the following holds:

$$\lim_{N \rightarrow \infty} \mathbb{E}|\hat{f}(\mathbf{x}) - f(\mathbf{x})| = 0 \quad (10)$$

$$\lim_{N \rightarrow \infty} \mathbb{E}|\hat{f}(\mathbf{x}) - f(\mathbf{x})|^2 = 0 \quad (11)$$

<sup>1</sup>To elaborate on the local linearity, we note that Gaussian distribution is essentially a special case of Elliptical distribution  $f(\mathbf{x}) = k * g((\mathbf{x} - \boldsymbol{\mu})^T \boldsymbol{\Sigma}^{-1}(\mathbf{x} - \boldsymbol{\mu}))$ . Therefore, the local Gaussian approximation actually assumes a rotated hyper-ellipsoid locally at each point.

The above theorem states that LGDE is asymptotically unbiased and L2-consistent.

## 5 LGDE-based Estimators for Entropy and Mutual Information

We now introduce our estimators for entropy and mutual information that are inspired by the local density estimation approach defined in the previous section.

Let us again consider  $N$  i.i.d samples  $(\mathcal{X}, \mathcal{Y}) = \{(\mathbf{x}, \mathbf{y})^{(i)}\}_{i=1}^N$  drawn from an unknown joint distribution  $f_{XY}$ , where  $\mathbf{x}$  and  $\mathbf{y}$  are random vectors of dimensionality  $d$  and  $b$ , respectively. Let us construct the following estimators for entropy,

$$\widehat{H}(\mathbf{x}) = -\frac{1}{N} \sum_{i=1}^N \log \widehat{f}(\mathbf{x}_i), \quad (12)$$

and mutual information

$$\widehat{I}(\mathbf{x} : \mathbf{y}) = \frac{1}{N} \sum_{i=1}^N \log \frac{\widehat{f}(\mathbf{x}_i, \mathbf{y}_i)}{\widehat{f}(\mathbf{x}_i) \widehat{f}(\mathbf{y}_i)} \quad (13)$$

where  $\widehat{f}(\mathbf{x})$ ,  $\widehat{f}(\mathbf{y})$ ,  $\widehat{f}(\mathbf{x}, \mathbf{y})$  are the local Gaussian density estimators for  $f_X(\mathbf{x})$ ,  $f_Y(\mathbf{y})$ ,  $f_{XY}(\mathbf{x}, \mathbf{y})$  respectively, defined in the previous section.

Recall that the entropy and mutual information can be written as appropriately defined expectations; see Eqs. 4 and 5. Then the proposed estimator simply replaces the expectation by the sample averages, and then plugs in density estimators from Section 4 into those expectations.

The next two theorems state that the proposed estimators are asymptotically unbiased.

**Theorem 2 (Asymptotic Unbiasedness of Entropy Estimator)**  
If the conditions in Eq. 9 hold, then the entropy estimator given by Eq. 12 is asymptotically unbiased, i.e.,

$$\lim_{N \rightarrow \infty} \mathbb{E} \widehat{H}(\mathbf{x}) = H(\mathbf{x}) \quad (14)$$

**Theorem 3 (Asymptotic Unbiasedness of MI Estimator)**  
If the conditions in Eq. 9 hold, then the mutual information estimator given by Eq. 13 is asymptotically unbiased:

$$\lim_{N \rightarrow \infty} \mathbb{E} \widehat{I}(\mathbf{x} : \mathbf{y}) = I(\mathbf{x} : \mathbf{y}) \quad (15)$$

We provide the proofs of the above theorems in the next section.

## 6 Proofs of the Theorems

Before getting to the actual proofs, we first introduce the Lebesgue's dominated convergence theorem.

**Theorem 4 (Lebesgue dominated convergence theorem)**  
Let  $\{f_N\}$  be a sequence of functions, and assume this sequence converges point-wise to a function  $f$ , i.e.,  $f_N(\mathbf{x}) \rightarrow f(\mathbf{x})$  for any  $\mathbf{x} \in \mathbb{R}^d$ . Furthermore, let us assume that  $f_N$  is dominated by an integrable function  $g$ , e.g., we have for any  $\mathbf{x}$

$$|f_N(\mathbf{x})| \leq g(\mathbf{x})$$

Then we have

$$\lim_{N \rightarrow \infty} \int_{\mathbf{x} \in \mathbf{X}} |f_N(\mathbf{x}) - f(\mathbf{x})| d\mathbf{x} = 0$$

### 6.1 Proof of Theorem 2

Consider  $N$  i.i.d. samples  $\{\mathbf{x}^{(i)}\}_{i=1}^N$  drawn from the probability density  $f(\mathbf{x})$ , and let  $F_N(\mathbf{x})$  denote the empirical cumulative distribution function.

Let us define the following two quantities:

$$H_1 = -\frac{1}{N} \sum_{i=1}^N \ln \mathbb{E} \widehat{f}(\mathbf{x}_i) \quad (16)$$

$$H_2 = -\frac{1}{N} \sum_{i=1}^N \ln f(\mathbf{x}_i) \quad (17)$$

Then we have,

$$\begin{aligned} & \mathbb{E} |\widehat{H}(\mathbf{x}) - H(\mathbf{x})| \\ &= \mathbb{E} |(\widehat{H} - H_1) + (H_1 - H_2) + (H_2 - H)| \\ &\leq \mathbb{E} |\widehat{H} - H_1| + \mathbb{E} |H_1 - H_2| + \mathbb{E} |H_2 - H| \end{aligned} \quad (18)$$

We now proceed to show that each of the terms in Eq. 18 individually converges to 0 in the limit  $N \rightarrow \infty$ , which will then yield Eq. 14.

First, we note that according to the mean value theorem, for any  $\mathbf{x}$ , there exist  $t_{\mathbf{x}}$  and  $t'_{\mathbf{x}}$  in  $(0, 1)$ , such that

$$\begin{aligned} \ln \widehat{f}(\mathbf{x}) &= \ln \mathbb{E} \widehat{f}(\mathbf{x}) + \\ & (\widehat{f}(\mathbf{x}) - \mathbb{E} \widehat{f}(\mathbf{x})) \ln (t_{\mathbf{x}} \widehat{f}(\mathbf{x}) + (1 - t_{\mathbf{x}}) \mathbb{E} \widehat{f}(\mathbf{x})) \end{aligned} \quad (19)$$

and

$$\begin{aligned} \ln \mathbb{E} \widehat{f}(\mathbf{x}) &= \ln f(\mathbf{x}) + \\ & (\mathbb{E} \widehat{f}(\mathbf{x}) - f(\mathbf{x})) \ln (t'_{\mathbf{x}} f(\mathbf{x}) + (1 - t'_{\mathbf{x}}) \mathbb{E} \widehat{f}(\mathbf{x})) \end{aligned} \quad (20)$$

For the first term in Eq. 18, we use Eq. 19 to obtain

$$\begin{aligned}
& \mathbb{E} \left| \widehat{H} - H_1 \right| \\
&= \mathbb{E} \left| \int [\ln \widehat{f}(\mathbf{x}) - \ln \mathbb{E} \widehat{f}(\mathbf{x})] dF_N(\mathbf{x}) \right| \\
&= \mathbb{E} \left| \int \frac{|\widehat{f}(\mathbf{x}) - \mathbb{E} \widehat{f}(\mathbf{x})|}{t_{\mathbf{x}} \widehat{f}(\mathbf{x}) + (1 - t_{\mathbf{x}}) \mathbb{E} \widehat{f}(\mathbf{x})} dF_N(\mathbf{x}) \right| \\
&\leq \frac{1}{1-t} \mathbb{E} \left| \int \frac{|\widehat{f}(\mathbf{x}) - \mathbb{E} \widehat{f}(\mathbf{x})|}{\mathbb{E} \widehat{f}(\mathbf{x})} dF_N(\mathbf{x}) \right| \\
&= \frac{1}{1-t} \mathbb{E} \left( \frac{1}{N} \sum_{i=1}^N \frac{|\widehat{f}(\mathbf{x}_i) - \mathbb{E} \widehat{f}(\mathbf{x}_i)|}{\mathbb{E} \widehat{f}(\mathbf{x}_i)} \right) \\
&= \frac{1}{1-t} \mathbb{E} \left( \mathbb{E} \left( \frac{|\widehat{f}(\mathbf{u}) - \mathbb{E} \widehat{f}(\mathbf{u})|}{\mathbb{E} \widehat{f}(\mathbf{u})} \right) \middle| \mathbf{x} = \mathbf{u} \right) \\
&= \frac{1}{1-t} \int |\widehat{f}(\mathbf{u}) - \mathbb{E} \widehat{f}(\mathbf{u})| \frac{\widehat{f}(\mathbf{u})}{\mathbb{E} \widehat{f}(\mathbf{u})} d\mathbf{u} \quad (21)
\end{aligned}$$

where  $t$  is the maximum value among all  $t_{\mathbf{x}}$ . Using Theorem 1, we have  $|\widehat{f}(\mathbf{u}) - \mathbb{E} \widehat{f}(\mathbf{u})| \rightarrow 0$  as  $N \rightarrow \infty$ . Furthermore, it is possible to show that  $\exists N_0$ , so that for any  $N > N_0$  one has  $|\widehat{f}(\mathbf{u}) - \mathbb{E} \widehat{f}(\mathbf{u})| \frac{\widehat{f}(\mathbf{u})}{\mathbb{E} \widehat{f}(\mathbf{u})} < 2f(\mathbf{u})$ . Thus, using Theorem 4, we obtain

$$\lim_{N \rightarrow \infty} \mathbb{E} |H - H_1| = 0 \quad (22)$$

Similarly, using Eq. 20,  $\mathbb{E} |H_1 - H_2|$  can be written as

$$\begin{aligned}
& \mathbb{E} |H_1 - H_2| \\
&= \mathbb{E} \left| \int [\ln \mathbb{E} \widehat{f}(\mathbf{x}) - \ln f(\mathbf{x})] dF_N(\mathbf{x}) \right| \\
&= \mathbb{E} \left| \int \frac{|\mathbb{E} \widehat{f}(\mathbf{x}) - f(\mathbf{x})|}{t'_{\mathbf{x}} f(\mathbf{x}) + (1 - t'_{\mathbf{x}}) \mathbb{E} \widehat{f}(\mathbf{x})} dF_N(\mathbf{x}) \right| \\
&\leq \frac{1}{t'} \mathbb{E} \left| \int \frac{|\mathbb{E} \widehat{f}(\mathbf{x}) - f(\mathbf{x})|}{f(\mathbf{x})} dF_N(\mathbf{x}) \right| \\
&= \frac{1}{t'} \mathbb{E} \left( \frac{1}{N} \sum_{i=1}^N \frac{|\mathbb{E} \widehat{f}(\mathbf{x}_i) - f(\mathbf{x}_i)|}{f(\mathbf{x}_i)} \right) \\
&= \frac{1}{t'} \int f(\mathbf{x}) \frac{|\mathbb{E} \widehat{f}(\mathbf{x}) - f(\mathbf{x})|}{f(\mathbf{x})} d\mathbf{x} \\
&= \frac{1}{t'} \int |\mathbb{E} \widehat{f}(\mathbf{x}) - f(\mathbf{x})| d\mathbf{x} \quad (23)
\end{aligned}$$

where  $t'$  is the minimum value among all  $t'_{\mathbf{x}}$ .

Invoking Theorem 1 again, we observe that the last term in Eq. 23  $|\mathbb{E} \widehat{f}(\mathbf{x}) - f(\mathbf{x})| \rightarrow 0$  as  $N \rightarrow \infty$ , and is bounded by  $2f(\mathbf{x})$  for sufficiently large  $N$  (e.g., when  $\widehat{f}(\mathbf{u})$  and  $\mathbb{E} \widehat{f}(\mathbf{u})$  are sufficiently close). Therefore, by Theorem 4, we have

$$\lim_{N \rightarrow \infty} \mathbb{E} |H_1 - H_2| = 0 \quad (24)$$

Finally, for the last term in Eq. 18, we note that

$$\mathbb{E} H_2 = -\frac{1}{N} \mathbb{E} \sum_{i=1}^N \ln f(\mathbf{x}_i) = \mathbb{E} [-\ln f(\mathbf{x})] \quad (25)$$

Thus,  $\mathbb{E} H_2$  is simply the entropy in Definition 1; see Eq. 4. Therefore,

$$\lim_{N \rightarrow \infty} \mathbb{E} |H_2 - H| = 0 \quad (26)$$

Combining Eqs. 22, 24, 26 and 18, we arrive at Eq. 14, which concludes the proof.

## 6.2 Proof of Theorem 3

For mutual information estimation, we use Eq. 3 to get

$$\begin{aligned}
\mathbb{E} |\widehat{I}(\mathbf{x} : \mathbf{y}) - I(\mathbf{x} : \mathbf{y})| &\leq \mathbb{E} |H(\mathbf{x}) - \widehat{H}(\mathbf{x})| \\
&\quad + \mathbb{E} |H(\mathbf{y}) - \widehat{H}(\mathbf{y})| \\
&\quad + \mathbb{E} |H(\mathbf{x}, \mathbf{y}) - \widehat{H}(\mathbf{x}, \mathbf{y})| \quad (27)
\end{aligned}$$

Using Theorem 2, we see that all three terms on the right hand side in Eq. 27 converge to zero as  $N \rightarrow \infty$ , therefore  $\lim_{N \rightarrow \infty} \mathbb{E} |\widehat{I}(\mathbf{x} : \mathbf{y}) - I(\mathbf{x} : \mathbf{y})| = 0$ , thus concluding the proof.

## 7 Experiments

### 7.1 Implementation Details

Our main computational task is to maximize the local likelihood function in Eq. 8. Since computing the second term on the right hand side of Eq. 8 requires integration that can be time-consuming, we choose the kernel function  $K(\cdot)$  to be a Gaussian kernel,  $\mathbf{K}_{\mathbf{H}}(\mathbf{t} - \mathbf{x}) = \mathcal{N}_d(\mathbf{t}; \mathbf{x}, \mathbf{H})$  so that the integral can be performed analytically, yielding

$$\int \mathbf{K}_{\mathbf{H}}(\mathbf{t} - \mathbf{x}) \mathcal{N}_d(\mathbf{t}; \boldsymbol{\mu}, \boldsymbol{\Sigma}) d\mathbf{t} = \mathcal{N}_d(\mathbf{x}; \boldsymbol{\mu}, \mathbf{H} + \boldsymbol{\Sigma}) \quad (28)$$

Thus, Eq. 8 reduces to

$$\begin{aligned}
\mathcal{L}(\mathbf{x}, \boldsymbol{\mu}, \boldsymbol{\Sigma}) &= \frac{1}{N} \sum_{i=1}^N \mathcal{N}_d(\mathbf{x}_i; \mathbf{x}, \mathbf{H}) \log \mathcal{N}_d(\mathbf{x}_i; \boldsymbol{\mu}, \boldsymbol{\Sigma}) \\
&\quad - \mathcal{N}_d(\mathbf{x}; \boldsymbol{\mu}, \mathbf{H} + \boldsymbol{\Sigma}) \quad (29)
\end{aligned}$$

Maximizing Eq. 29 is a constrained non-convex optimization problem with the condition that the covariance matrix  $\boldsymbol{\Sigma}$  is positive semi-definite. We use Cholesky parameterization to enforce the positive semi-definiteness of  $\boldsymbol{\Sigma}$ , which allows to reduce our constrained optimization problem into an unconstrained one. Also, since we would like to preserve the local structure of the data, we select the bandwidth to be close to the distance between pair of k-nearest points (averaged over all the points).

We use Newton-Raphson method to do the maximization although the function itself is not exactly concave. The full algorithm for our estimator is given in Algorithm 1 which takes Algorithm 2 as a subroutine. Note that in Algorithm 2, the Wolfe condition is a set of inequalities in performing quasi-Newton methods (Wolfe, 1969).

---

### Algorithm 1 Mutual Information Estimation with Local Gaussian Approximation

---

**Input:** points  $(\mathbf{x}, \mathbf{y})^{(1)}, (\mathbf{x}, \mathbf{y})^{(2)}, \dots, (\mathbf{x}, \mathbf{y})^{(N)}$   
**Output:**  $\hat{I}(\mathbf{x}; \mathbf{y})$   
 Calculate entropy  $\hat{H}(\mathbf{x})$  using samples  $\mathbf{x}^{(1)}, \mathbf{x}^{(2)}, \dots, \mathbf{x}^{(N)}$   
 Calculate entropy  $\hat{H}(\mathbf{y})$  using samples  $\mathbf{y}^{(1)}, \mathbf{y}^{(2)}, \dots, \mathbf{y}^{(N)}$   
 Calculate joint entropy  $\hat{H}(\mathbf{x}, \mathbf{y})$  using input samples  $(\mathbf{x}, \mathbf{y})^{(1)}, (\mathbf{x}, \mathbf{y})^{(2)}, \dots, (\mathbf{x}, \mathbf{y})^{(N)}$   
 Return estimated mutual information  $\hat{I} = \hat{H}(\mathbf{x}) + \hat{H}(\mathbf{y}) - \hat{H}(\mathbf{x}, \mathbf{y})$

---

---

### Algorithm 2 Entropy Estimation with Local Gaussian Approximation

---

**Input:** points  $\mathbf{u}^{(1)}, \mathbf{u}^{(2)}, \dots, \mathbf{u}^{(N)}$   
**Output:**  $\hat{H}(\mathbf{u})$   
 Initialize  $\hat{H}(\mathbf{u}) = 0$   
**for** each point  $\mathbf{x}^{(i)}$  **do**  
   initialize  $\boldsymbol{\mu} = \boldsymbol{\mu}_0, \mathbf{L} = \mathbf{L}_0$   
   **while** not  $\mathcal{L}(\mathbf{x}^{(i)}, \boldsymbol{\mu}, \boldsymbol{\Sigma} = \mathbf{L} * \mathbf{L}^T)$  converge **do**  
     Calculate  $\mathcal{L}(\mathbf{x}^{(i)}, \boldsymbol{\mu}, \boldsymbol{\Sigma} = \mathbf{L} * \mathbf{L}^T)$   
     Calculate gradient vector  $\mathbf{G}$  of  $\mathcal{L}(\mathbf{x}^{(i)}, \boldsymbol{\mu}, \boldsymbol{\Sigma} = \mathbf{L} * \mathbf{L}^T)$ , with respect to  $\boldsymbol{\mu}, \mathbf{L}$   
     Calculate Hessian matrix of  $\mathbf{H}$  of  $\mathcal{L}(\mathbf{x}^{(i)}, \boldsymbol{\mu}, \boldsymbol{\Sigma} = \mathbf{L} * \mathbf{L}^T)$ , with respect to  $\boldsymbol{\mu}, \mathbf{L}$   
     Do Hessian modification to ensure the positive semi-definiteness of  $\mathbf{H}$   
     Calculate descent direction  $\mathbf{D} = -\alpha \mathbf{H}^{-1} \mathbf{G}$ , where we compute  $\alpha$  to satisfy Wolfe condition  
     Update  $\boldsymbol{\mu}, \mathbf{L}$  with  $(\boldsymbol{\mu}, \mathbf{L}) + \mathbf{D}$   
   **end while**  
    $\hat{f}(\mathbf{x}^{(i)}) = \mathcal{N}(\mathbf{x}; \boldsymbol{\mu}, \boldsymbol{\Sigma} = \mathbf{L} * \mathbf{L}^T)$   
    $\hat{H}(\mathbf{u}) = \hat{H}(\mathbf{u}) - \frac{\log \hat{f}(\mathbf{x}^{(i)})}{N}$   
**end for**

---

In a single step, evaluating the gradient and Hessian in Algorithm 2 would take  $O(N)$  time because Eq. 8 is a summation over all the points. However, for points that are far from the current point  $\mathbf{x}^{(i)}$ , the kernel weight function is very close to zero and we can ignore those point and do the summation only over a local neighborhood of  $\mathbf{x}^{(i)}$ .

## 7.2 Experiments with synthetic data

**Functional relationships** We test our MI estimator for near-functional relationships of form  $Y = f(X) + \mathcal{U}(0, \theta)$ ,

where  $\mathcal{U}(0, \theta)$  is the uniform distribution over the interval  $(0, \theta)$ , and  $X$  is drawn randomly uniformly from  $[0, 1]$ . Similar relationships were studied in (Reshef et al., 2011), (Kinney and Atwal, 2014) and (Gao et al., 2015).

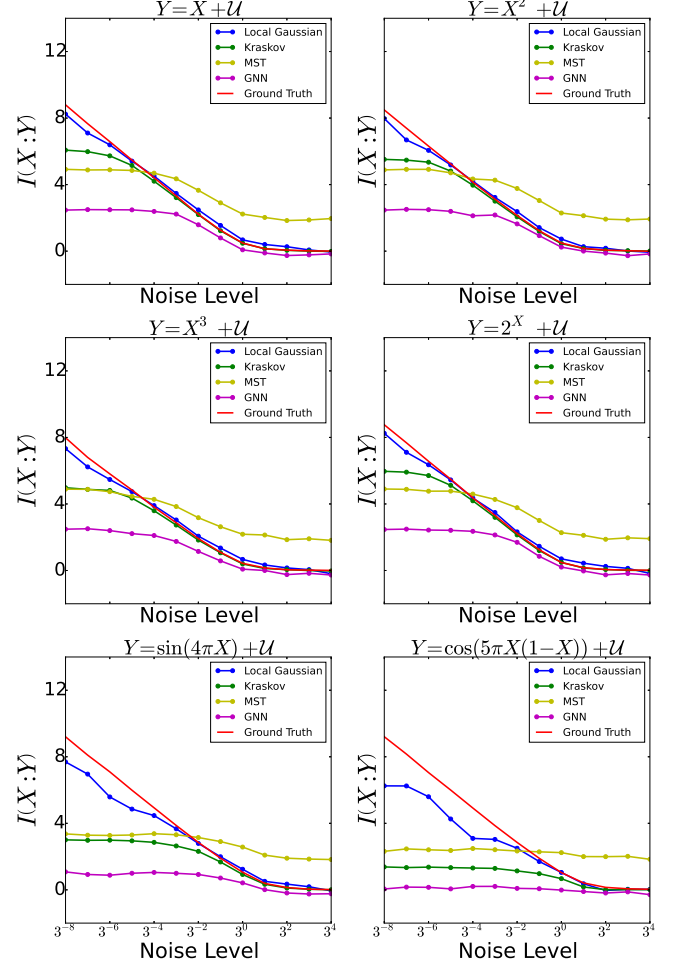

Figure 2: Functional relationship test for mutual information estimators. The horizontal axis is the value of  $\theta$  which controls the noise level; the vertical axis is the mutual information in nats. For the Kraskov and GNN estimators we used nearest neighbor parameter  $k = 5$ . For the local Gaussian estimator, we choose the bandwidth to be the distance between a point and its 5rd nearest neighbor.

We compare our estimator to several baselines that include the kNN estimator proposed by (Kraskov et al., 2004), an estimator based on generalized nearest-neighbor graphs (GNN) (Pál et al., 2010), and minimum spanning tree method (MST) (Yukich and Yukich, 1998). We evaluate those estimators for six different functional relationships as indicated in Figure 2. We use  $N = 2500$  sample points for each relationship. To speed up the optimization, we limited the summation in Eq. 29 to only  $k$  nearest neighbors, thus reducing the computational complexity from  $O(N)$  to  $O(k)$  in every iteration step of Algorithm 2.

One can see from Fig. 2 that when  $\theta$  is relatively large, all methods except MST produce accurate estimates of MI. However, as one decreases  $\theta$ , all three baseline estimators start to significantly underestimate mutual information. In this low-noise regime, our proposed estimator outperforms the baselines, at times by a significant margin. Note also that all the estimators, including ours, perform relatively poorly for highly non-linear relationships (the last row in Figure 2). According to our intuition, this happens when the scale of the non-linearity becomes sufficiently small, so that the linear approximation of the relationship around the local neighborhood of each sample point does not hold. Under this scenario, accuracy can be recovered by adding more samples.

## 8 Related Work

**Mutual Information Estimators** Recently, there has been a significant amount of work on estimating information-theoretic quantities such as entropy, mutual information, and divergences, from i.i.d. samples. Methods include k-nearest-neighbors (Singh et al., 2003), (Kraskov et al., 2004), (Pál et al., 2010), (Póczos et al., 2011); minimum spanning trees (Yukich and Yukich, 1998); kernel density estimate (Moon et al., 1995), (Singh and Poczos, 2014); maximum likelihood density ratio (Suzuki et al., 2008); ensemble methods (Moon and Hero, 2014), (Sricharan et al. (2013), etc. As pointed out earlier, all of those methods underestimate the mutual information when two variables have strong dependency. (Gao et al., 2015) addressed this shortcoming by introducing a local non-uniformity correction, but their estimator depended on a heuristically defined threshold parameter and lacked performance guarantees.

**Density Estimation and Boundary Bias** Density estimation is a classic problem in statistics and machine learning. Kernel density estimation and k-nearest-neighbor density estimates are the two most popular and successful non-parametric methods. However, it has been recognized that these non-parametric techniques often suffer from the problem of so-called “boundary bias”. Researchers have proposed a variety of methods to overcome the bias, such as the reflection method (Schuster, 1985), (Silverman, 1986); the boundary kernel method (Zhang and Karunamuni, 2000), the transformation method (Marron and Ruppert, 1994), the pseudo-data method (Cowling and Hall, 1996) and others. All these methods are useful in some particular settings. But when it comes to mutual information estimation, how can we choose the most efficient one to use? It seems that local likelihood method (Hjort and Jones, 1996), (Loader, 1996), is a good choice for estimating the mutual information due to its ability to detect the boundary without any prior knowledge. Previous studies have already proven the power of *local regression*, which can automatically overcome the boundary bias. Methods based on *local likelihood* estimation has traditionally at-

tracted less attention due to their computational complexity. However, advances in computational power allow us to re-consider this class of method.

## 9 Conclusion and Future Work

Past research on mutual information estimation has mostly focused on distinguishing weak dependence from independence. However, in the era of big data, we are often interested in highlighting the strongest dependencies among a large number of variables. When those variables are highly inter-dependent, traditional non-parametric mutual information estimators fail to accurately estimate the value due to the boundary bias.

We have addressed this shortcoming by introducing a novel semi-parametric method for estimating entropy and mutual information based on local Gaussian approximation of the unknown density at the sample points. We demonstrated that the proposed estimators are asymptotically unbiased. We also showed empirically that the proposed estimator has a superior performance compared to a number of popular baseline methods, and can accurately measure strength of the relationship even for strongly dependent variables, and limited number of samples.

There are several potential avenues for future work. First of all, we would like to validate the proposed estimator in higher-dimensional settings. In principle, the approach is general and can be applied in any dimensions. However, the optimization procedure may be computationally expensive in higher dimensions, since the number of parameters scales as  $O(d^2)$  with dimensionality  $d$ . An intuitive solution would be to initialize the parameters with the results obtained from the close points, which can facilitate convergence.

Another interesting issue is the bandwidth selection, which is an important problem in general density estimation problems. If the bandwidth is too large, the local Gaussian assumption may not be valid, whereas very small bandwidth will result in non-smooth densities. Ideally, we would like to choose the bandwidth in a way that preserves the local Gaussian structure in the neighborhood of each point. Another interesting extension would be choosing the bandwidth adaptively for each point.

Finally, while here we have focused on the asymptotic unbiasedness of the proposed estimator, it will be very valuable to establish theoretical results about the convergence rates of the estimators, as well as its variance in the large sample limit.

## Abstract

Psychophysical detection tests are ubiquitous in the study of human sensation and the diagnosis and treatment of virtually all sensory impairments. In many of these settings, the goal is to recover, from a series of binary observations from a human subject, the latent function that describes the discriminability of a sensory stimulus over some relevant domain. The auditory detection test, for example, seeks to understand a subject’s likelihood of hearing sounds as a function of frequency and amplitude. Conventional methods for performing these tests involve testing stimuli on a pre-determined grid. This approach not only samples at very uninformative locations, but also fails to learn critical features of a subject’s latent discriminability function. Here we advance active learning with Gaussian processes to the setting of psychophysical testing. We develop a model that incorporates strong prior knowledge about the class of stimuli, we derive a sensible method for choosing sample points, and we demonstrate how to evaluate this model efficiently. Finally, we develop a novel likelihood that enables testing of multiple stimuli simultaneously. We evaluate our method in both simulated and real auditory detection tests, demonstrating the merit of our approach.

## 1 INTRODUCTION

Psychophysical tests are a fundamental tool for investigating human perception: does a particular stimulus produce sensation for a particular person? The most common form of psychophysical tests – *detection tests* – present  $n$  sensory stimuli to a subject, and ask for  $n$  binary reports as

to whether each stimulus was detected or not. Detection tests exist for vision (Schiefer et al., 2005), pain (Carter and Shieh, 2009), and many other settings. Perhaps the most common example is audiometry (Carhart and Jerger, 1959; Don et al., 1978; Hughson and Westlake, 1944): a subject is presented with a sequence of  $n$  tones  $\mathbf{x}_t \forall t = 1, \dots, n$ , where each tone  $\mathbf{x}_t \in \mathbb{R}^2$  is a pure tone with a specific frequency (pitch) and intensity (volume). The subject reports an observation  $y_t = 1$  if he/she heard the tone, and a  $y_t = 0$  is concluded in the absence of a positive report. The purpose of the test is to infer, from this sequence of observations, the underlying *audiometric function*  $g(\mathbf{x})$ , a function that describes how likely the subject is to hear sounds over the domain of typical frequencies and intensities. There is substantial variability in each person’s audiogram, particularly for those with partial, selective, or degenerative hearing loss (Gosztonyi Jr et al., 1971; Robinson, 1991; Schmuziger et al., 2004). Accurate estimates of audiograms are thus essential to understanding human audition, and to all medical studies and treatments of various forms of hearing loss.

A standard auditory detection test is carried out by playing an  $n$ -length sequence of pure tones on a pre-defined grid in frequency-intensity space. This approach, while simple, has several salient drawbacks that lead to an unnecessarily large  $n$ . First, a given tone is played multiple times, even if it is highly audible or highly inaudible. Second, information is not shared between previous outcomes. For example, human audition is monotonically increasing in intensity, but in the standard test, even if a particular frequency of sound is heard at a given intensity, tones with the same frequency but higher intensity will still be tested. Finally, owing to limitations on the size of sequence  $n$ , a standard detection test probes only six discrete frequencies (Madison et al., 2005). The coarseness of this grid can cause significant errors, as human hearing loss can span a range narrow enough to be entirely missed by these six frequen-

cies (Jerger, 1960; Zhao et al., 2002; Zhao and Stephens, 1998). All of these issues, combined with the impracticality and burden to human subjects of a large  $n$  sequence, motivate an active learning approach.

Here we treat psychophysical detection tests as an active learning problem, extending and adapting recent work on active learning with Gaussian processes (GPs) (Garnett et al., 2013; Houlsby et al., 2011; Iwata et al., 2013). Our method addresses all the drawbacks of grid-sampling by performing Bayesian active learning of the audiometric function  $g(\mathbf{x})$ . Specifically, we place a GP prior on the latent audiogram  $f(\mathbf{x})$ , which we transform to a  $[0, 1]$  valued quantity using a probit transformation (Kuss and Rasmussen, 2005), such that  $g(\mathbf{x}) \approx \Phi(f(\mathbf{x}))$ . We use this model to sequentially sample at each time step  $t$  the most informative next tones conditioned on the previous  $t-1$  observations  $y_1, \dots, y_{t-1}$ . This model significantly enhances the accuracy and efficiency of learning audiograms. Our work offers two main contributions:

1. We extend and adapt existing work on Bayesian optimization and active learning to the setting of psychophysical detection tests. We present a model that incorporates strong prior knowledge about the auditory stimulus space, and we present experimental results demonstrating the effectiveness of a Bayesian active learning approach.
2. We develop a novel ‘OR-channel’ likelihood that allows the query of *multiple tones simultaneously*. We analyze this likelihood in the active learning context, clarifying the non-obvious intuition for why and when such an approach can outperform single-tone queries.

We evaluate our algorithm on both simulated and real audiometric detection tests. Our active learning approach obtains finer grained estimates of the audiogram  $g(\mathbf{x})$  with substantially fewer stimuli queries (lower  $n$ ). We note that, in the remainder of this work (notably our experiments), we will continue to use the example and nomenclature of audiometry, though our algorithm is precisely equivalent for other psychophysical detection tests as well.

## 2 GAUSSIAN PROCESSES

Throughout this paper we will make extensive use of Gaussian processes (GPs). A GP is formally a prior over functions,  $f \sim \mathcal{GP}(\mu_0(\cdot), k(\cdot, \cdot))$ , parameterized by a mean function  $\mu_0(\mathbf{x}) = \mathbb{E}[f(\mathbf{x})]$  and covariance function  $k(\mathbf{x}, \mathbf{x}') = \mathbb{E}[(f(\mathbf{x}) - \mu_0(\mathbf{x}))(f(\mathbf{x}') - \mu_0(\mathbf{x}'))]$ .

For any set of  $n$  observations  $\mathbf{X} = [\mathbf{x}_1, \dots, \mathbf{x}_n]$ , the GP implies that their function values  $\mathbf{f} = [f(\mathbf{x}_1), \dots, f(\mathbf{x}_n)]^\top$  are jointly Gaussian distributed,  $\mathbf{f} \sim \mathcal{N}(\mu(\mathbf{X}), \mathbf{K})$ , where  $\mathbf{K}$  defines the covariance  $\mathbf{K}_{ij} = \text{Cov}[f_i, f_j] = k(\mathbf{x}_i, \mathbf{x}_j)$ .

If we add a test point  $\mathbf{x}^*$  with unknown function value  $f^*$  this distribution extends naturally by one dimension to

$$\begin{bmatrix} \mathbf{f} \\ f^* \end{bmatrix} \sim \mathcal{N}\left(\begin{bmatrix} \mu(\mathbf{X}) \\ \mu(\mathbf{x}^*) \end{bmatrix}, \begin{bmatrix} \mathbf{K} & \mathbf{k}^* \\ \mathbf{k}^{*\top} & k(\mathbf{x}^*, \mathbf{x}^*) \end{bmatrix}\right).$$

We can utilize standard Gaussian conditioning rules (Rasmussen and Williams, 2006) to derive the posterior distribution,  $p(f^*|\mathbf{X}, \mathbf{f}, \mathbf{x}^*)$ , which is Gaussian with mean and variance

$$\begin{aligned} \mu^*(\mathbf{x}^*) &= \mu_0(\mathbf{x}^*) + \mathbf{k}^{*\top} \mathbf{K}^{-1}(\mathbf{f} - \mu_0(\mathbf{x}^*)) \quad (1) \\ \sigma^{*2}(\mathbf{x}^*) &= k(\mathbf{x}^*, \mathbf{x}^*) - \mathbf{k}^{*\top} \mathbf{K}^{-1} \mathbf{k}^*. \quad (2) \end{aligned}$$

Here  $\mathbf{k}^* = [k(\mathbf{x}^*, \mathbf{x}_1), \dots, k(\mathbf{x}^*, \mathbf{x}_n)]^\top$  denotes the kernel vector between the test input  $\mathbf{x}^*$  and each training input.

In practice, we often do not observe  $f_i$  directly, but rather some dependent random variable  $y_i$ . A popular example is to assume additive Gaussian noise,  $y_i = f_i + \epsilon$  with  $\epsilon \sim \mathcal{N}(0, \sigma_n^2)$ . In this setting, the distribution for  $f^*$  remains Gaussian, with a mean and variance similar to eqs. (1) and (2) (where  $\mathbf{K}$  is replaced with  $\mathbf{K} + \sigma_n^2 \mathbf{I}$ ).

However, with most observation models, the posterior distribution of  $f^*$  conditioned on  $\mathbf{y}$  is not Gaussian, and exact inference becomes impossible. Approximate inference may be performed using a Gaussian approximation to the likelihood (Kuss and Rasmussen, 2005; Minka, 2001). In particular, by using a Gaussian approximation to the likelihood, we recover the Gaussianity of the posterior. For a full treatment of Gaussian processes, see (Rasmussen and Williams, 2006).

Note that in many cases, our goal is to make predictions, for which we use the posterior predictive distribution—a distribution over  $y^*$ :

$$p(y^*|\mathbf{X}, \mathbf{y}, \mathbf{x}^*) = \int_{f^*} p(y^*|f^*)p(f^*|\mathbf{X}, \mathbf{y}, \mathbf{x}^*)df^*, \quad (3)$$

This distribution is typically not computable analytically. However, if the posterior distribution for  $f^*$  is Gaussian (e.g., because a Gaussian likelihood or Gaussian approximate likelihood was used), this integral can often be computed efficiently.

### 2.1 BAYESIAN ACTIVE LEARNING

The goal of Bayesian active learning is to sequentially choose samples so as to accurately model an unknown function  $g(\cdot)$  with as few samples as possible. In the audiometric setting,  $g(\mathbf{x})$  is the probability that the patient hears the tone  $\mathbf{x}$ . If we query whether the patient can hear a set of tones  $\mathbf{X}$ , we would like for our predictive posterior belief  $p(y^*|\mathbf{X}, \mathbf{y}, \mathbf{x}^*)$  to match  $g(\mathbf{x}^*)$  as well as possible and as *confidently* as possible. Suppose that at iteration  $t < n$  the points  $\mathbf{X} = [\mathbf{x}_1, \dots, \mathbf{x}_t]$  and corresponding labels  $\mathbf{y}$  are

known. Houlshby et al. (2011) propose to use mutual information,

$$I(\mathbf{f}, y_t | \mathbf{x}_t) = H[\mathbf{f} | \mathbf{X}, \mathbf{y}] - \mathbb{E}[H[\mathbf{f} | \mathbf{X}, \mathbf{y}, y_t]]_{p(y_t | \mathbf{x}, \mathbf{y}, \mathbf{x}_t)} \quad (4)$$

where  $H[A]$  denotes the differential entropy of a random variable  $A$ , to identify a new point  $\mathbf{x}_t$ , with future label  $y_t$ , to be queried in iteration  $t$ —*i.e.*  $\mathbf{x}_t$  is chosen to be

$$\mathbf{x}_t = \arg \max_{\mathbf{x}} I(\mathbf{f}, y | \mathbf{x}) \quad (5)$$

### 3 METHOD

In this section, we discuss our model and approach to psychophysical detection testing using Gaussian processes. As a running example, we will use audiometry. In an audiometric detection test, a patient is presented with tones of varying frequency and intensity. The patient is asked to respond (*e.g.*, by pressing a button) if he/she hears the sound. In the absence of a timely reaction the tone is assumed to be inaudible to the patient. The delay between tones is sufficiently randomized to prevent patients from responding to predictable patterns (Gosztonyi Jr et al., 1971).

At time step  $t$ , we choose a tone  $\mathbf{x}_t = (\omega, i)$  with frequency  $\omega$  and intensity  $i$  to present to the subject. In return, we receive a response  $y_t \in \{0, 1\}$ , where  $y_t = 1$  indicates that the patient heard the sound and  $y_t = 0$  indicates that he/she did not. There is inherent observation noise in patient responses. When patients become uncertain when presented with sounds very close to their threshold (*i.e.*, the sounds become faint and hard to hear). Patients do not have perfect detection boundaries, and only hear tones near their hearing threshold with some probability. This uncertainty is observed in reality for a number of reasons. First, patient attention may waver, or they may be unable to distinguish between tones near their hearing threshold and slight background noise. Alternatively, this uncertainty may derive from physical sources. For example, if a tone is faint enough, a patient may be able to hear that tone between—but not during—heart beats. Our goal is therefore to predict the probability that a patient is able hear a given sound.

#### 3.1 PRIOR

In the case of audiometric testing, we have valuable prior knowledge about a patient’s audiometric function that we can encode in our GP model. In particular, the probability that a patient hears a sound  $(\omega, i)$  is *monotonically increasing* in the intensity  $i$ . In other words, if a tone is audible to a patient, then an even louder tone is more likely to be audible. Furthermore, audition is a *smooth function* with respect to the frequency  $\omega$ . Human nerves that detect similar frequencies are co-located in the cochlea and, as a result, a partial loss of hearing in one frequency is likely to cause a loss of hearing in nearby frequencies. A GP prior

can encode both properties naturally through its covariance function. A combination of a linear kernel in intensity and a squared exponential kernel in frequency ensures the monotonicity and smoothness properties:

$$k((\omega, i), (\omega', i')) = ii' + \exp\left\{-\frac{1}{\ell} \|\omega - \omega'\|_2^2\right\}. \quad (6)$$

Here,  $\ell$  regulates the smoothness (characteristic length-scale) w.r.t. frequency. Note that a GP prior is technically incapable of supporting only monotonically increasing functions. However, we only need that the posterior probability of detection,  $3$ , be monotonic, which is generally true after a few tones are sampled (for example, see figure 3).

For the mean function  $\mu_0$ , we note that intensity is typically measured in dB HL, which is an empirical unit of measurement normalized based on population data so that at each frequency the typical human hearing threshold is around 0 dB HL. As a result we choose a constant mean function.

#### 3.2 OBSERVATION MODEL

This mean function,  $\mu_0(\cdot)$ , and covariance function,  $k(\cdot, \cdot)$ , define a prior over real-valued latent functions  $f \sim \mathcal{GP}(\mu_0(\cdot), k(\cdot, \cdot))$ . Our goal is to predict the *probability* (*i.e.* within  $[0, 1]$ ) that a patient hears a tone with a specified frequency and intensity. We can never observe these probabilities directly. For any tone, we can instead only observe the outcome of a Bernoulli trial with the true probability. This setting is akin to Gaussian Process classification (Kuss and Rasmussen, 2005) and similarly we use a Bernoulli likelihood, where  $\Pr(y = 1 | f) = \Phi(f)$  and  $\Phi(\cdot)$  denotes the standard normal cumulative density function (CDF).

The linear component of the kernel in (6) results in a function that, after being warped by  $\Phi(\cdot)$ , is sigmoidal in the intensity dimension: after the slope is fixed (by conditioning on the first few points), the posterior belief about  $\Phi(f)$  will tend to 0 as the intensity decreases and 1 as the intensity increases. This reflects our prior knowledge that tones of extremely low intensity are unlikely to be heard, whereas tones of high intensity are more likely to be audible.

**Predictions.** Once we have collected data, we can use the predictive distribution  $p(y^* | \mathbf{X}, \mathbf{y}, \mathbf{x}^*)$  to summarize our belief about whether the patient will hear a test tone  $\mathbf{x}^*$ . As our likelihood is non-Gaussian, the posterior  $p(f^* | \mathbf{X}, \mathbf{y}, \mathbf{x}^*)$  has no closed form solution. However, an approximate Gaussian posterior over  $f^*$  can be obtained with the standard Laplace approximation to the likelihood (Kuss and Rasmussen, 2005; Rasmussen and Williams, 2006).

### 3.3 MULTIPLE TONES

An interesting property of audiometry (that may also be common to other psychophysical domains, *e.g.* visual or touch sensory tests), is that multiple tone stimuli can be presented to a patient simultaneously by overlaying tones. In this setting however, we can still only query whether the patient heard the overlaid tones. A negative response to a multi-tone sample indicates that the patient did not hear any of the overlaid tones; a positive response indicates that the patient heard *at least one* of them.

**OR-Channel.** Presenting a patient with  $k$  tones leads to a novel extension to the standard Bernoulli likelihood used in classification. We present the patient with  $k$  tones  $\mathbf{x}_1, \dots, \mathbf{x}_k$ . The patient hearing the individual tone  $\mathbf{x}_i$  is still the outcome of a Bernoulli trial with  $\Pr(y_i|f_i) = \Phi(f_i)$ , as the individual trials are independent *conditioned* on  $f$ . However, we cannot directly observe any individual  $y_i$ . Rather, we record them through an *OR-channel*, that is we observe  $\bar{y}$ , which is 1 if the patient hears *at least one* of the  $k$  tones presented, and is 0 otherwise. This leads to the *OR-channel likelihood*:

$$\begin{aligned} \Pr(\bar{y} = 1 | \mathbf{f}_{1..k}) &= 1 - \prod_j (1 - \Phi(f_j)) \\ &= 1 - \prod_j \Phi(-f_j) \end{aligned} \quad (7)$$

Note when  $k=1$ , eq. (7) reduces to the standard Bernoulli likelihood for single tones,  $\Pr(\bar{y} = 1 | f_1) = \Phi(f_1)$ .

### 3.4 QUERY SELECTION

In iteration  $t$  we present the subject with a query set of overlaid tones  $\mathbf{q}_t = [\{\mathbf{x}_1, \dots, \mathbf{x}_k\}]$  and query the response  $\bar{y}_t$ . To select  $\mathbf{q}_t$  we pick the point set that maximizes the expected decrease in posterior entropy, analogous to eq. (4).

**Single tone mutual information.** We first consider the setting of picking a single tone, *i.e.* where  $\mathbf{q}_t = [\{\mathbf{x}_t\}]$ . Houlshy et al. (2011) derive an analytical approximation to the mutual information, eq. (5), when using a Bernoulli likelihood. These results directly apply when picking a single tone  $\mathbf{x}_t$ . When  $f_t$  is known, the entropy of the Bernoulli variable  $y_t$  is given by  $h(\Phi(f_t))$ , where

$$h(p) = -p \log p - (1-p) \log(1-p),$$

is the Bernoulli entropy function. We can rephrase the entropy in eq. (4) as

$$I(\mathbf{f}, y_t | \mathbf{q}_t) = H[y_t | \mathbf{X}, \mathbf{y}] - \mathbb{E}[H[y_t | \mathbf{f}]]_{p(\mathbf{f} | \mathbf{X}, \mathbf{y})}, \quad (8)$$

and rewrite both terms on the right hand side through  $h$ . If  $\mathbf{f}$  is unknown and  $y_t$  is conditioned on  $\mathbf{X}, \mathbf{y}$ , the entropy can

be expressed in terms of the expectation over the posterior for  $f_t$ :

$$H[y_t | \mathbf{X}, \mathbf{y}] = h(\mathbb{E}[\Phi(f_t)]). \quad (9)$$

If  $f_t$  is known we have  $\Pr(y|\mathbf{f}) = \Phi(f_t)$ , yielding

$$H[y_t | \mathbf{f}] = h(\Phi(f_t)). \quad (10)$$

Substituting eqs. (9), (10) into (8) leads us to the following expression for the mutual information between  $\mathbf{f}$  and  $y_t$  in the single tone scenario:

$$I_1(\mathbf{f}, y_t | \mathbf{q}_t) = h(\mathbb{E}[\Phi(f_t)]) - \mathbb{E}[h(\Phi(f_t))]. \quad (11)$$

The computation of  $I_1$  involves an intractable integral, which can be approximated through numerical integration. This approach is very fast in practice as the integral is only one dimensional and can be computed efficiently using quadrature.

**Multiple tone mutual information** The above results can be extended to compute the mutual information when sampling multiple tones  $\mathbf{q}_t = [\{\mathbf{x}_1, \dots, \mathbf{x}_k\}]$ . In particular, the probability of observing  $\bar{y}_t = 1$  changes from  $\Phi(f_t)$  to the OR-channel probability, (7). Thus, when  $f_1, \dots, f_k$  are known, the entropy of the Bernoulli variable  $\bar{y}_t$  is  $h\left(1 - \prod_{i=1}^k \Phi(-f_i)\right)$ .

To simplify notation, let us define  $\bar{p}_1 = \Pr(\bar{y} = 1 | \mathbf{f}_{1..k})$  as defined in (7). Substituting  $\bar{p}_1$  for  $\Phi(f_t)$  in (11) gives the mutual information of paired tone sample  $\mathbf{q}_t$  after observing the outcome  $\bar{y}_t$ :

$$\begin{aligned} I_k(\mathbf{f}, \bar{y}_t | \mathbf{q}_t) &= h(\mathbb{E}[\bar{p}_1]) - \mathbb{E}[h(\bar{p}_1)] \\ &= h\left(\mathbb{E}\left[\prod_j \Phi(-f_j)\right]\right) - \mathbb{E}\left[h\left(\prod_j \Phi(-f_j)\right)\right] \end{aligned} \quad (12)$$

where the second equality holds by the linearity of expectation and because  $h(p)$  is a concave function that is symmetric about  $p=0.5$  (*i.e.*  $h(p) = 1 - h(p)$ ). The last term leads again to an intractable integral. However, similar to the one tone scenario,  $I_k$  can also be evaluated efficiently using numerical integration, as  $k$  is relatively small.

**Computational Considerations** Finding a set of  $k \leq K$  tones  $\mathbf{q}_t^{(k)}$  to maximize  $I_k(\mathbf{f}, \bar{y}_t | \mathbf{q}_t)$  from a candidate set  $\mathcal{X}$  of size  $S$  requires  $O\left(\binom{S}{k}\right)$  considerations. In order to ensure that patients do not have to wait for a lengthy duration between sounds are played, we construct a set of multiple tones to play greedily. We select the best single tone by exhaustively searching  $\mathcal{X}$ . Then, to select the best set of size  $k$ , we exhaustively add each  $\hat{\mathbf{x}} \in \mathcal{X}$  to the best set of size  $k-1$ ,  $\mathbf{q}_t^{(k-1)}$  and compute the expected decrease in posterior entropy of  $\mathbf{q}_t^{(k-1)} \cup \hat{\mathbf{x}}$ . This greedy selection procedure reduces the computational complexity of considering tone sets of up to size  $k$  to  $O(Sk)$ , and in practice requires only a few seconds of computation time.

Figure 1: Difference in mutual information  $I_2 - I_1$  between a paired query and a single query: **(a)** discrete distribution with two atoms  $(\alpha, \beta) = 0.05, 0.65$ , and corresponding  $\bar{\alpha} = 1 - (1 - \alpha)^2 \approx 0.1$ ,  $\bar{\beta} \approx 0.88$ ). Here  $I_2 - I_1 \approx 0.18$ ; **(b)**  $I_2 - I_1$  as a function of  $\alpha, \beta$  (white cross denotes the specific example of panel a); **(c)** the normally distributed latent input case.  $I_2 - I_1$  is shown as a function of the mean  $\mu$  and correlation  $\rho$ . Colorbar at right is for both panel b and c.

### 3.5 OR-CHANNEL ANALYSIS

We first investigate the OR-channel likelihood of eq. (7), as it is unclear if this elaboration can provide any benefit over a standard Bernoulli likelihood. Intuitively, the result of  $\bar{y} = 0$  from an OR-channel is quite informative: all inputs into that channel must have been 0 (in the auditory example, no sounds were heard). On the other hand, the result of  $\bar{y} = 1$  is much less informative than in the Bernoulli channel, as it means only that one or more of the inputs were 1 (some sound or sounds were heard), but there is no information about which. Here we analyze simple models that support the use of the OR-channel likelihood. We compare a *single* input, corresponding to the standard Bernoulli likelihood, to a *paired* input, corresponding to an OR-channel likelihood with two inputs. That is, with inputs  $\{f_1, f_2\}$  and output  $y \in \{0, 1\}$  as above, our quantities of interest are  $I_1 := I(y, f_1)$  and  $I_2 := I(y, \{f_1, f_2\})$ , and we seek to understand if more information about the inputs can exist in the paired-input query, than in the single-input query.

#### 3.5.1 OR-channel Inputs With Discrete Support

The simplest case involves perfectly correlated inputs  $f_1 = f_2$ , and further, a discrete distribution on  $f_1$  with two atoms of equal mass. The implied probability  $\phi(f_1)$  will then have the same discrete distribution, which we write as  $p(\phi(f_1)) = \frac{1}{2}\delta(\phi(f_1) = \alpha) + \frac{1}{2}\delta(\phi(f_1) = \beta)$ , for some atoms  $\alpha$  and  $\beta$ . Then, the mutual information of the single query is:

$$\begin{aligned} I_1 &= H(y) - H(y|f_1) \\ &= h(\mathbb{E}_f[\phi(f_1)]) - \mathbb{E}_f[h(\phi(f_1))] \\ &= h\left(\frac{1}{2}(\alpha + \beta)\right) - \frac{1}{2}(h(\alpha) + h(\beta)), \end{aligned} \quad (13)$$

where  $\mathbb{E}_f$  is the expectation under the distribution on  $f$ . The OR-channel likelihood for two terms is similarly

$p(y = 1|\{f_1, f_2\}) = 1 - (1 - \phi(f_1))(1 - \phi(f_2)) = 1 - (1 - \phi(f_1))^2$ . The mutual information of a paired-input query becomes

$$I_2 = h\left(\frac{1}{2}(\bar{\alpha} + \bar{\beta})\right) - \frac{1}{2}(h(\bar{\alpha}) + h(\bar{\beta})), \quad (14)$$

where  $\bar{\alpha} = 1 - (1 - \alpha)^2$  and  $\bar{\beta} = 1 - (1 - \beta)^2$ .  $I_2$  and  $I_1$  offer a convenient geometric interpretation by viewing mutual information as the Jensen's inequality gap of  $h$  (eqs. (13) and (14)). With this simple discrete distribution,  $\alpha$  and  $\beta$  can be chosen such that  $I_2 - I_1$  will be positive or negative. We show the critical case  $I_2 > I_1$  in Figure 1a, where the blue line segment connects  $(\alpha, h(\alpha))$  to  $(\beta, h(\beta))$  with  $(\alpha, \beta) = (0.05, 0.65)$ , and the red line segment is then implied by those choices of  $\alpha, \beta$  (that is,  $(\bar{\alpha}, \bar{\beta}) \approx (0.10, 0.88)$  in the figure). Here the difference is  $I_2 - I_1 = 0.18$  bits. The contours of  $I_2 - I_1$  as a function of  $(\alpha, \beta)$  is shown in Figure 1b.

#### 3.5.2 OR-channel Inputs With Normal Densities

We next analyze the OR-channel likelihood with two latent factors  $f_1 = f(x_1)$  and  $f_2 = f(x_2)$ , which are jointly Gaussian according to the GP model of Section 3:  $[f_1, f_2] \sim \mathcal{N}(m, S)$ . We calculate  $I_2 - I_1$  numerically using eq. (11) (note that, compared to the previous example, only the expectation over  $f$  has changed). We simplify the parameter space with  $m = \begin{bmatrix} \mu \\ \mu \end{bmatrix}$  and  $S = \begin{bmatrix} 1 & \rho \\ \rho & 1 \end{bmatrix}$  (but note that the function  $I_2 - I_1$  is not invariant to either of these simplifications). We plot the contours of  $I_2 - I_1$  as a function of correlation  $\rho$  and mean  $\mu$  in Figure 1c, which indeed has substantial regions of both positive and negative mass.

In summary, though intuitively non-obvious, the above analyses clarify that the OR-channel likelihood can, but need not, increase mutual information between the input distribution and the binary outcome  $y$ . This finding offers a

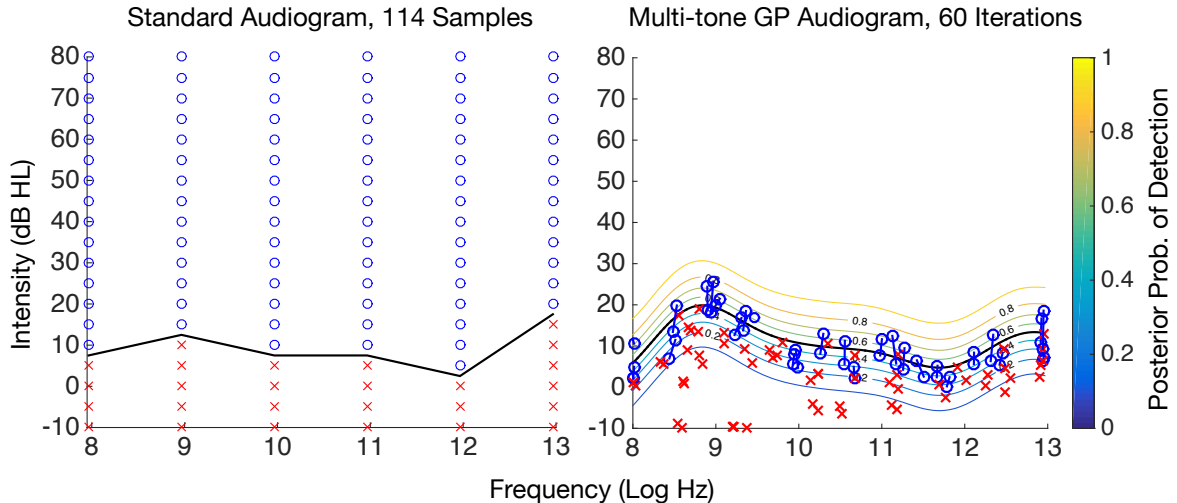

Figure 2: Standard grid search audiogram with tones played at every octave from 250 to 8000 Hz, and every 5 dB HL from -10 dB to 80 dB, compared to a multi-tone GP audiogram with 60 iterations (and therefore 119 “samples”).

critical takeaway: the OR-channel can be used effectively, but only in the setting where a judicious choice of input distribution can be made. Indeed, this is exactly what our framework will achieve: it will choose pairs of input points (paired sounds) to learn more about the underlying audiogram than a single point alone. Thus, the OR-channel likelihood offers benefit beyond this scheme, which we already expect to outperform a naive approach to learning these latent functions. In this work we only consider paired inputs; a future question for study is how the information gain distribution changes with increasing numbers of inputs.

## 4 RELATED WORK

A number of papers have been recently published on Bayesian active learning. Many papers have considered Bayesian active learning using mutual information in the regression setting (Guestrin et al., 2005; Krause and Guestrin, 2007; Srinivas et al., 2009). However, the computation of mutual information is significantly less tractable in the classification setting. To our knowledge, Housby et al. (2011) is the first paper to leverage the rewriting of mutual information in (12), allowing for tractable computation of mutual information with the Bernoulli observation model. This paper is most similar to ours, as the Bernoulli observation model is identical to our single tone audiometric algorithm. A number of other, orthogonal applications and extensions of this method have since been published (Garnett et al., 2013; Iwata et al., 2013).

Alternative techniques for estimating audiograms have existed for many years. Sweep-based audiometry, such as Bekesy audiometry and Audioscan, are able to produce a more continuous estimate of the audiogram that can often detect notches, but with the disadvantage of a partic-

ularly time- and attention-demanding task (Jerger, 1960; Meyer-Bisch, 1996). Several Bayesian audiogram estimation techniques, such as parameter estimation by sequential testing (PEST) and maximum likelihood methods also exist, although most do not simultaneously estimate multiple frequencies (Green, 1993; Leek et al., 2000; Özdamar et al., 1990; Pentland, 1980; Taylor and Creelman, 1967). More recent advances in audiometric testing have focused on improving the accessibility of hearing screening by distribution over telephone, Internet, or mobile devices (Smits et al., 2004; Swanepoel et al., 2014; Vlaming et al., 2014; Watson et al., 2012; Williams-Sanchez et al., 2014).

## 5 RESULTS

In this section, we empirically evaluate our proposed algorithms for psychophysical detection. We focus on our application to audiometry, and seek to evaluate the merits of using Gaussian processes for audiometry in general, as well as to compare single-tone and multi-tone audiometry, focusing on the machine learning aspects of our algorithms.

We have since published a small clinical trial in a medical journal evaluating the novel GP audiometric techniques discussed here from a clinical point of view as well, and refer readers to Song et al. (2015) for additional results comparing GP audiometry and standard audiometry.

To begin, we compare the audiograms found by a standard grid audiometric test and by our multi-tone GP model. In both cases we run the same human subject in the same audiometric setting. The only differences are the tones presented and the method used to infer the audiometric function. All audiometric tests were run in accordance with an approved IRB. In the standard setting, tones from this

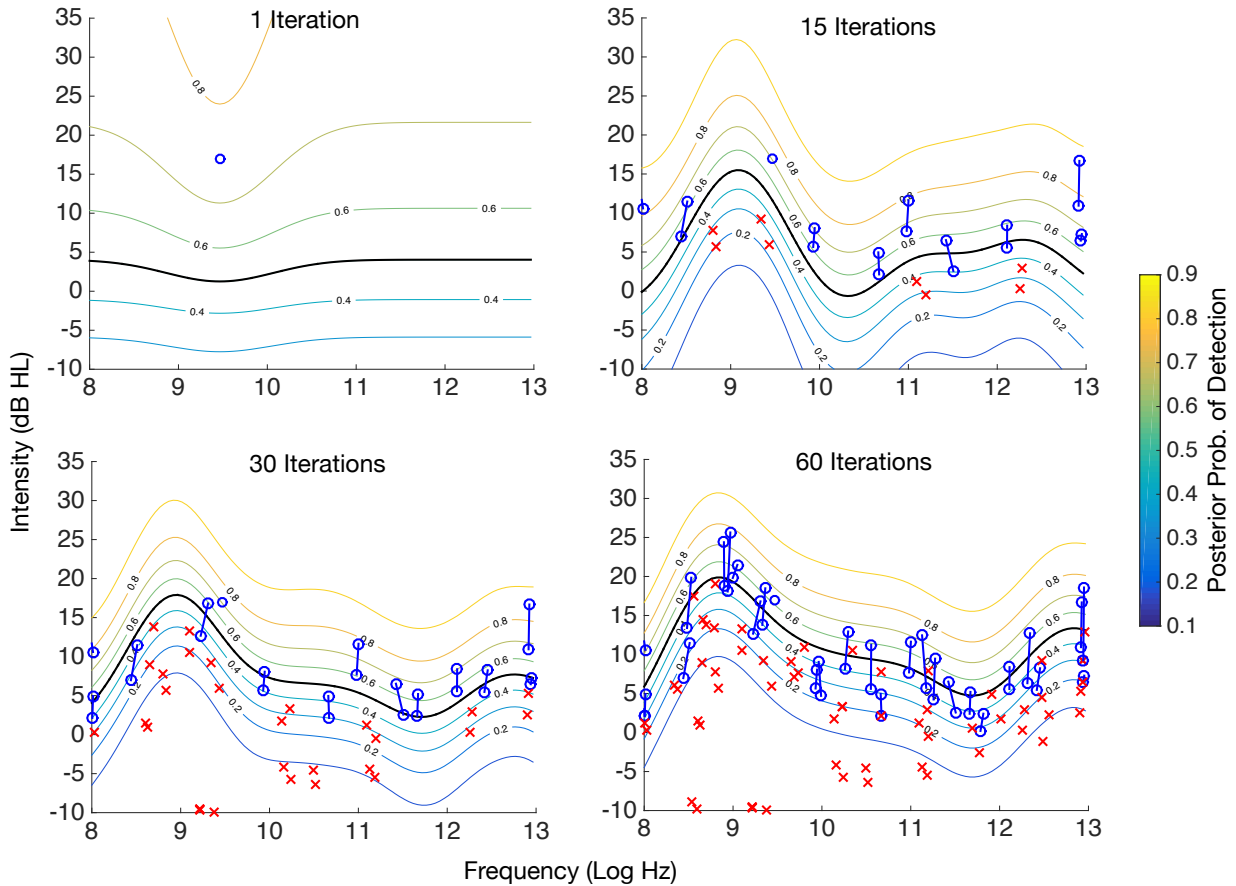

Figure 3: The posterior probability of detection within the frequency / intensity space during a GP audiometric test on a human subject. Panels show the learned GP after 1, 15, 30, and 60 iterations. Queries consist of a single or a paired tone (as selected by the model). Blue circles indicate a positive outcome (sound was heard), red crosses indicate a negative outcome. Paired tones with positive outcome (at least one of the two tones was heard) are connected by a blue line. Almost all queries are close to the final audible threshold (0.5 posterior detection probability), which is well approximated even after only 15 iterations.

grid are presented in a pre-determined order, typically ascending in frequency and decreasing in intensity. In the GP model, pairs of tones were actively selected given all previous pairs of tones and the responses to those tones. A random delay of up to 3 seconds was inserted between tone presentations to prevent subjects from memorizing a pattern in the test. Figure 2 shows the resulting data and inferred audiograms plotted in frequency-intensity space (left panel: standard audiometric test; right panel: GP method).

For both the standard and GP experiments, tones that were detected by the patient are plotted as blue circles, and tones that were not detected are plotted as red crosses. For the paired-tone GP test (right panel), paired samples that were detected are plotted as blue circles connected by a blue line (recall that, due to the OR-channel likelihood, we do not know which tone was heard). Paired tones that were not detected are again plotted as individual red crosses, as these data are functionally equivalent to two single-tone samples

that were not detected (again due to the OR-channel observation model).

In the standard audiometric test, the inferred audiogram is simply an “audible threshold” that is the piecewise linear function connecting the detection threshold at each frequency. This threshold is depicted as a black line in the left panel of Figure 2. In the GP case, we infer a full posterior distribution on the detection threshold. We plot contours of the posterior detection probability in Figure 2, with a solid black line at 50% posterior detection probability.

This confirmatory comparison offers several key points of interpretation. First, the tests agree with each other: the 50% posterior detection probability in the GP case is within 5dB of the standard audiogram, giving confidence to the general sensibility of this model. Second, perhaps most importantly to the active learning goal, the GP active learning

(a) A GP trained on 100 single tones. Blue circles denote tones detected by the subject, and red crosses denote tones that were not detected. The posterior probabilities are shown as color contours.

(b) Log likelihood of random presentation of tones (no active learning, shown in gray), active learning presentation of single tones (shown in blue), and active learning with paired tones (shown in red), under the ground truth audiometric function from Figure 4a. Log likelihood is plotted as a function of iterations in each audiometric testing strategy. Shaded areas denote standard error.

Figure 4: Comparison of multi-tone and single-tone GP audiometrics

model presents approximately half as many iterations (60 actively learned paired tones compared to 114 single tones preselected from a grid). Thus the GP model is able to explore substantially more of the frequency space than the standard grid test, and it does so in many fewer overall iterations, reducing the burden of these tests. Third, note that the GP model does not explore uninformative regions of tone space: above a certain intensity (at which the model is confident that tones are certainly heard), there are no tones queried. This observation differs sharply from the standard test, which squanders numerous samples at intensities well above this subject’s audible threshold, where little to no information is available. Fourth, by design our GP model offers a full posterior distribution over tone space, and thus produces a richer and more descriptive audiogram than the piecewise linear audible threshold function in the standard test. Finally, it is worth noting that, though the paired tones in the right panel of Figure 2 appear to be sampled at very similar frequencies in log-space, the differences were often nontrivial, up to four or five half steps in an octave.

Next, Figure 3 investigates the convergence of our GP model after 1, 15, 30, 60 iterations of our paired-tone GP audiometric algorithm. The posterior after a single iteration (upper left panel) reflects primarily the prior mean and the covariance of the model, which incorporates our knowledge about the general shape of human audiograms. As the active learning procedure continues (other panels), the GP posterior quickly converges to the audiogram of this particular subject. After only 30 iterations, the GP model

has already captured the audiogram shape, and subsequent changes are very minor.

To investigate the performance of our GP active learning method in greater detail, we construct a synthetic data set with known ground truth (a known audiometric function). We begin by training a GP on 100 single tones and the detection of those tones reported by a second human subject. The tones sampled and the inferred audiogram are presented in Figure 4a. We use this posterior GP as the true audiogram of a simulated subject.

This ground truth audiometric function allows for the critical assessment of performance shown in Figure 4b. We compare three strategies of data presentation: random presentation of tones (no active learning, shown in gray), active learning presentation of single tones (shown in blue), and active learning with paired tones (shown in red). For each strategy, at each iteration (tone presentation), we infer the GP posterior mean, which is the MAP estimate of the audiometric function, given each stream of data. We evaluate the log likelihood of each strategy’s GP posterior mean under the ground truth GP from Figure 4a. This step offers a quantitative assessment of how closely each strategy has approximated the true audiometric function. The maroon dashed line depicts the log likelihood of the ground truth GP itself, which is thus the maximum achievable performance of any strategy. All three strategies (random, single tone active learning, paired tone active learning) should, with enough iterations, converge to ground truth. Thus, the essential question of this work, and indeed of any active

learning method, is how much more quickly a particular strategy approaches the ground truth than competing strategies.

We ran the single and paired tone active learning methods ten times each, and standard errors are plotted as shaded regions. Because of the very high standard error of the random tone audiogram, these results were averaged over 100 runs.

Figure 4b has a few key findings. Both the single and paired tone active learning strategies significantly outperform random sampling. Thus our strong prior rapidly learns that large portions of the tone space are either very likely or very unlikely to be heard, and is able to quickly learn to sample in regions of high information. After 80-90 iterations the paired tone algorithm matches the ground truth model very closely. This result is in significant contrast to randomly choosing tones, which not only has very large standard error, but also rarely converges to a good model. Finally, we observe that the paired tone active learning strategy significantly outperforms the single tone strategy. In fact, the paired tone strategy requires only half as many iterations to achieve the same level of likelihood. Compared to random sampling, paired tone active learning reduces the number of iterations by 85%.

## 6 DISCUSSION

In this paper, we explored the problem of adapting Bayesian active learning to psychophysical testing, and improving upon standard techniques used in audiometric testing. In the process of our investigation, we developed a novel OR-channel likelihood that allows us to present multiple tones to a subject simultaneously, leading to an audiometric testing strategy that not only yields good audiogram estimation using significantly fewer samples, but also leads to much better coverage of the frequency dimension. We demonstrate a non-obvious result, that multiple tones played through an OR-channel can, but do not have to, yield more information than a single tone. As future work we will continue to investigate the theoretical properties of this likelihood function and its use in active learning. We also hope that the drastic improvements of our method over the state-of-the-art will convince experts in medicine and psychology to adapt machine learned approaches for psychophysical testing.

## Abstract

Conditioned Belief Propagation (CBP) is an algorithm for approximate inference in probabilistic graphical models. It works by conditioning on a subset of variables and solving the remainder using loopy Belief Propagation. Unfortunately, CBP’s runtime scales exponentially in the number of conditioned variables. Locally Conditioned Belief Propagation (LCBP) approximates the results of CBP by treating conditions locally, and in this way avoids the exponential blow-up. We formulate LCBP as a variational optimization problem and derive a set of update equations that can be used to solve it. We show empirically that LCBP delivers results that are close to those obtained from CBP, while the computational cost scales favorably with problem size.

## 1 INTRODUCTION

Modern SAT solvers are capable of solving problem instances with hundreds of thousands of variables (Katebi et al., 2011), despite the fact that SAT is an NP-hard problem. Most of today’s practical solvers are CDCL (conflict-driven, clause-learning) solvers (Marques-Silva et al., 2009). Their main algorithmic components are branching, unit propagation, and clause learning (Katebi et al., 2011). Generalizing these concepts, we could talk of branching as analysis by cases, unit propagation as inference within a single case (both already found in the classic DPLL algorithm (Davis et al., 1962)), and clause learning (Silva and Sakallah, 1996) as reusing inference results across cases.

The #P-hard (Roth, 1996) problem of computing marginal probabilities (or the partition function) in discrete-valued graphical models is closely related to #SAT—the task of counting the models of a propositional formula. Probabilistic inference generalizes the boolean conjunction of

clauses to a product over local real-valued functions. The #SAT problem is usually tackled using modified CDCL solvers (Bayardo Jr and Pehoushek, 2000; Sang et al., 2004; Huang and Darwiche, 2005). Both for probabilistic inference and #SAT, it is not enough to find one satisfying case, but one has to take into consideration all cases. But while SAT problems are usually sparse, probabilistic problems can often be strictly positive. It is thus not very surprising that the basic probabilistic inference algorithms do not employ analysis by cases, but rely on inference by propagation only: Variable elimination (Koller and Friedman, 2009, Chapter 9), the Junction tree method (Shenoy and Shafer, 1990), loopy Belief Propagation (Pearl, 1986), and more generally the class of algorithms with variational interpretations (Wainwright and Jordan, 2008) can be counted towards this class.

But there are also algorithms that complement propagation with an analysis by cases, such as the exact Recursive Conditioning (Darwiche, 2001) and Value Elimination (Bacchus et al., 2002). Also there exist approximate instances: Cutset Sampling (Bidyuk and Dechter, 2007), SampleSearch (Gogate and Dechter, 2011), Conditioned Belief Propagation (Eaton and Ghahramani, 2009) and collapsed sampling algorithms in general, just to name a few. These approaches appear to have an advantage when the problem encodes a distribution that is not strictly positive, i.e., factors can evaluate to zero (we call these factors deterministic dependencies). Under the presence of deterministic dependencies, analysis by cases is able to reveal context-specific independencies, and prune the search space without incurring an approximation error.

The third algorithmic component in SAT solvers is reusing results across cases. Notably both named exact algorithms heavily rely on this concept under the name of caching. Of the named approximate inference algorithms that employ analysis by cases, only the importance sampler SampleSearch shares work across cases, and only for deterministic dependencies, by using no-good learning (Dechter, 1990). Conditioned Belief Propagation (CBP) (Eaton and Ghahramani, 2009; Geier et al., 2014a) is the straight-

Figure 1: Iterative CBP (Geier et al., 2014a) is a divide-and-conquer algorithm that splits the problem by recursive conditioning. The state of the algorithm is defined by a tree, where edges represent assignments to variables, and nodes represent the partial assignment defined by their path from the root (or the sub-problem obtained by conditioning on this assignment). In each iteration a leaf node (case, context) is chosen and further refined by splitting on an unassigned variable. An approximation to the partition function is obtained by summing the partition function estimates found by BP on each leaf. Marginal probabilities can be obtained by forming a convex combination of the corresponding estimates for the leaves, using their estimated partition functions as weights.

forward combination of systematic analysis by cases (conditioning) with loopy Belief Propagation (BP) as approximate inference within each case. It works by recursively splitting on the assignments to single variables, producing an unbalanced and dynamically ordered tree in the process (Figure 1). This appears to be a fertile combination, as BP yields good results in weakly coupled (high entropy) models and suffers under the presence of strong dependencies (Montanari and Rizzo, 2005; Mooij and Kappen, 2007). Contrarily, conditioning provides benefits for low entropy models with strong dependencies, but fails when the probability mass is spread out evenly over a large number of similar conditions. As shown empirically by Geier et al. (2014b), CBP is indeed able to deliver good improvements over plain BP in particular for low entropy distributions (Figure 2). But the same work also highlights one major shortcoming of CBP: To sustain the same proportional improvement, the number of cases CBP has to evaluate increases exponentially with problem size (Figure 2).

In this essay we describe a method to improve the CBP algorithm in such a way that work between cases is shared approximately—thus adding the third algorithmic component found in modern SAT solvers. The basic idea focuses on the observation that the influence of conditioning on variables usually diminishes with graphical distance. We underpin this assumption empirically by visualizing the effect of conditioning a single variable in randomly generated grid problems in Figure 3. We exploit this “locality of ef-

Figure 2: The plots show the typical behavior of iterative CBP on random binary-valued  $8 \times 8$  grid problems (Geier et al., 2014b). The left plot shows the relative error in  $\ln Z$  (median over 500 problems, factor values sampled from  $\exp(\mathcal{N}(0, \sigma))$  with  $\sigma = 1$ ), which *improves only logarithmically* with the number of distinguished cases (Iterations). The right plot shows the CBP error after 64 iterations as a fraction of the BP error for problems with varying strength of interaction (higher  $\sigma$  corresponds to stronger interactions,  $\sigma = 0$  excluded, median over 250 problems). The approximation error of CBP compared to the error of BP consistently decreases with stronger dependencies.

fect” assumption in the proposed *Locally Conditioned Belief Propagation* (LCBP) model. LCBP conceptually works by merging nodes of the BP graph between different cases of CBP, thus effectively sharing message values. An intuition of the difference between CBP and LCBP is conveyed by Figure 4.

## 2 PRELIMINARIES

We focus on undirected graphical models over  $n$  random variables  $X_1, X_2, \dots, X_n$ , referring to the set of all variables as  $\mathcal{X}$ . Each variable  $X_i \in \mathcal{X}$  may assume values out of its finite domain  $\text{Dom}(X_i)$ . A problem is given by a finite set  $\Phi$  of non-negative local functions (factors). Each function  $\phi_a \in \Phi$  is defined over the valuations  $\text{Val}(\mathbf{X}_a)$  (assignments of values to variables) for a subset  $\mathbf{X}_a \subseteq \mathcal{X}$  of variables. The (unnormalized) product over all factors is  $\tilde{p}(x) = \prod_a \phi_a(x_a)$ , and it implies a proper distribution by

$$p(x) = \frac{1}{Z} \tilde{p}(x) \text{ with } Z = \sum_x \tilde{p}(x). \quad (1)$$

The normalizing constant  $Z$  is called the *partition function*.

### 2.1 BELIEF PROPAGATION AS OPTIMIZATION

Given a factorized distribution  $p$ , the basic problem of probabilistic inference is to compute some property of it. These properties are usually expectations, marginal probabilities, the partition function, or most probable

Figure 3: Comparison between two runs of BP on a  $16 \times 16$  grid problem of binary-valued variables. The color encodes the difference of the marginal probabilities after conditioning the variable in the lower left (median over 100 random instances). Factor values are drawn from an exponentiated normal distribution  $\exp(\mathcal{N}(0, \sigma))$  with standard deviation  $\sigma \in \{0.1, 0.5, 1\}$ . Gray means the difference is lower than numerical accuracy. One can see that the effect of the conditioning is local to the conditioned variable. The range of the effect increases with stronger potentials.

assignments—and their exact computation is often intractable (Roth, 1996). Variational inference (Wainwright and Jordan, 2008) is a form of approximate inference that works by substituting  $p$  by some element  $q$  from a class of (pseudo-) distributions  $\mathcal{Q}$ , on the members of which inference is tractable. The instance  $q$  is chosen to be as close to  $p$  as possible. The notion of closeness is captured by some distance measure, which is often taken to be the Kullback-Leibler divergence—though other measures are possible (Minka, 2005).

From the KL-divergence between  $q$  and  $p$  one can obtain

$$\ln Z = \mathbb{E}_q[\ln \tilde{p}] + \mathbb{H}(q) + \text{KL}(q \parallel p). \quad (2)$$

Here,  $\mathbb{H}(q)$  denotes the entropy of  $q$ , and  $\mathbb{E}_q[f(x)]$  denotes the expectation of  $f(x)$  taken with respect to the measure  $q$ . From Equation 2 we identify the functional  $F(q)$ , known as the negative free energy:

$$F(q) = \mathbb{E}_q[\ln \tilde{p}] + \mathbb{H}(q) \quad (3)$$

It yields the exact log-partition function if  $q = p$ , and can serve as a lower bound to  $Z$  if the class  $\mathcal{Q}$  contains only valid distributions. The task in variational inference is to find a  $q^*$  that maximizes  $F$ . In general, either because there exists no exact representation of  $p$  in  $\mathcal{Q}$ , because the class  $\mathcal{Q}$  also contains non-distribution functions, or because we cannot solve the optimization problem perfectly, the found value of  $F(q)$  can only serve as an approximation for  $\ln Z$ . In addition, for many interesting classes  $\mathcal{Q}$ , the functional cannot be given in closed form and one has to resort to further approximations.

We briefly summarize how to express the BP algorithm as

Figure 4: The upper row represents how CBP works by making full copies of the problem for each case. The lower row shows how LCBP only makes copies of the nodes that are local to the conditioned variable.

a variational optimization problem. A more detailed exposition can be found in Yedidia et al. (2005) and Koller and Friedman (2009, Chapter 11). For deriving the BP message update equations using the variational approach, members  $q$  of class  $\mathcal{Q}_{\text{BP}}$  are defined by marginal distributions  $q_i(X_i)$  over the variables (called variable beliefs), and marginal distributions  $q_a(\mathbf{X}_a)$  over the factors in  $\Phi$  (called factor beliefs):

$$q(x) = \prod_a q_a(x_a) \prod_i q_i(x_i)^{(1-d_i)} \quad (4)$$

Here,  $d_i = |\{\phi_a \in \Phi \mid X_i \in \mathbf{X}_a\}|$  represents the number of factors that depend on variable  $X_i$ . In addition to being proper probability measures (sum to one, non-negative), the variable and factor beliefs have to be consistent with respect to their marginal probabilities. This is formalized by requiring for all factors  $\phi_a$ , adjacent variables  $X_i \in \mathbf{X}_a$ , and values  $x_i \in \text{Val}(X_i)$ :

$$\sum_{x_a \models x_i} q_a(x_a) = q_i(x_i) \quad (5)$$

Note that we write  $x_a \models x_i$  for all the (partial) assignment  $x_a \in \text{Val}(\mathbf{X}_a)$  that are an extension of  $x_i$ . A further ingredient in the variational derivation of standard BP exists in an approximation to the entropy, known as the Bethe-Peierls (also BP) approximation and given by

$$\mathbb{H}_{\text{BP}}(q) = \sum_a \mathbb{H}(q_a) + \sum_i (1 - d_i) \mathbb{H}(q_i). \quad (6)$$

A justification for  $\mathbb{H}_{\text{BP}}$  is usually given by the fact that it is exact for tree-structured problems. The BP approximation together with the assumption that the functions  $q_a$  resemble marginal distributions of  $q$  over the variables in  $\mathbf{X}_a$  yields the functional

$$F_{\text{BP}}(q) = \sum_a \mathbb{E}_{q_a}[\ln \phi_a] + \mathbb{H}_{\text{BP}}(q). \quad (7)$$

Optimizing  $F_{\text{BP}}(q)$  under the given constraints using the method of Lagrange multipliers yields the update equations

of the BP algorithm. Loosely speaking, the Lagrange multipliers assume the role of messages between variables and factors ( $m_{i \rightarrow a}(x_i)$  and  $m_{a \rightarrow i}(x_i)$ ), each encoding a distribution over the respective variable  $X_i$ . With abuse of notation, writing  $i \in \mathbf{X}_a$  instead of  $X_i \in \mathbf{X}_a$ , the update equations are

$$m_{i \rightarrow a}(x_i) \propto \prod_{b: i \in \mathbf{X}_b, b \neq a} m_{b \rightarrow i}(x_i), \quad (8)$$

$$m_{a \rightarrow i}(x_i) \propto \sum_{x_a \models x_i} \phi_a(x_a) \prod_{j \in \mathbf{X}_a, j \neq i} m_{j \rightarrow a}(x_j). \quad (9)$$

The BP algorithm recomputes the message values according to those equations until convergence (which is not guaranteed). The variable beliefs can then be computed by  $b_i(x_i) = \prod_{a: i \in \mathbf{X}_a} m_{a \rightarrow i}(x_i)$ , and factor beliefs are given by  $b_a(x_a) = \phi_a(x_a) \prod_{i \in \mathbf{X}_a} m_{i \rightarrow a}(x_i)$ .

### 3 VARIATIONAL CBP

Before introducing the LCBP model, we want to interpret CBP in a variational way as a mixture model. For this we reduce the iterative CBP algorithm (Figure 1) to the BP inference on the induced partitioning into cases (the leafs of the tree), and ignore the way in which the partition was obtained. We call this non-iterative interpretation *variational CBP*, and use the term *iterative CBP* when we want to emphasize the recursive conditioning aspect. In variational CBP, we are given a set of partial assignments/conditions  $C$  whose extensions partition the set of all assignments  $\text{Val}(\mathcal{X})$ . The set  $C$  corresponds to the leafs of a tree produced when running iterative CBP. A member  $q$  of class  $\mathcal{Q}_{\text{CBP}}$  is then defined by

$$q(x) = \sum_{c \in C} q_C(c) \prod_a q_a^c(x_a) \prod_i q_i^c(x_i)^{1-d_i}. \quad (10)$$

It can be interpreted as a mixture of BP approximations, where  $q_C(c)$  encodes the mixture weight. The necessary constraints are the BP constraints for each set of beliefs  $q_a^c, q_i^c$ . The weight vector  $q_C : C \rightarrow [0, 1]$  is required to be a proper distribution (non-negative, sum to one). And in addition to the BP constraints, we require  $q_i^c(x_i) = 1$  for  $c \models x_i$  to enforce the conditions within the mixture components. As a result of this constraint, the mixture components have mutually exclusive support. By defining an appropriate energy functional, and solving the variational problem for  $\mathcal{Q}_{\text{CBP}}$ , one finds that a solution can be found by solving the BP variational problem for each mixture component independently.

The computational cost of CBP is about linear in the number of conditions, as each condition implies one run of the BP algorithm. Let us assume that the number of conditioned variables has to attain a certain ratio of the total number of variables for CBP to be able to produce a good approximation. This implies that the number of distinguished

conditions  $|C|$  (and thus inference cost) grows exponentially with problem size when sustaining good approximation quality.

## 4 LCBP

LCBP is designed with the goal that its computational cost scales sub-exponentially in the number of (fully) conditioned variables. This means, we want to approximate variational CBP for an exponentially large set  $C$ , and have the computational cost scaling only polynomially with  $\ln |C|$ . To achieve this we have to overcome two obstacles. The first one is getting rid of the exponential number of parameters  $q_a^c, q_i^c$  present in the variational CBP approximation. Under the assumptions that BP messages do not differ much when far away from a disturbance (Figure 3), we can substitute some  $q_a^{c_1}$  by  $q_a^{c_2}$  in equation 10 given that factor  $\phi_a$  is far enough from all variables where conditions  $c_1$  and  $c_2$  differ. The second problem is representing the weight distribution  $q_C$ . As we will observe in the sequel, this problem will be solved by representing  $q_C$  in factored form, necessitating probabilistic inference over the condition variables.

### 4.1 CONDITIONING SCHEME

To formalize which local functions  $q_a^c, q_i^c$  can be shared between conditions, we introduce a concept termed *conditioning scheme*. We focus on a particular form of conditioning scheme that we call factored, local scheme (FL-scheme). FL-schemes are not powerful enough to capture all aspects of iterative CBP, i.e., they emulate only balanced and statically ordered search trees. But their simple structure allows a formal derivation of the LCBP algorithm, while they are expressive enough to capture the essential improvement LCBP offers over CBP. For a discussion on lifting the restrictions implied by FL-schemes see Section 6.1.

An FL-scheme  $\mathcal{S} : \mathcal{X} \rightarrow 2^{\mathcal{X}}$  assigns a set of conditioning variables (conditioners) to each variable in  $\mathcal{X}$ . The idea is that, locally at a variable  $X_i$ , we have a copy of the BP messages and beliefs for each assignment to the conditioners  $\mathcal{S}(X_i)$  of  $X_i$ . We use the notations  $S_i = \mathcal{S}(X_i)$  and  $S_a = \bigcup_{i \in \mathbf{X}_a} \mathcal{S}(X_i)$  for the set of variable conditioners and factor conditioners respectively. We write  $C = \bigcup_{X_i \in \mathcal{X}} \mathcal{S}(X_i)$  for the set of all conditioners. Given some variable  $X_c$ , we call the set  $\{X_i \mid X_c \in S_i\}$  the area of influence of conditioner  $X_c$  or the set of  $X_c$ 's conditionees. For the lower right example in Figure 4, we have  $C = \{X\}$ . The three variables around  $X$ , and  $X$  itself are the conditionees of  $X$ . They have only  $X$  as their conditioner, and thus are replicated for each possible value of  $X$  (0 and 1). The variable at the left-most corner is not conditioned, and thus has an empty set assigned by the scheme. Note that an FL-scheme only tells how to split variables and the associated variable

beliefs. Factor beliefs are split by assignments to the union of the conditioners of the variables in their scope  $S_a$ . They are thus always split in a more fine-grained way than the adjacent variables.

## 4.2 APPROXIMATING CLASS $\mathcal{Q}_{\text{LCBP}}$

Given an FL-scheme  $\mathcal{S}$  for a problem  $\Phi$ , we define a pseudo distribution  $q$  from class  $\mathcal{Q}_{\text{LCBP}}$ . The parameters are the variable beliefs  $q_i^{c_i}$  and factor beliefs  $q_a^{c_a}$  known from BP, but now each in multiple versions for each local variable condition  $c_i \in \text{Val}(S_i)$  or local factor condition  $c_a \in \text{Val}(S_a)$ . In addition we require a normalized probability measure  $q_C : \text{Val}(C) \rightarrow [0, 1]$  over all possible conditions. Until the end of this section we assume that  $q_C$  is represented as a flat (unstructured) function. Writing  $x[A]$  for restricting the assignment  $x \in \text{Val}(\mathcal{X})$  to the variables in  $A \subseteq \mathcal{X}$ , we define one mixture component  $q^c$  as

$$q^c(x) = \prod_a q_a^{c[S_a]}(x_a) \prod_i \left( q_i^{c[S_i]}(x_i) \right)^{1-d_i}. \quad (11)$$

We define the pseudo distribution for the LCBP model as

$$q(x) = \sum_{c \in \text{Val}(C)} q_C(c) q^c(x). \quad (12)$$

To enforce that  $q$  is close to a probabilistic measure, we formulate a set of constraints on its parameters. Non-negativity constraints are assumed implicitly.

The normalization of the conditioning distribution:

$$\sum_c q_C(c) = 1 \quad (13)$$

The normalization of factor beliefs for all  $\phi_a \in \Phi, c_a \in \text{Val}(S_a)$ :

$$\sum_{x_a} q_a^{c_a}(x_a) = 1 \quad (14)$$

The normalization of variable beliefs for all  $X_i \in \mathcal{X}, c_i \in \text{Val}(S_i)$ :

$$\sum_{x_i} q_i^{c_i}(x_i) = 1 \quad (15)$$

The marginal consistency constraints for all  $\phi_a \in \Phi, X_i \in \mathbf{X}_a, c_i \in \text{Val}(S_i), x_i \in \text{Val}(X_i)$ :

$$\sum_{c_a \models c_i} q_C(c_a | c_i) \sum_{x_a \models x_i} q_a^{c_a}(x_a) = q_i^{c_i}(x_i) \quad (16)$$

We enforce the condition for all  $X_i \in C, c_i \in \text{Val}(S_i)$ :

$$q_i^{c_i}(x_i) = 1 \quad (17)$$

Equation 16 is the LCBP version of the marginal consistency constraints of the BP approximation. It formalizes the way in which beliefs are merged between conditions by taking the expectation with respect to the distribution over conditions  $q_C$ .

## 4.3 FREE ENERGY APPROXIMATION

We are now going to derive a set of fixed-point equations that can be used to implement a message passing algorithm. By partitioning the set of variables into conditioners and the rest  $\bar{C} = \mathcal{X} \setminus C$ , applying the identity  $\mathbb{H}(C, \bar{C}) = \mathbb{H}(C) + \mathbb{H}(\bar{C}|C)$  for the conditioned entropy, and using the Bethe-Peierls approximation (6), we obtain

$$\mathbb{H}_{\text{LCBP}}(q) = \mathbb{H}(q_C) + \mathbb{E}_{q_C}[\mathbb{H}_{\text{BP}}(q^c)]. \quad (18)$$

Under the assumption that the conditioned factor beliefs  $q_a^{c_a}$  are truly the marginals of  $q$  over  $\mathbf{X}_a$  under given condition  $c$ , we can write the energy functional for LCBP as

$$F_{\text{LCBP}}(q) = \sum_a \sum_{c_a} q_C(c_a) \sum_{x_a} q_a^{c_a}(x_a) \ln \phi_a(x_a) + \mathbb{H}_{\text{LCBP}}(q). \quad (19)$$

## 4.4 UPDATE EQUATIONS

Optimizing (19) under the constraints (13) to (17) using the method of Lagrange multipliers lets us derive the message update rules<sup>1</sup>. The update equations work on these additional entities:

1.  $m_{i \rightarrow a}^{c_i}(x_i)$  is a message from variable  $i$  to factor  $a$  under variable condition  $c_i \in \text{Val}(S_i)$ .
2.  $m_{a \rightarrow i}^{c_a}(x_i)$  is a message from factor  $a$  to variable  $i$  under variable condition  $c_i \in \text{Val}(S_i)$ .
3.  $n_{a \rightarrow i}^{c_a}(x_i)$  is a message from factor  $a$  to variable  $i$  under factor condition  $c_a \in \text{Val}(S_a)$ .

We use the artificial factor  $\rho_i^{c_i}(x_i) = \mathbf{1}[c_i[X_i] = x_i]$  to enforce condition (17) on the variable beliefs<sup>2</sup>. The update equations are as following:

$$m_{i \rightarrow a}^{c_i}(x_i) \propto \rho_i^{c_i}(x_i) \prod_{b: i \in \mathbf{X}_b, b \neq a} m_{b \rightarrow i}^{c_b}(x_i) \quad (20)$$

$$m_{a \rightarrow i}^{c_a}(x_i) \propto \sum_{c_a \models c_i} q_C(c_a | c_i) \cdot n_{i \rightarrow a}^{c_a}(x_i) \quad (21)$$

$$n_{a \rightarrow i}^{c_a}(x_a) \propto \sum_{x_a \models x_i} \phi_a(x_a) \prod_{j \in \mathbf{X}_a, j \neq i} m_{j \rightarrow a}^{c_a[S_j]}(x_j) \quad (22)$$

The variable and factor beliefs are computed from the messages via the following formulas:

$$q_a^{c_a}(x_a) \propto \phi_a(x_a) \prod_{i \in \mathbf{X}_a} m_{i \rightarrow a}^{c_i}(x_i) \quad (23)$$

$$q_i^{c_i}(x_i) \propto \rho_i^{c_i}(x_i) \prod_{a: i \in \mathbf{X}_a} m_{a \rightarrow i}^{c_a}(x_i) \quad (24)$$

<sup>1</sup>A more detailed derivation of the update equations is provided in the appendix available in the supplied materials.

<sup>2</sup> $\mathbf{1}[A]$  represents the indicator function that yields 1 when the condition  $A$  is true and 0 otherwise.

And the update equation for the condition distribution is

$$q_C(c) \propto \exp [F_{\text{BP}}(q^c)] \prod_a \prod_{i \in \mathbf{X}_a} \prod_{x_i} \delta_{ai}^{c_a}(x_i), \quad (25)$$

with

$$\delta_{ai}^{c_a}(x_i) = m_{i \rightarrow a}^{c_i}(x_i)^{m_{i \rightarrow a}^{c_i}(x_i)(n_{a \rightarrow i}^{c_a}(x_i) - m_{a \rightarrow i}^{c_i}(x_i))}. \quad (26)$$

The fact that the stated update equations are suited to optimize the formulated variational problem is formalized by the following theorem.

**Theorem 1.** *The interior stationary points of the variational problem specified by maximizing the LCBP functional (19) under the given constraints (13) through (17) are exactly the fixed points of the LCBP update equations (20) through (25).*

The proof is given by the derivation in the appendix available in the extended version of this paper.

The term (26) (and thus the triple product in (25)) vanishes when the messages  $m_{a \rightarrow i}^{c_a}$  agree with the aggregate message  $m_{a \rightarrow i}^{c_i}$ . According to Figure 3 this can happen when the set of conditionees is chosen to be large. Empirically we could not detect a significant difference in inference quality between calculating the  $\delta_{ai}^{c_a}$  terms according to (26) or setting them to 1.

Until now we have treated the distribution over the conditions  $q_C(c)$  as flat. Taking a closer look at equation (25), we notice that the right hand side is a product, with factors coming from the exponentiated BP energy and the  $\delta_{ai}^{c_a}$  terms. These factors all depend on different subsets of variables from  $C$ . Thus the right side of equation (25) describes an undirected graphical model. We call it the *condition problem*, while referring to the original problem as the *primal problem*. When calibrating the message beliefs, it becomes necessary to calculate conditional probabilities  $q_C(c_a|c_i)$  for this problem, and this can be done using any inference algorithm for graphical models. The graphical structure of the condition problem is determined by the overlap between the sets of conditionees for different conditioners, and exact inference in the condition problem can become intractable.

## 5 EMPIRICAL EVALUATION

We conducted two experiments examining the performance of LCBP on randomly generated problem instances. The first experiment is meant to demonstrate that the quality of the LCBP approximation approaches that of variational CBP when increasing the area of influence around conditioned nodes. A second experiment examines how the computational effort of LCBP scales when the problem size increases. In both experiments we condition fully on all conditioners to obtain the variational CBP approximation.

For the experiments, we have implemented two variants of LCBP using the derived update equations. The first variant (LCBP-JT) employs exact inference over the condition problem using the Junction tree method (Shenoy and Shafer, 1990). The second variant (LCBP-BP) uses BP to approximate the marginals of the condition problem. All algorithms are implemented using Round-robin message schedules with no damping. Except for plain BP, the algorithms managed to converge every time. When reporting accuracy we remove all instances where BP did not converge, and thus favor BP in our presentation. We like to remark that when running algorithms from the CBP class, the tolerance for the convergence check has to be set very low. Otherwise the numerical errors may pile up and deteriorate the result even below BP level.

For the first set of experiments, we applied LCBP-JT and CBP to  $6 \times 6$  grid problems with binary variables and random interactions (Figure 5). We selected four fixed variables as conditioners. We varied both the number of conditionees and the interaction strength of the random grids. As expected, the error produced by LCBP-JT approaches the error of CBP both with decreasing interaction strength, and with growing area of influence. We can thus conclude that LCBP-JT acts as an approximation to the CBP result.

The second set of experiments is meant to examine the scaling behavior of LCBP. While the number of parameters of the variational approximation of LCBP grows more slowly than variational CBP, it is conceivable that LCBP takes significantly longer to converge (or even fails to converge at all). To be able to demonstrate that LCBP can yield good quality approximations, we designed a special problem class that we call two-layer grid model (Figure 6). Models with a similar geometry are used in image classification (Kato et al., 1996), sometimes called hierarchical Markov random fields. CBP can achieve good results for this class of problems when conditioning on the nodes of the upper layer, if the variables in the remaining problem (the lower layer) interact only weakly and can thus be approximated well by BP. We applied BP, CBP, LCBP-JT and LCBP-BP to two-layer grid problems with weak interaction on the first and second layer, and strong interactions between layers. We varied the size of the problems to examine the computational effort of the various algorithms. The chosen FL-scheme marks all second layer nodes as conditioners, with all directly connected first layer nodes as respective conditionees.

Figure 7a shows the relative error in the inferred log partition function for varying problem sizes. Notice how all examined algorithms maintain about the same approximation quality once boundary effects are overcome; starting with widths greater than 10. We can observe that all conditioning algorithms improve over the plain BP approximation. CBP performs best, followed closely by LCBP-JT. LCBP-BP produces the worst result among the condition-

ing approaches, though its result is still better than BP by about two orders of magnitude. The difference between the LCBP-JT and the LCBP-BP result was expected, since the condition problem is not acyclic—it contains strong dependencies induced by the explicit interactions between the variables in the second layer. Experiments without interactions in the second layer (not shown) put the LCBP-BP result much closer to LCBP-JT, as paths going through the lower grid induce only weak coupling in the condition problem, while experiments with stronger interactions put LCBP-BP closer to the BP results. For all examined parameter combinations the experiment produces the same qualitative result, i.e., the same order among the examined algorithms. Figure 7b shows the CPU time for the different algorithms. As expected CBP shows an exponential growth with problem size and thus the number of conditioners. In contrast, the effort for the LCBP variants grows approximately linearly with problem size. Note that the LCBP implementations underwent only moderate optimization, as we are interested only in their asymptotic behavior. Thus, one should not draw any conclusions from the concrete slopes of the curves in Figure 7b. Also note that the generated problems have fixed tree-width; both the primal problem and the condition problem. This explains the linear scaling of LCBP-JT.

## 6 DISCUSSION AND FUTURE WORK

The presented LCBP algorithm provides a scalable approximation to the variational interpretation of CBP. By shifting our focus from iterative CBP to variational CBP, we have lost the anytime behavior that iteratively refines the approximation over time in a heuristically guided way. The step from variational CBP to LCBP further removed the possibility of having an unbalanced and dynamically ordered tree to represent the set of examined conditions. This was necessary to achieve the factorization of the condition problem. According to our assessment, LCBP can be extended to resemble iterative CBP more closely, although we expect that this requires substantial further work. The situation is not much different for Generalized Belief Propagation (Yedidia et al., 2005), though. An iterative and heuristically guided construction of region graphs for GBP is as desirable as the adaptive construction of conditioning schemes in the LCBP setting. Approaches to this problem for GBP are still rare, although some work does exist (Welling, 2004; Sibel et al., 2012). In this section we will discuss some steps that point in this direction. Note that some of the discussion is also applicable to GBP.

### 6.1 DESIGNING CONDITIONING SCHEMES

When looking at the iterative CBP algorithm, it is apparent that one of its main strengths is its ability to focus its work on the modes of the target distribution. The trees that can

Figure 5: Evaluation results comparing LCBP-JT relative error in log partition function with CBP relative error on randomly generated binary,  $6 \times 6$  grid networks. Four symmetrically placed variables are conditioned. The set of conditionees for LCBP-JT is increased along the rows, including variables with a distance of at most 0, 1 or 2 according to the max norm on the grid coordinates. The columns stand for grids with stronger potentials from left to right (sampled from  $\exp(\mathcal{N}(0, \sigma))$ , with  $\sigma \in \{0.25, 1, 4\}$ ). One can see that both with growing area of influence (going down), and with weaker coupling (right to left!) the result of LCBP-JT approaches that of CBP. If both algorithms disagree, CBP yields a lower error.

be constructed have no constraint on their shape, and they can become very deep and narrow. This is also an advantage of iterative CBP over GBP, where the approximation is improved by using marginals over larger clusters of variables than the factor clusters  $q_a$  used in BP. Given a cluster, GBP can only improve by adding another variable to the cluster, which multiplies the computational burden associated with the cluster by the domain size of the added variable. CBP can circumvent this problem by refining single leaves of its tree; basically making context-specific refinements. LCBP faces the same problem as GBP, because of the limited expressiveness of FL-schemes. With FL-schemes the complexity of LCBP scales exponentially with the number of conditioners a conditionee has—they define the size of the factor scopes for the condition problem. For practical purposes one would aim at using more expressive schemes that allow for context-specific refinements, e.g., conditioning some variable on the conditions  $\{X_1 = 0, X_2 = 0\}, \{X_1 = 0, X_2 = 1\}, \{X_1 = 1\}$ , thus condition only on  $X_2$  for  $X_1 = 0$ . A simple improvement for problems with large variable domains is to branch on elements of arbitrary partitions of assignments to single

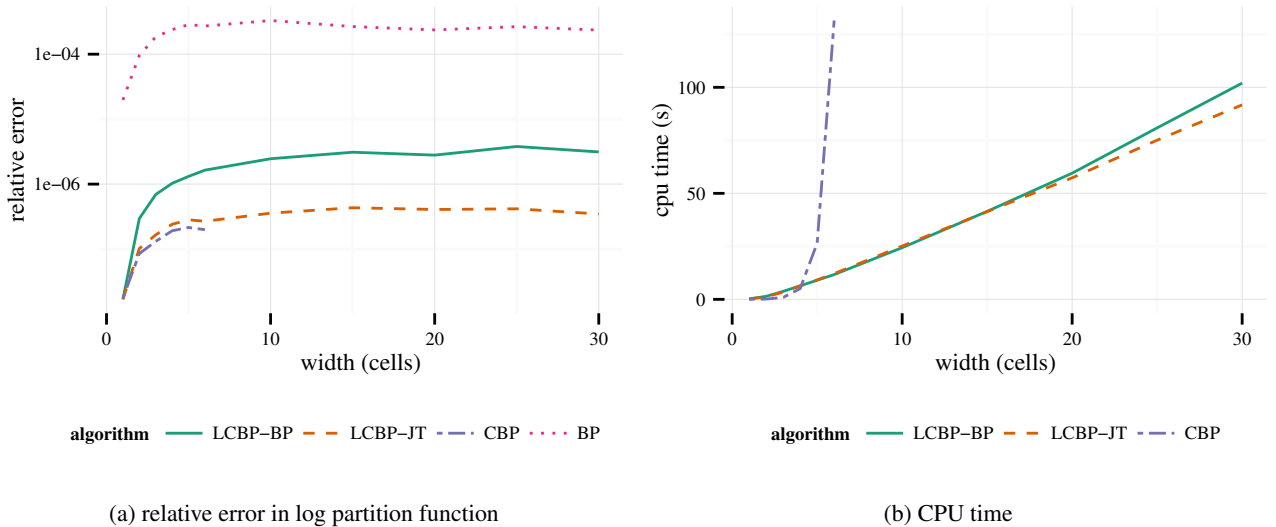

Figure 7: Inference results and used CPU time for two-layer grid problems of varying size (see Figure 6). The x-axis shows the number of columns (width) of the upper grid, where a “cell” is supposed to be a group of nodes on the lower layer connected to a single node on the upper layer. The height of the upper grid is fixed to 2 to obtain problems where exact inference is tractable. All variables have binary domains. Interactions within the lower and the upper layer are weak (factor values drawn from  $\exp\{\mathcal{N}(0, 0.5)\}$ ), while interactions between layers are strong (factor values drawn from  $\exp\{\mathcal{N}(0, 4)\}$ ). CBP was not applied to the larger instances, due to resource constraints. All lines are means over 500 random instances.

Figure 6: Illustration of the two-layer grid model used for evaluation. Each upper node is connected to  $3 \times 3$  lower nodes. The upper nodes form a two-by- $n$  grid, where  $n$  is varied to obtain problems of different size.

variables, e.g., distinguish between  $X_1 < 3$  and  $X_1 \geq 3$ .

## 6.2 ITERATIVE, HEURISTIC CONSTRUCTION OF SCHEMES

The iterative CBP algorithm has the big advantage of offering an anytime approximation scheme that can be sensitive both to problem structure, and to parameters. This is achieved through the use of different types of heuristics, choosing how to refine the approximation over the course of the computation (Geier et al., 2014b).

Looking at iterative CBP, it appears natural to build the scheme for LCBP incrementally—refining the approximation after running inference and looking at the result. For CBP there exist basically two decision points: Choose the condition/leaf on which to work, then choose the variable to condition on. For LCBP with an FL-scheme choosing

a branch is not possible, as this requires context-specific schemes. If those are available, then LCBP must blur both decision points of CBP into one: Choose which variable to refine under which condition—as the available conditions depend on the chosen variable. This is in contrast to CBP, where all variables are available under every condition (unless they are already conditioned). In addition, for LCBP there exists the new choice of extending the set of conditionees of a conditioner. For this decision we can think of promising candidates for evaluation, like the disagreement among the aggregated messages of the sub-conditions. Using this heuristic would result in splitting variables on the condition until the effect of conditioning has fallen below some threshold (remember Figure 3). Clearly this requirement is too strong, as for tree-structured problems the messages under different conditions can be combined at any moment while still obtaining an exact result.

To find truly informed heuristics, we have to look at the source of the error within the BP approximations. A promising way to construct heuristics for iteratively refining LCBP appears to be exploitation of the loop series expansion (Montanari and Rizzo, 2005). It specifies a correction for the BP functional (Equation 4), that allows to reconstruct the exact value of the partition function. This is done by adding a term for each generalized loop of the graph. Since error contribution is associated with loops, it is not focused on variables, but decentralized. By conditioning on one variable of a loop, while placing the complete loop in the area of influence, the loop can be cor-

rected. In this way the loop series expansion could provide guidance on choosing both conditioners *and* conditionees consistently in an error-oriented manner.

### 6.3 THE CONDITION PROBLEM

One nice aspect about FL-schemes is their property to induce ordinary Markov networks as condition problem. As demonstrated in the evaluation, one can use any algorithm that computes (conditional) marginal probabilities for Markov networks to solve the condition problem. This choice can be influenced by the expected characteristics of the condition problem. If the primal problem contains deterministic dependencies, it is conceivable to “pre-solve” the condition problem. When inference during pre-solving assigns zero probability to some marginal assignments, the corresponding elements of the LCBP calculation can be safely pruned. In addition, elements with very low marginal probability can be pruned on a heuristic basis, incurring a further approximation of the final result.

If a message passing algorithm is chosen for inference within the condition problem, it becomes possible to run it interleaved with the LCBP message updates. This opens the door to using more sophisticated message update schedules, for example Residual Belief Propagation (Elidan, 2006), making it possible to balance the ratio of LCBP updates against inference in the condition problem.

An interesting idea is recursively using LCBP for inference in the condition problem. A perceivable application are hierarchical grid problems with more layers. We expect this construction to scale well, meaning that nesting analysis by cases using LCBP does not incur an exponential growth in model size. It is not clear how to create such a deep hierarchical approximation using other variational techniques, such as GBP.

## 7 RELATED WORK

There exists some prior work on using mixture models for variational inference. Jaakkola and Jordan (1998) use mixtures of mean field approximations to improve inference quality. Beside the weaker approximation of mean field compared to BP and the locality of conditions, the main difference to LCBP is the use of mixture components with overlapping support in contrast to mutually exclusive conditions. The overlapping approach is more powerful in theory, because the mixture components are not restricted in the sense that they are clamped to an intended condition. But in contrast to this, only a weaker approximation to the entropy is used by Jaakkola and Jordan (1998) as the mutually exclusiveness allows for better analytical treatment. Split Variational Inference (Bouchard and Zoeter, 2009) is another application of conditioning and the variational method applied to arbitrary integrals.

The “Gates” model (Minka and Winn, 2008) is also intended as a variational treatment of local mixture components, and arrives at similar update equations for expectation propagation and variational message passing. The LCBP model can be described using Gates with the conditioners being the selector variables, and the conditionees (and incident factors) being placed inside the gate. The LCBP derivation is more explicitly cast as a variational problem by specifying the variational distribution and the constraints, and, more importantly, it allows overlap between gates, which Minka and Winn explicitly forbid. One could say that FL-schemes are more expressive than the (implicit) schemes allowed by Minka and Winn.

## 8 CONCLUSION

We have formulated a variational interpretation of CBP as a mixture of BP approximations. Based on this, we have derived LCBP, which yields inference results that approximate those obtained from CBP. We have shown empirical evidence that supports the claims that LCBP approximates CBP, while scaling much more favorably with problem size.

LCBP allows a non-trivial integration between an arbitrary probabilistic inference algorithm used for solving the condition problem and BP used for inference over the remainder. The automatic construction of good conditioning schemes for LCBP remains an open research question. But we were able to construct schemes for a motivated problem class resembling hierarchical Markov random fields, which are used in image recognition. We are currently working on formulating more expressive classes of conditioning schemes, together with an informed heuristic based on the loop series expansion for BP. We also plan to investigate the relationship between LCBP and GBP more closely.

## Abstract

We present a Discriminative Switching Linear Dynamical System (DSLDS) applied to patient monitoring in Intensive Care Units (ICUs). Our approach is based on identifying the state-of-health of a patient given their observed vital signs using a discriminative classifier, and then inferring their underlying physiological values conditioned on this status. The work builds on the Factorial Switching Linear Dynamical System (FSLDS) (Quinn *et al.*, 2009) which has been previously used in a similar setting. The FSLDS is a generative model, whereas the DSLDS is a discriminative model. We demonstrate on two real-world datasets that the DSLDS is able to outperform the FSLDS in most cases of interest, and that an  $\alpha$ -mixture of the two models achieves higher performance than either of the two models separately.

Condition monitoring of patients in intensive care units (ICUs) based on vital signs (e.g. heart rate, blood pressure) is of critical importance, as they can be subject to a number of serious physiological events such as bradycardia and hypotension. However, a variety of artifactual processes can “contaminate” the data, e.g. the taking of blood samples, performing suction, recalibrating sensors, etc. These artifactual processes complicate the task of identifying the important physiological events and are the main source of false alarms in ICUs. Moreover, it is of interest to maintain beliefs about the true physiological values of a patient when these cannot be directly observed due to artifact. For example, it would be desirable to display the patient’s estimated blood pressure, when the corresponding measuring device has been disconnected or is otherwise displaying artifactual values (as is the case during a blood sample event). Of course, this estimate should be clearly distinguishable from the raw data (e.g. by using a different display colour).

One approach to this problem is to build a latent variable

model, using a number of discrete latent variables to model the physiological and artifactual events through time, and a linear dynamical system (LDS) conditional on these discrete variables to model the associated dynamics in the vital signs observations. This is the factorial switching LDS (or FSLDS) of Quinn *et al.* (2009). However, we have noticed that in building such systems it is necessary to construct quite detailed models of the artifactual events in order to capture them properly. This can be non-trivial since some of these events can be highly variable, which is hard to capture with a generative model. Despite this high variability, the vital signs can still contain informative features which could act as input to a discriminative model. Thus, if it is possible to build such a model that can fairly easily distinguish between the various events, then it would seem simpler and easier to make the discrete-state inference be discriminative, and use FSLDS-style inference for the continuous latent variables conditional on the inferred discrete state. We call this a *discriminative switching linear dynamical system* (DSLDS). In this paper we compare the FSLDS and DSLDS models on two ICU condition monitoring datasets. The results show that using the DSLDS gives increased performance in most cases of interest, and that an  $\alpha$ -mixture of the two methods was able to achieve a higher performance than either of the two models separately.

To summarise, our goal is to build a model with increased performance for the following tasks:

- Identifying artifactual processes (e.g. blood samples), which will reduce the high false alarm rate in ICUs and facilitate the task of identifying physiological processes.
- Identifying physiological processes which can be of critical importance (e.g. bradycardias).
- Providing an estimate of a patient’s true physiological values when these are obscured by artifact.

The structure of the remainder of the paper is as follows: in Section 1 we give a description of our proposed model and

compare its graphical structure and inference methods to those of the FSLDS, and briefly describe related work. In Section 2 we describe our experiments and provide results for the comparison between the DSLDS and the FSLDS. Finally, in Section 3 we conclude with general remarks about our proposed model and suggestions for future work.

## 1 MODEL DESCRIPTION

The graphical model of the FSLDS is depicted in Figure 1 (top). It operates on three different sets of variables: The observed variables,  $\mathbf{y}_t \in \mathbb{R}^{d_y}$  represent the patient’s vital signs obtained from the monitoring devices at time  $t$ , which act as the input to our model. The continuous latent variables,  $\mathbf{x}_t \in \mathbb{R}^{d_x}$ , track the evolution of the dynamics of a patient’s underlying physiology. The discrete variable,  $s_t$ , represents the switch setting or regime which the patient is currently in (e.g. stable, a blood sample is being taken etc.). The switch variable can be factorised according to the cross-product of  $M$  factors, so that  $s_t = f_t^1 \otimes f_t^2 \otimes \dots \otimes f_t^M$ . Each factor variable,  $f_t^m$ , is usually a binary vector indicating the presence or absence of a factor, but in general it can take on  $L^{(m)}$  different values and  $K = \prod_{m=1}^M L^{(m)}$  is the total number of possible configurations of the switch variable,  $s_t$ . Also,  $s_t$  depends explicitly on the previous time step, so that  $p(s_t|s_{t-1}) = \prod_{m=1}^M p(f_t^m|f_{t-1}^m)$ . Conditioned on a particular regime, the FSLDS is equivalent to an LDS. The FSLDS can be seen then as a collection of LDS’s, where each LDS models the dynamics of a patient’s underlying physiology under a particular regime, and can also be used to generate a patient’s observed vital signs. An LDS provides a generative framework for modelling our belief over the state space, given observations.

We can alternatively adopt a discriminative view. We start by modelling  $p(s_t|\mathbf{y}_{t-l:t+r})$  with a discriminative classifier, where (features of) observations from the previous  $l$  and future  $r$  time steps affect the belief of the model about  $s_t$ . The inclusion of  $r$  frames of future context is analogous to fixed-lag smoothing in an FSLDS (see e.g. Särkkä, 2013, sec. 10.5). We note that inclusion of future observations in the conditioning set means that the DSLDS will operate with a delay of  $r$  seconds, since an output of the model at time  $t$  can be produced only after time  $t+r$ . Provided that  $r$  is small enough ( $r \leq 10$  in experiments), this delay is negligible compared to the increase in performance. The LDS can also be regarded from a similarly discriminative viewpoint which allows us to model  $p(\mathbf{x}_t|\mathbf{x}_{t-1}, \mathbf{y}_t)$ . This is similar to the Maximum Entropy Markov Model (MEMM) (McCallum *et al.*, 2000) with the difference that the latent variable is continuous rather than discrete. The main advantage of this discriminative view is that it allows for a rich number of (potentially highly correlated) features to be used without having to explicitly model their distribution or the interactions between them, as is the case in a generative model. A combination of these two discrimina-

tive viewpoints gives rise to the DSLDS graphical model in Figure 1 (bottom). The DSLDS, conditioned on  $s_t$ , can be seen then as a collection of MEMM’s, where each MEMM in the DSLDS plays a role equivalent to that of each LDS in the FSLDS.

The DSLDS can be defined as

$$p(\mathbf{s}, \mathbf{x}|\mathbf{y}) = p(s_1|\mathbf{y}_1)p(\mathbf{x}_1|s_1, \mathbf{y}_1) \times \prod_{t=2}^T p(s_t|\mathbf{y}_{t-l:t+r})p(\mathbf{x}_t|\mathbf{x}_{t-1}, s_t, \mathbf{y}_t) . \quad (1)$$

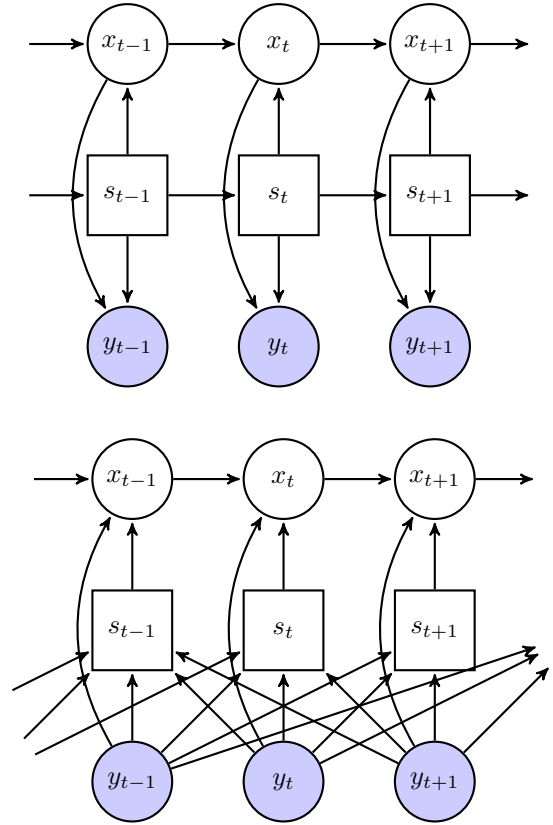

Figure 1: Graphical model of the FSLDS (top) and the DSLDS (bottom). The state-of-health and underlying physiological values of a patient are represented by  $s_t$  and  $\mathbf{x}_t$  respectively. The shaded nodes correspond to the observed physiological values,  $\mathbf{y}_t$ . Note that in the case of the DSLDS the conditional probability  $p(s_t|\mathbf{y}_{t-l:t+r})$  is modelled directly.

The simplest assumption we can make for the DSLDS is that  $p(s_t|\mathbf{y}_{t-l:t+r})$  factorises, so that

$$p(s_t|\mathbf{y}_{t-l:t+r}) = \prod_{m=1}^M p(f_t^{(m)}|\mathbf{y}_{t-l:t+r}) . \quad (2)$$

However, one could use a structured output model to predict the joint distribution of different factors.

## 1.1 Predicting $s_t$

Our belief about the state of health of a patient at time  $t$  is modelled by  $p(s_t | \mathbf{y}_{t-l:t+r})$ , the conditional probability of the switch variable given the observed vital signs. Following the factorisation of the switch variable in eq. 2, we model the conditional probability of each factor being active at time  $t$  given the observations with a probabilistic discriminative binary classifier, so that  $p(f_t^{(i)} = 1 | \mathbf{y}_{t-l:t+r}) = G(\phi(\mathbf{y}_{t-l:t+r}))$ , where  $G(\cdot)$  is a classifier-specific function, and  $\phi(\mathbf{y}_{t-l:t+r})$  is the feature vector that acts as input to our model at each time step as described in Section 2.1. As is evident from Figure 1 (bottom) there is no explicit temporal dependence on the switch variable sequence. However, temporal continuity is implicitly incorporated in our model through the construction of the features.

### 1.1.1 An $\alpha$ -mixture of $s_t$

The DSLDS model can be seen as complementary to the FSLDS, and they can be run in parallel. One way of combining the two outputs is to maintain an  $\alpha$ -mixture over  $s_t$ . If  $p_g(s_t)$  and  $p_d(s_t)$  are the outputs for the switch variable at time  $t$  from FSLDS and the DSLDS respectively, then their  $\alpha$ -mixture is given by:  $p_\alpha(s_t) = c \left( p_g(s_t)^{(1-\alpha)/2} + p_d(s_t)^{(1-\alpha)/2} \right)^{2/(1-\alpha)}$ , where  $c$  is a normalisation constant which ensures that  $p_\alpha(s_t)$  is a probability distribution. The family of  $\alpha$ -mixtures then subsumes various known mixtures of distributions and defines a continuum across them via the  $\alpha$  parameter. For example, for  $\alpha = -1$  we retrieve the mixture of experts (with equally weighted experts) framework, while for  $\alpha \rightarrow 1$ , the formula yields  $p_1(s_t) = c\sqrt{p_g(s_t)p_d(s_t)}$ , rendering it equivalent to a product of experts viewpoint. In general, as  $\alpha$  increases, the  $\alpha$ -mixture assigns more weight to the smaller elements of the mixture (with  $\alpha \rightarrow \infty$  giving  $p_\infty(s_t) = \min\{p_g(s_t), p_d(s_t)\}$ ), while as  $\alpha$  decreases, more weight is assigned to the larger elements (with  $\alpha \rightarrow -\infty$  giving  $p_{-\infty}(s_t) = \max\{p_g(s_t), p_d(s_t)\}$ ). A thorough treatment is given in Amari (2007).

## 1.2 Predicting $\mathbf{x}_t$

The model of the patient’s physiology should capture the underlying temporal dynamics of their observed vital signs under their current health state. The idea is that the current latent continuous state of a patient should be dependent on (a) the latent continuous state at the previous time step, (b) the current state of health and (c) the current observed val-

ues. We model these assumptions as follows

$$p(\mathbf{x}_t | \mathbf{x}_{t-1}, s_t, \mathbf{y}_t) \propto \exp\left\{-\frac{1}{2}(\mathbf{x}_t - \mathbf{A}^{(s_t)}\mathbf{x}_{t-1})^\top (\mathbf{Q}^{(s_t)})^{-1}(\mathbf{x}_t - \mathbf{A}^{(s_t)}\mathbf{x}_{t-1})\right\} \times \exp\left\{-\frac{1}{2}(\mathbf{C}^{(s_t)}\mathbf{x}_t - \mathbf{y}_t)^\top (\mathbf{R}^{(s_t)})^{-1}(\mathbf{C}^{(s_t)}\mathbf{x}_t - \mathbf{y}_t)\right\} . \quad (3)$$

The first term on the RHS of eq. 3 is the **system model** for an LDS and captures the dynamics of a patient’s latent physiology under state  $s_t$ . The second term can be seen as the discriminative counterpart of the **observation model** of an LDS. In our condition monitoring setting, the observed vital signs are considered to be noisy realisations of the true, latent physiology of a patient and thus, the observation model encodes our belief that  $\mathbf{x}_t$  is a noisy version of  $\mathbf{y}_t$ . Under this assumption,  $\mathbf{C}^{s_t}$  consists of 0/1 entries, which are set based on our knowledge of whether the observations  $\mathbf{y}_t$  are artifactual or not under state  $s_t$ . In the FSLDS, the corresponding observation model encodes the belief that the generated  $\mathbf{y}_t$  should be normally distributed around  $\mathbf{x}_t$  with covariance  $\mathbf{R}^{s_t}$ , whereas in our discriminative version, the observation model encodes our belief that  $\mathbf{x}_t$  should be normally distributed around  $\mathbf{y}_t$  with covariance  $\mathbf{R}^{s_t}$ . The idea behind this model is that at each time step we update our belief about  $\mathbf{x}_t$  conditioned on its previous value,  $\mathbf{x}_{t-1}$ , and the current observation,  $\mathbf{y}_t$ , under the current regime  $s_t$ . For example, under an artifactual process, the observed signals do not convey useful information about the underlying physiology of a patient. In that case, we drop the connection between  $\mathbf{y}_t$  and  $\mathbf{x}_t$  (for the artifact-affected channels) which translates into setting the respective entries of  $\mathbf{C}^{s_t}$  to zero. Then, the latent state  $\mathbf{x}_t$  evolves only under the influence of the appropriate system dynamics parameters  $(\mathbf{A}^{(s_t)}, \mathbf{Q}^{(s_t)})$ . Conversely, operation under a non-artifactual regime incorporates the information from the observed signals, effectively transforming the inferential process for  $\mathbf{x}_t$  into a product of two “experts”, one propagating probabilities from  $\mathbf{x}_{t-1}$  and one from the current observations.

We note that the step of conditioning on the current regime  $s_t$  in order to predict  $\mathbf{x}_t$  is required for our task, as we do not have training data for the  $\mathbf{x}$ -state. Otherwise, one could imagine building a simpler model such as a conditional random field (Lafferty *et al.*, 2001), to predict the  $\mathbf{x}$ -state directly from the observations. However, in our case, where only labels about the patient’s regime are available, this is not possible.

## 1.3 Learning

We first describe learning in the general SLDS setting. The parameters that need to be learned are:  $\{\mathbf{A}^s, \mathbf{Q}^s, \mathbf{C}^s, \mathbf{R}^s\}$ . Given training data for each switch setting, these can be learned independently as LDS parameters for each configuration of  $s$ . Following Quinn *et al.* (2009) we use an

independent ARIMA model with added observation noise for each channel. Casting such a model into state space form is a standard procedure as described in Brockwell and Davis (2009, sec. 12.1), and amounts into reformulating the parameters of the ARIMA model into the parameters of a state-space model. Once the model is in state space form,  $\mathbf{A}^s$ ,  $\mathbf{Q}^s$ ,  $\mathbf{C}^s$ ,  $\mathbf{R}^s$  can be fit according to the maximum likelihood criterion by using numerical optimisation methods (like Newton-Raphson, Gauss-Newton), as presented in Shumway and Stoffer (2000, sec. 2.6) or expectation maximisation (EM) as presented in Ghahramani and Hinton (1996). We note that the vector ARMA (VARMA) representation is used, where for example a one-dimensional AR( $p$ ) process can be encoded as a  $p + 1$ -dimensional VAR(1) process by maintaining a latent state representation of the form  $\mathbf{x}_t = [x_t \ x_{t-1} \ \dots \ x_{t-p}]$ .

In the DSLDS, the same set of parameters needs to be learned. As mentioned in Section 1.2, the assumptions for the DSLDS observation model constrain  $\mathbf{C}^s$  to be a binary matrix, whose values are set so as to pick the most recent value  $\mathbf{x}_t$  under the VARMA representation. For example, assuming that we are modelling one channel, under a physiological regime, as an AR(2) process, then  $\mathbf{C}^s = [1 \ 0 \ 0]$ . Under this constrained form of  $\mathbf{C}^s$  we obtain the remaining parameters,  $\mathbf{A}^s$ ,  $\mathbf{Q}^s$  and  $\mathbf{R}^s$ , using the same learning process as the one already described for the case of a general SLDS.

The task of determining the order of the respective ARIMA models is less straightforward. We have followed a practical approach as suggested in Diggle (1990, sec. 6.2). The autocorrelation and partial autocorrelation function (ACF and PACF respectively) of the stationary data (if a time series is not stationary, we make it stationary by successive differencing) were examined to provide an initial estimate of the appropriate model order. A clear cut-off at lag  $q$  in the ACF plot is suggestive of an MA( $q$ ) process, while a clear cut-off at lag  $p$  in the PACF plot is suggestive of an AR( $p$ ) process. Clear cut-offs are rare in a real world application, in which case we looked for less clear tail-offs in the PACF and ACF plots. After establishing a small number of potential model orders suggested by these tail-offs, further exploration of the model order around these initial estimates was carried out by calculating the Akaike Information Criterion (AIC) score (Akaike, 1972) for each of these potential model orders, and finally the one with the smallest AIC value was chosen.

#### 1.4 Inference

In this paper we are concerned with the task of computing the distribution  $p(s_t, \mathbf{x}_t | \mathbf{y}_{1:t+r})$ . According to our proposed model,  $p(s_t | \mathbf{y}_{t-l:t+r})$  can be inferred at each time step via a classifier as described in Section 1.1. However, exact inference for  $\mathbf{x}_t$  is still intractable. The same lim-

itation as in the case of a standard SLDS applies (Lerner and Parr, 2001): In order to maintain an exact belief over the posterior distribution of  $\mathbf{x}_t$  we need to keep track of all the potential combinations of switch variable settings that could have lead us from  $\mathbf{x}_{t-1}$  to  $\mathbf{x}_t$ , making inference scale exponentially with time. An approximation of this distribution can be maintained via the Gaussian Sum algorithm<sup>1</sup> (Alspach and Sorenson, 1972). The idea is that at each time step  $t$  we maintain an approximation of  $p(\mathbf{x}_t | s_t, \mathbf{y}_{1:t+r})$  as a mixture of  $J$  Gaussians. Moving one time step forward will result in the posterior  $p(\mathbf{x}_{t+1} | s_{t+1}, \mathbf{y}_{1:t+r+1})$  having  $KJ$  components, which are again collapsed to  $J$  components. In our experiments we use  $J = 1$ , which translates into matching moments (up to second order) of the distribution for each setting of  $s_t$ , as shown in Murphy (1998). Therefore inference in the DSLDS can be seen as a two-step process, where  $p(s_t | \mathbf{y}_{t-l:t+r})$  is inferred by our discriminative classifier, and  $p(\mathbf{x}_t | s_t, \mathbf{y}_{1:t+r})$  is inferred according to the Gaussian Sum algorithm.

#### 1.5 Related work

In terms of methodology, our proposed model bears some similarities to the one used by Lu *et al.* (2009). However, their model was used to model spatial relationships and they were only concerned with a binary discrete latent space. In our case, we are concerned with modelling temporal structure and we have a richer and more complex discrete latent space. More importantly, in their work the distribution maintained over the continuous latent space is a single multivariate Gaussian, whereas in our model, as described in the previous section, the belief over the continuous latent space is modelled as a mixture of  $KJ$  Gaussians. This allows us to keep track of multiple modes about the belief over a patient’s underlying physiology, since this is potentially affected by multiple factors.

In terms of application, our work is mostly similar to the one presented in Quinn *et al.* (2009). The same task of inferring artifactual and physiological processes was considered there. However a generative approach was taken there via the use of an FSLDS. In Lehman *et al.* (2014), a switching vector autoregressive model was used on minute-by-minute heart rate and blood pressure vital signs to provide inputs for a logistic regression classifier with the goal of patient outcome prediction. Also, Nemati *et al.* (2013) propose training a SLDS in a discriminative manner so as to optimize prediction of the  $s$  sequence given the observations, and apply this to identifying four postural categories under a controlled protocol. Stanculescu *et al.* (2014) use a hierarchical structure in the discrete space of an SLDS motivated by expert knowledge on modelling sepsis. In our work, we use a discriminative SLDS, capable of mod-

<sup>1</sup>The Gaussian Sum algorithm is also known as the Generalised Pseudo Bayesian (GPB) algorithm as mentioned in Murphy (1998).

elling both discrete and continuous latent states in a unified framework, applied to two challenging real-world datasets. It yields superior results for state-of-health identification, and maintains at the same time beliefs about a patient’s underlying physiology.

## 2 EXPERIMENTS

In this section we describe experiments on two challenging datasets comprising of patients admitted to ICUs in two different hospitals, namely a neonatal ICU and an adult ICU. We emphasise that it is highly non-trivial to obtain annotations for medical datasets as it requires the very scarce resource of experienced clinicians. Indeed, for the adult ICU, the annotated data are the product of a one-year collaboration with that ICU. Physionet (Goldberger *et al.*, 2000), a freely available medical dataset, is not suitable for our task since the only available time-series annotations are a limited set of life threatening/terminal events, for which identification would not be of practical use in the ICU.

For both datasets, we evaluate the performance of the DSLDS compared to the FSLDS. We also report the performance of an  $\alpha$ -mixture of the two models. Note that the FSLDS has been shown in Quinn *et al.* (2009) to achieve superior results compared to more basic models such as a factorial hidden Markov model (FHMM) for the task of condition monitoring in ICUs. We first provide a short description of the various features that were used as input to the state-of-health model as described in Section 1.1, followed by an outline of the main characteristics of the two datasets. We conclude this section by providing results on two tasks: a) inferring a patient’s state of health and b) inferring a patient’s underlying physiology in the presence of artifact corruption.

### 2.1 Features & Classifiers

As described in Section 1.1, the estimate of  $s_t$  is the output of a discriminative classifier. For both datasets, we found that using a random forest (Breiman, 2001) as our classification method yields the best performance. Suggestions for judicious selection of various tree-construction parameters can be found in Hastie *et al.* (2009, Ch. 15). The Gini index was used as the criterion for splitting nodes for each tree in the random forest. The output of the random forest for a new test point is an average of the predictions produced by each tree, where the prediction of each tree is the proportion of the observations that belong to the positive class in the leaf node in which the test point belongs to. Apart from their high performance, another appealing property of random forests is that they can handle missing observations via the construction of surrogate variables and splits within each decision tree as explained in Hastie *et al.* (2009, sec. 9.2.4).

We use a variety of features to capture interesting temporal structure between successive observations. At each time step, a sliding window of length  $l + r + 1$  is computed. For some features we also divide the window into further sub-windows and extract additional features from them. More precisely, the full set of features that are being used are: (i) the observed, raw values of the previous  $l$  and future  $r$  time steps ( $\mathbf{y}_{t-l:t+r}$ ); (ii) the slopes (calculated by least squares fitting) of segments of that sliding window that are obtained by dividing it in segments of length  $(l + r + 1)/k$ ; (iii) an exponentially weighted moving average of this window of raw values (with a kernel of width smaller than  $l + r + 1$ ); (iv) the minimum, median and maximum of the same segments; (v) the first order differences of the original window; and (vi) differences of the raw values between different channels.

### 2.2 Neonatal ICU

The first dataset is the one used in Quinn *et al.* (2009)<sup>2</sup>. It comprises 24-hour periods from fifteen neonates admitted to the ICU of the Edinburgh Royal Infirmary, with events of interest annotated by two clinical experts. These annotations include: i) blood sample events (BS), ii) periods during which an incubator is open (IO), iii) core temperature probe disconnections (TD), iv) bradycardias (BR), and v) periods that are clearly not stable but no further identification was made by the clinicians (X). These last cases can be collectively considered as a “none-of-the-above” factor, which is referred to as the X-factor by Quinn *et al.* (2009). More details about the events of interest can be found in the aforementioned work. We used the same parameters for the underlying physiology model as the ones used there.

### 2.3 Adult ICU

The second dataset comprises data collected from nine adults admitted to the neuro ICU of the Southern General Hospital in Glasgow. An average of 33-hour periods were collected from each of these patients, consisting of measurements recorded on a second-by-second basis for four different channels: heart rate (HR), systolic and diastolic blood pressure (BP<sub>sys</sub>, BP<sub>dia</sub>), and systolic intracranial pressure (ICP<sub>sys</sub>). These data were then annotated by a clinical expert. We give a brief description of the learning process for stability periods and modelled factors, which include blood samples, damped traces (DT), suction events (SC), and the X-factor.

**Stable periods** correspond to time periods when no annotation occurred from the experts, suggesting that the patient is in a stable condition. In Williams and Stanculescu (2011) it was found that in a similar setting a 15 minute period of stability provides an adequate amount of training data. We

<sup>2</sup>The dataset has been anonymised and is available at: [www.cit.mak.ac.uk/staff/jquinn/software.html](http://www.cit.mak.ac.uk/staff/jquinn/software.html)

use the same time interval for our experiments. We found that ARIMA(2,1,0) models were adequate for all channels.

An example of a **blood sample** is shown in Figure 4 (bottom). Changes in BPsyst and BPDia can be modelled as a four-stage process: i) the blood is diverted to a syringe for blood sampling, which causes an artifactual ramp in the observed measurements. This is similar to the blood sample model described in Quinn *et al.* (2009) and we follow the same approach here. ii) A recalibration stage follows, causing measurements to drop to zero which can be modelled similarly to a dropout event as in Quinn *et al.* (2009). iii) BP measurements continue as a stable period for a brief period. iv) The blood sample is concluded with a flushing event for hygiene purposes which causes a sharp increase in measurements. This stage is modelled as an AR(3) process for both the BPsyst and BPDia channels. A total number of 64 blood sample events have been annotated, with an average duration of 1.6 minutes.

During a **suction event**, a flexible catheter is inserted into the airway of the patient to remove secretions that have accumulated over time in their pulmonary system. This event is observed as a significant increase in the values of all observed channels. An AR(2) process models the HR channel, while AR(3) processes were used to model the remaining channels. A total number of 53 suction events have been annotated, with an average duration of 4.3 minutes.

A **damped trace**, an example of which is shown in Figure 4 (top), is usually observed due to blood residues being accumulated in the line used for measuring the blood pressure channel, which leads both BPsyst and BPDia to converge to a similar mean value while at the same time the measurements exhibit high variability. Both channels were modelled with AR(3) processes. A total number of 32 damped trace events have been annotated, with an average duration of 14 minutes.

Except for the aforementioned factors which we explicitly model, there are a multitude of other factors present in our training data, corresponding to either known but not yet modelled factors (such as hygiene events, tachycardias etc.) or to unknown factors (clear abnormalities which however have not been identified by the clinicians). We collectively treat those events as unknown and model them according to the X-factor model proposed in Quinn *et al.* (2009). A total number of 278 X-factor events have been annotated, with an average duration of 7.5 minutes. Channels which are unaffected by an artifactual process (as shown in Table 1) are modelled as in the stable case. In every case the parameters of the x-state models were further optimised by EM.

Table 1: Channels affected by different processes for the adult ICU are marked by ●.

|              | HR | BPsyst | BPDia | ICPsyst |
|--------------|----|--------|-------|---------|
| Blood sample |    | ●      | ●     |         |
| Damped trace |    | ●      | ●     |         |
| Suction      | ●  | ●      | ●     | ●       |
| X-factor     | ●  | ●      | ●     | ●       |

Table 2: Comparison of DSLDS, FSLDS and  $\alpha$ -mixture performance for the Neonatal ICU dataset. Optimal value of the  $\alpha$  parameter is shown inside parenthesis.

| AUC                                | BS   | IO   | TD   | BR   | X    |
|------------------------------------|------|------|------|------|------|
| DSLDS                              | 0.98 | 0.83 | 0.90 | 0.94 | 0.57 |
| FSLDS                              | 0.92 | 0.87 | 0.88 | 0.85 | 0.66 |
| $\alpha$ -mixture <sup>(0.5)</sup> | 0.98 | 0.89 | 0.93 | 0.92 | 0.67 |

## 2.4 Results

For both datasets we compare the performance of the DSLDS and the FSLDS for the task of inferring a patient’s state of health. Having obtained estimates  $s_t$  for each factor and each time step, we proceed to calculate Receiver Operating Characteristic (ROC) curves for the classification of each factor. We also measure the performance of the models by reporting the Area under each ROC curve (AUC). Plots of the ROC curves, comparing the DSLDS, FSLDS, and an  $\alpha$ -mixture of the two models, are shown in Figures 2 and 3.

In the case of the DSLDS, the features described in Section 2.1 involve a number of hyperparameters that need to be chosen. Fitting them with a standard cross-validation (CV) scheme when data are not abundant poses a non-negligible risk of overfitting. As is shown in Varma and Simon (2006), using CV to evaluate performance of a model when the model’s hyperparameters have been themselves tuned using CV can lead to an optimistic bias of the estimate of the true performance. In that same work, a nested CV approach is shown to yield an almost unbiased estimate of the true performance, which we also follow in our experiments. In the outer loop the data are partitioned into  $P$  disjoint test sets. After choosing one of these partitions, the rest of the data are used in the inner loop in a standard CV setup to select the hyperparameters. The hyperparameters which yielded the highest performance (average cross-validated AUC across factors in our case) in the inner loop are then used to estimate the performance of the model on the partition (test set) in the outer loop. This process is repeated  $P$  times, once for each partition in the outer loop. For both datasets, we use leave-one-patient-out CV for the

inner loop and 3-fold CV for the outer loop. In the inner loop, we perform a grid search over hyperparameters in the following sets: a) number of trees of random forest classifiers in  $\{10, 25, 50, 100, 200\}$ ; b)  $l$  in  $\{4, 9, 14, 19, 29, 49\}$ ; c)  $r$  in  $\{0, 5, 10\}$ . The sub-segments lengths (for slope features) were always set to  $\max\{5, (l + r + 1)/5\}$  and the kernel widths (for moving average features) were always set to  $\max\{5, (l + r + 1)/5\}$ .

In the case of the FSLDS, it is not necessary to follow the same procedure. Using the AIC score, as shown in Section 1.3, for choosing the orders of the ARIMA processes (which constitute the model’s hyperparameters) avoids potential overfitting by penalising the model’s likelihood as the parameters grow. We therefore use 3-fold CV to evaluate the FSLDS’s performance.

To evaluate the  $\alpha$ -mixture model, we have chosen the optimal  $\alpha$  value as the one that maximises the average AUC across factors, via 3-fold CV. This also allowed us to explore the behaviour of the model as a function of  $\alpha$  for both datasets.

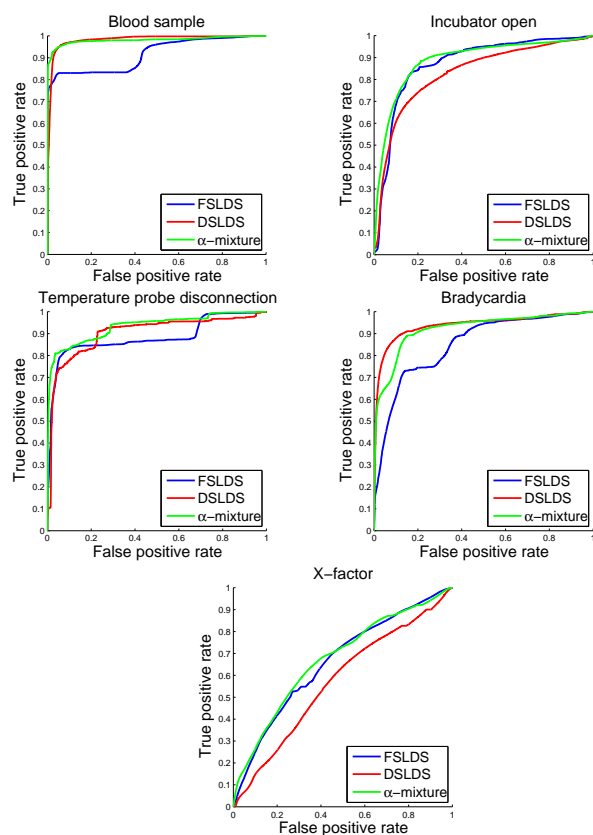

Figure 2: ROC curves per modelled factor in the case of the neonatal ICU.

## 2.4.1 Neonatal ICU

In the case of the neonatal ICU we compare the two models on the full set of annotated factors reported in Quinn *et al.* (2009). The results are shown in Table 2<sup>3</sup>. The DSLDS outperforms the FSLDS in three out of the four clinically identified factors. The difference in favour of the DSLDS is clear for bradycardias and blood samples, but less pronounced for core temperature disconnections. The FSLDS achieves slightly higher performance in the case of the incubator open factor, and clearly outperforms the DSLDS in the case of the X-factor. The FSLDS models the presence of outliers by the inclusion of an extra factor, which is essentially governed by the same parameters as stability with the only difference being that the system noise covariance is an inflated version of the respective covariance of the stability dynamics (for more details, see Quinn *et al.*, 2009). Such an approach has the potential to address the issue of outlier detection in a more general and thus more satisfactory way. In the case of the DSLDS, our approach is to collectively treat all abnormal events, other than the ones attributed to known factors, as an “X-class” and build a binary classifier to distinguish that class. As the training datapoints for this class are highly inhomogeneous in terms of shared discriminative features, and test points belonging to the X-class may not exhibit a high degree of similarity to the training set, it is not surprising that the DSLDS may perform rather poorly for the X-factor. However, by considering an  $\alpha$ -mixture of the two models, we can combine the discriminative power of the DSLDS for known factors with the increased performance of the FSLDS for the X-factor, thus achieving a higher performance (bottom line of Table 2) compared to considering the two models separately. The behaviour of the  $\alpha$ -mixture model as a function of  $\alpha$  is shown in Figure 5 (top). The optimal  $\alpha$ -mixture ( $\alpha = 0.5$ ) yields the best average AUC across factors (in fact,  $\alpha = 0.5$  yields optimal performance for each factor separately except bradycardia, where it is almost optimal) compared to all other considered  $\alpha$  values and also outperforms the DSLDS and the FSLDS in all cases except for the bradycardia factor, where the DSLDS performs slightly better.

## 2.4.2 Adult ICU

In the case of the adult ICU, inferences for two example events are shown in Figure 4. In the top, a damped trace event is shown, which lasts for almost one hour before being resolved by a flushing event (spiking of both channels). The DSLDS accurately identifies the damped trace event,

<sup>3</sup>The FSLDS results were obtained using code provided by Quinn *et al.* (2009) with the same parameters as the ones mentioned there. The results are very close with the exception of the core temperature disconnection factor (for which the reported AUC in Quinn *et al.* (2009) was 0.79, while we obtained a value of 0.88), and the blood sample factor (for which the reported AUC in Quinn *et al.* (2009) was 0.96, while we obtained a value of 0.92).

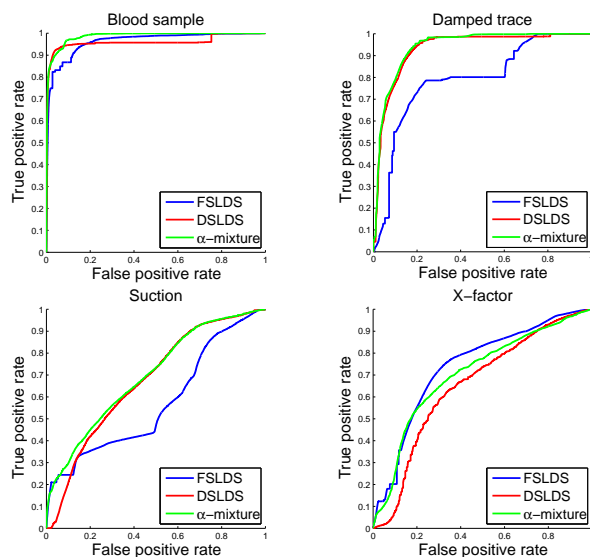

Figure 3: ROC curves per modelled factor in the case of the adult ICU.

Table 3: Comparison of DSLDS, FSLDS and  $\alpha$ -mixture performance for the Adult ICU dataset. Optimal value of the  $\alpha$  parameter is shown inside parenthesis.

| AUC                              | BS   | DT   | SC   | X    |
|----------------------------------|------|------|------|------|
| DSLDS                            | 0.96 | 0.93 | 0.67 | 0.65 |
| FSLDS                            | 0.95 | 0.79 | 0.57 | 0.74 |
| $\alpha$ -mixture <sup>(0)</sup> | 0.99 | 0.94 | 0.70 | 0.71 |

while the FSLDS fails totally to detect it, but hypothesises several incorrect blood sample events. In the bottom panel a blood sample event is shown, where the multiple stages are clearly visible. The event starts with two artifactual ramps, followed by a flushing, a zeroing, and finally with another flushing. This is slightly different than the description we have already given, but slight deviations from the standard protocol due to human error is to be expected. In this case, both models manage to capture the event in a generally satisfactory manner. Summary results are reported in Table 3. The DSLDS outperforms the FSLDS on all of the known factors. The damped trace and suction events particularly are characterised by high variability which is hard to capture with a generative process. However, simple discriminative features are able to capture them with higher accuracy. As was expected, the FSLDS achieves a higher AUC for the X-factor. Again, the optimal  $\alpha$ -mixture ( $\alpha = 0$ ) outperforms the DSLDS and the FSLDS in all cases except for the X-factor, where the FSLDS achieves a slightly higher AUC. Contrary to the neonatal ICU dataset, as shown in Figure 5 (bottom) there are alternative  $\alpha$  values

Figure 4: Example of DSLDS and FSLDS inferences for a damped trace event (top) and a blood sample event (bottom).

which can yield higher AUC across different factors. For example, an X-factor AUC value of 0.76 can be obtained by setting  $\alpha = 5$ . However, apart from the superior (on average) performance of the  $\alpha$ -mixture, another appealing property is that  $\alpha$  could be treated as a user-tunable parameter. In a practical setting, the model could be preset with the optimal  $\alpha$  value, but a clinician could decide, for example, to make the model focus on maximising its predictive performance on the X-factor (or some important physiological factor like bradycardia) to the potential detriment of other factors. Then the model could adjust its  $\alpha$  parameter in real-time based on training data results to maximise its performance on the desired factor.

### 2.4.3 Inference for x-state

Finally, Figure 6 shows the inferred distribution of underlying physiology during a blood sample taken from a neonate for both models. In both cases, estimates are propagated with increased uncertainty under the correctly inferred artifactual event. Note a small difference at the start of the event: The DSLDS partially identifies the event causing an increase in uncertainty, while the FSLDS (incorrectly) identifies this part as stable and thus its x-state update exhibits lower uncertainty. Maintaining an estimate of the underlying vital signs in the presence of artifacts can then be used for data imputation. Another use, which has been deemed important by our clinical experts, is that such an estimate can help doctors maintain an approximate view of a patient’s underlying physiology during artifactual events that would otherwise completely obscure a patient’s vital signs. This can be crucial during treatment of a patient un-

Figure 5: Performance of the  $\alpha$ -mixture models as a function of  $\alpha$  ( $step = 0.25$ ) for the Adult ICU (top) and the neonatal ICU dataset (bottom). The asterisk marks the optimal value for  $\alpha$ .

der critical conditions, such as the ones found in an ICU.

### 3 DISCUSSION

We have presented a discriminative approach for the very important application of patient monitoring in ICUs. We show that our new approach is able to outperform the previous generative approach used for the same task in most of the investigated cases. We also show that an  $\alpha$ -mixture of the two approaches yields better results than either model separately. In our approach we have assumed that the prediction of the switching variable factorises over the state space. However, one could use a structured output model to predict the joint distribution of different factors. Finally, another issue is the lack of explicit temporal continuity in the  $s$ -chain. Implicitly, this is handled by the feature construction process. However, a future direction could be to establish a Markovian connection on the  $s$ -chain too and compare with our current approach.

## Abstract

While influence maximization in social networks has been studied extensively in computer science community for the last decade the focus has been on the *progressive* influence models, such as independent cascade (IC) and Linear threshold (LT) models, which cannot capture the *reversibility of choices*. In this paper, we present the Heat Conduction (HC) model which is a *non-progressive influence model* with real-world interpretations. We show that HC unifies, generalizes, and extends the existing non-progressive models, such as the Voter model [1] and non-progressive LT [2]. We then prove that selecting the optimal seed set of influential nodes is NP-hard for HC but by establishing the submodularity of influence spread, we can tackle the influence maximization problem with a scalable and provably near-optimal greedy algorithm. We are the first to present a scalable solution for influence maximization under non-progressive LT model, as a special case of the HC model. In sharp contrast to the other greedy influence maximization methods, our fast and efficient C2GREEDY algorithm benefits from two analytically computable steps: *closed-form* computation for finding the influence spread as well as the greedy seed selection. Through extensive experiments on several large real and synthetic networks, we show that C2GREEDY outperforms the state-of-the-art methods, in terms of both influence spread and scalability.

## 1 INTRODUCTION

Motivated by viral marketing and other applications, the problem of influence maximization in a social network has attracted much attention in recent years. Given a social network where nodes represent users in a social group, and edges represent relationships and interactions between the

users (and through which they influence each other), the basic idea of influence maximization is to select an initial set of “most influential” users (often referred to as the *seeds*) among all users so as to maximize the total influence under a given diffusion process (often referred to as the *influence model*) on the social network. In the context of viral marketing, this amounts to initially targeting a set of influential customers, e.g., by providing them with free product samples, with the goal to trigger a cascade of influence through “word-of-mouth” or recommendations to friends to maximize the total number of customers adopting the said product. Domingos and Richardson [3] introduced this algorithmic problem to the Computer Science community and Kempe et al. [2] made the topic vastly popular under the name of *influence maximization*. They studied two influence models, the independent cascade (IC) model and the linear threshold (LT) model, and applied a greedy method to tackle the influence maximization problem [2]. Unfortunately Kempe et al.’s approach [2] for calculating the influence spread is based on Monte Carlo simulations which does not scale to large networks [4,5]. As the result, it motivated researchers to either improve the scalability [4,5] or study more tractable influence models [6,7].

The focus of almost all of these earlier studies are, however, *progressive* influence models, including LT and IC models, in which once a customer adopts a product or a user performs an action she cannot revert it. Retweeting news and sharing videos in online social network websites, are examples of progressive, i.e. irreversible actions. Nevertheless, there are numerous real world instances where the actions are *non-progressive*, especially in the technology adoption domain. For example, adopting a cell phone service provider, such as AT&T and T-mobile, is a non-progressive action where a user can switch between providers. The objective of influence maximization in this example is to persuade more users to adopt the intended provider for a longer period of time. To capture the reversibility of choices in real scenarios, we present the Heat Conduction (HC) model that unifies, generalizes, and extends the existing non-progressive models, including non-progressive LT (NLT) [2] and Voter model [1] (see Section 5). In contrast

---

\* G. Golnari and A. Asiaee contributed equally to this work.

to the Voter model, HC does not *necessarily* reach consensus, where one product dominates and extinguishes the others after finite time, so the proposed HC model can explain the *coexistence of multiple product adoptions*, which is a typical phenomena in the real world. In addition, the HC model incorporates both “social” and “non-social” factors, e.g., intrinsic inertia or reluctance of some users in adopting a new idea or trying out a new product, external “media effect” which exerts a “non-social” influence in promoting certain ideas or products.

We tackle the influence maximization problem under the HC influence model with a *scalable* and provably *near-optimal* solution. The approach by Kempe et al. [2] for influence maximization under NLT model, is to reduce the model to (progressive) LT by replicating the network as many as time progresses and compute the influence spread by the same slow Monte Carlo method for the resulted huge network. This approach is practically impossible for large networks, specially for the *infinite time horizon*. We also prove that contrary to the Voter model, for which the influence maximization can be solved *exactly* in polynomial time [1], the influence maximization for HC is NP-hard. We develop an approximation (greedy) algorithm for influence maximization under HC for infinite time horizon with guaranteed *near-optimal* performance. We are able to provide *closed form* solution for both computing the influence spread and greedy selection step which entirely removes the need to explicitly evaluate each node as the best seed candidate. Our fast and scalable algorithm, C2GREEDY, for influence maximization under the HC model removes the computational barrier that prevented the literature from considering the non-progressive influence models.

Our extensive experiments on several large real and synthetic networks validate the efficiency and effectiveness of our method which outperforms the state-of-the-art in terms of both influence spread and scalability. We show that the most influential nodes under progressive models does not necessarily act as the most influential nodes under non-progressive models and a *designated* non-progressive algorithm is necessary. Moreover, we present the first real non-progressive cascade dataset which models the non-progressive propagation of research topics among network of researchers. Our contribution in this paper is as follows:

- We propose the HC influence model which unifies, generalizes, and extends the existing non-progressive models.
- We show that the HC has three key properties which enables us to solve the influence maximization efficiently.
- To the best of our knowledge, we are the first to present a scalable solution for influence maximization under non-progressive LT model.
- We demonstrate high performance and scalability of our algorithm via extensive experiments and present the first ever real non-progressive cascade dataset.

The rest of this paper is organized as follows. After a brief

review on the related work, we introduce our HC model in Section 2. Next, we show how to compute the influence spread for HC in closed form in Section 3. In Section 4, we present our efficient algorithm C2GREEDY for influence maximization under the HC model. Section 5 explains how HC unifies other non-progressive models and provides a more complete view of the HC model. Finally we conduct comprehensive experiments in Section 6 to illustrate performance of our algorithm.

**Related work.** After the debut of influence maximization as a data mining problem [3], it is formulated as a discrete optimization problem based on progressive influence models (LT and IC) from social and physical sciences [2]. Kempe et al. [2] show that influence maximization is NP-hard under LT and IC models but the influence spread is submodular for the models which enables them to use the greedy method. Although the algorithm is greedy it usually does not scale, because it needs to compute influence spread many times in each iteration while influence spread has no known closed form and is estimated by Monte Carlo simulation. The follow-up studies [4–9] attempt to speed up this process by avoiding or decreasing the need for the MC simulation (for further details of the studies on progressive influence model please refer to Supplementary). Kempe et al. [2] also introduce a non-progressive version of the LT influence model (NLT) and try to tackle the influence maximization problem under NLT by reducing the model to (progressive) LT, discussed in Section 1.

The Voter model, as the most well-known non-progressive model, is originally introduced in [10, 11] and adopted for viral marketing in [1]. Even-Dar and Shapira show that under the Voter model, highest degree nodes are the solution of influence maximization [1]. Unfortunately since the Voter model reaches consensus, i.e. one product remains in long term, it can not explain the coexistence of multiple product adoptions, which is a typical case in many real product adoptions.

## 2 HEAT CONDUCTION INFLUENCE MODEL

The heat conduction (HC) influence model is inspired by the resemblance of influence diffusion through a social network to heat conduction through an object, where heat is transferred from the part with higher temperature to the part with lower temperature. We provide a simple description of HC in this section and defer the complete view of it as well as its unification property to Section 5.

Considering a directed graph  $G = (\mathcal{V}, \mathcal{E})$  which represents a social (influence) network, where the directed edge from node  $i$  to node  $j$  declares that  $i$  follows  $j$  (or equivalently  $j$  influences  $i$ ). The edge weight  $\omega_{ij}$  indicates the amount that  $i$  trusts  $j$ , and  $0 \leq \omega_{ij} \leq 1$ . The set of  $i$ 's neighbors, representing the nodes that influence  $i$ , is denoted by  $\mathcal{N}(i)$ . The influence cascade can be assumed as a *binary* process in which a node who adopts the “desired” product is called

*active*, and *inactive* otherwise. Note that this assumption holds for the cases with multiple products as well, where the objective is to maximize the influence (publicity) of the “desired” product, and the rest are all considered “undesired”. *Seed* is a node that has been selected for the direct marketing and remains active during the entire process. In the HC model, the influence cascade is initiated from a set of seeds  $S$  and arbitrary values for other nodes. The *choice* of node  $i$  to become active or inactive at time  $t + 1$  is a linear function of the choices of its neighbors at time  $t$  as well as its intrinsic (or non-social) bias toward activeness:

$$Pr(\delta_i(t+1) = 1 | \mathcal{N}(i)) = \beta_i b + (1 - \beta_i) \sum_{j \in \mathcal{N}(i)} \omega_{ij} \delta_j(t), \quad (1)$$

where  $\beta_i \in (0, 1)$ ,  $b \in [0, 1]$ , and  $\sum_{j \in \mathcal{N}(i)} \omega_{ij} = 1$ . Indicator function  $\delta_i(t)$  is 1 when node  $i$  adopts the desired product at time  $t$  and 0 otherwise. We refer to (1) as the *choice rule*. The dependence on neighbors in (1) represents the “social” influence and the bias value  $b$  accounts for “non-social” influence which comes from any source out of the neighbors, e.g. media. The “non-social” influence can explain the cases where the “social” influence alone fails to model the cascades [12]. We discuss further interpretation and extensions of HC in Section 5.

Replacing the choice rule (1) in  $Pr(\delta_i(t + 1)) = \sum Pr(\delta_i(t + 1) | \mathcal{N}(i)) Pr(\mathcal{N}(i))$  results in the following *probabilistic* interpretation of the original binary HC model. Each node  $i$  has a value at time  $t$  denoted by  $u(i, t)$  which represents the *probability* that she adopts the desired product at time  $t$ :

$$u(i, t + 1) = \beta_i b + (1 - \beta_i) \sum_{j \in \mathcal{N}(i)} \omega_{ij} u(j, t), \quad (2)$$

Simple calculation shows that the bias value  $b$  can be integrated into the network by adding a bias node  $n$  (assuming that the network has  $n - 1$  nodes) with adoption probability  $b$ . Therefore, HC dynamics converts to the following:

$$u(i, t + 1) = \sum_{j \in \mathcal{EN}(i)} P_{ij} u(j, t), \quad (3)$$

where  $\mathcal{EN}(i) = \mathcal{N}(i) \cup \{n\}$  is the extended neighborhood,  $P_{in} = \beta_i$ ,  $u(n, t) = b$ , and  $\forall j \neq n : P_{ij} = (1 - \beta_i) \omega_{ij}$ . Rewriting (3) in the following form shows that HC follows the discrete form of **Heat Equation** [13], which reveals the naming reason of HC influence model:  $u(:, t + 1) - u(:, t) = (P - I)u(:, t)$ , where  $\mathcal{L} = I - P$  is the Laplacian matrix,  $u(i, t)$  is the temperature of particle  $i$  at time  $t$ , and “:” denotes the vector of all entries.

### 3 HC INFLUENCE SPREAD

The influence spread of set  $S$  for time  $t$  is defined as the expected number of active nodes at time  $t$  of a cascade started with  $S$ . Knowing that  $u(i, t)$  is the probability of node  $i$  being active at time  $t$ , *influence spread* (or function)  $\sigma(\mathcal{S}, t)$

is computed from:

$$\sigma(\mathcal{S}, t) = \sum_{i \in \mathcal{V}} u(i, t). \quad (4)$$

Motivated by the classical heat transfer methods, the initial and the boundary conditions should be specified to solve the heat equation and find  $u(i, t)$  uniquely. In HC, the seeds  $S$  and the bias node are the boundary nodes and the rest are interiors. Assuming  $\mathcal{S} = \{n - 1, n - 2, \dots, n - |\mathcal{S}|\}$  and  $n$  as the bias node, HC is defined by the following heat equation system:

$$\begin{aligned} \text{Main equation} & : u(:, t + 1) - u(:, t) = -\mathcal{L}u(:, t) \\ \text{Boundary conditions} & : u(n, t) = b, \\ & u(s, t) = 1 \quad \forall s \in \mathcal{S} \\ \text{Initial condition} & : u(:, 0) = z + [0, \dots, 0, \underbrace{1, \dots, 1}_{|\mathcal{S}|}, b]', \end{aligned} \quad (5)$$

where, as indicated in this formula, initial value  $u(:, 0)$  is the sum of two vectors: the initial values of the interior nodes ( $z$ ) and the initial values of boundaries (the second vector). The corresponding entries of boundaries in  $z$  are zero. In the continue, exploiting probability theory and novel Markov chain metrics, we provide a closed form solution to this heat equation system.

Social network  $G$  can be interpreted as an absorbing Markov chain where the absorbing states (boundary set  $\mathcal{B}$ ) are the seeds and bias node,  $\mathcal{B} = \mathcal{S} \cup \{n\}$ , and  $P_{ij}$  is the probability of transition from  $i$  to  $j$ . The adoption probability of the nodes at time  $t$ , i.e.  $u(:, t)$ , can be written as a linear function of initial condition (3):

$$u(:, t) = P^t u(:, 0), \quad (6)$$

where  $P$  is row-stochastic and has the following block form:  $P = \begin{bmatrix} R & B \\ \mathbf{0} & I \end{bmatrix}$ . The superscript indicates the time here. The boundary set by definition have fixed values over time and do not follow any other nodes which leads to the zero and identity blocks  $I_{(|\mathcal{S}+1|) \times (|\mathcal{S}+1|)}$ . Blocks  $R$  and  $B$  represent transition probabilities of interior-to-interior and interior-to-boundary respectively. Note that different boundary conditions in (5), like different seed set, result in a different  $P$ . Therefore both  $P$  and  $u(:, t)$  implicitly depend on  $\mathcal{S}$ .

When  $t$  goes to infinity, transient part of  $u$  vanishes and it converges to the steady-state solution  $v = u(:, \infty)$ , which is independent of time and is Harmonic, meaning that it satisfies  $Pv = v$  [14]. Assume  $v = (v_{\mathcal{I}}, v_{\mathcal{B}})^T$  where  $\mathcal{I} = \mathcal{V} \setminus \mathcal{B}$  is the set of interior nodes, then the value of interior nodes is computed from boundary nodes [14]:

$$v_{\mathcal{I}} = (I - R)^{-1} B v_{\mathcal{B}} = F B v_{\mathcal{B}} = Q v_{\mathcal{B}}. \quad (7)$$

where  $F = (I - R)^{-1}$  is the *fundamental matrix* and  $F_{ij}$  indicates the average number of times that a random walk

started from  $i$  passes  $j$  before absorption by any absorbing (boundary) nodes [14]. Also, the *absorption probability* matrix  $Q = FB$  is a  $(n - |\mathcal{S}| - 1) \times (|\mathcal{S}| + 1)$  row-stochastic matrix, where  $Q_{ij}$  denotes the probability of absorption of a random walk started from  $i$  by the absorbing node  $j$  [14].

From here on, without loss of generality, we assume  $b$  to be zero in equation (5). Using (6) and (7), the influence spreads for infinite time can be computed in closed form:

$$\sigma(\mathcal{S}, \infty) = \sum_{i=1}^n v(i) = |\mathcal{S}| + \sum_{i \in \mathcal{I}} \sum_{s \in \mathcal{S}} Q_{is}^{\mathcal{S}}. \quad (8)$$

The superscript in  $Q^{\mathcal{S}}$  and  $P^{\mathcal{S}}$  explicitly indicates that they are functions of seed set  $\mathcal{S}$ . Note that in fact they are depending on the total boundary set,  $\mathcal{B} = \mathcal{S} \cup \{n\}$ , but since the bias node is always a boundary, throughout this paper we discard it from the superscripts to avoid clutter.

## 4 INFLUENCE MAXIMIZATION FOR HC

In this section we solve the influence maximization problem for *infinite time horizon* under the HC model:

$$\mathcal{S}^* = \operatorname{argmax}_{\mathcal{S} \subseteq \mathcal{V}} \sigma(\mathcal{S}, \infty), \quad s.t. \quad |\mathcal{S}| \leq K. \quad (9)$$

### 4.1 INFLUENCE MAXIMIZATION FOR $K = 1$

Based on (8) and (9), the most influential person (MIP) is the solution of the following optimization problem:  $\operatorname{argmax}_{\mathcal{V} \setminus \{n\}} \sum_{i \in \mathcal{V} \setminus \{s, n\}} Q_{is}^{\{s\}}$ . This equation states that to find the MIP, we need to pick each candidate  $s$  and make it absorbing and compute the new  $P$  as  $P^{\{s\}}$  which in turn changes  $Q$  to  $Q^{\{s\}}$ , and repeat this procedure  $n - 1$  times for all  $s$ . This procedure is problematic because for each  $Q^{\{s\}}$  we require to recompute matrix  $F^{\{s\}}$  which involves matrix inversion. But, in the following theorem we show that we are able to do this by only one matrix inversion instead of  $n - 1$  matrix inversions, and having matrix  $F^{\emptyset}$  is enough to find the most influential person of the network ( $\emptyset$  sign indicated no seed is selected):

**Theorem 1.** *MIP under HC (1) when  $t \rightarrow \infty$  can be computed in closed form from the following formula:*

$$MIP = \operatorname{argmax}_{s \in \mathcal{V} \setminus \{n\}} \sum_{i \in \mathcal{V} \setminus \{n\}} \frac{F_{is}^{\emptyset}}{F_{ss}^{\emptyset}} = \operatorname{argmax} \mathbf{1}' \check{F}^{\emptyset}, \quad (10)$$

where  $\check{F}^{\emptyset}$  is  $F^{\emptyset}$  when each of its columns is normalized by the corresponding diagonal entry. Note that left multiplication of all ones row vector is just a column-sum operation.

### 4.2 INFLUENCE MAXIMIZATION FOR $K > 1$

Although the influence maximization can be solved optimally for  $K = 1$ , the general problem (9) under HC for  $K > 1$  is NP-hard:

**Theorem 2.** *Given a network  $G = (\mathcal{V}, \mathcal{E})$  and a seed set  $\mathcal{S} \subseteq \mathcal{V}$ , influence maximization for infinite time horizon (9) under HC defined by (1) is NP-hard.*

In spite of being NP-hard, we show that the influence spread  $\sigma(\mathcal{S}, \infty)$  is *submodular* in the seed set  $\mathcal{S}$  which enables us to find a provable near-optimal greedy solution. A set function  $f : 2^{\mathcal{V}} \rightarrow \mathbb{R}$  maps subsets of a finite set  $\mathcal{V}$  to the real numbers and is submodular if for  $\mathcal{T} \subseteq \mathcal{S} \subseteq \mathcal{V}$  and  $s \in \mathcal{V} \setminus \mathcal{S}$ ,  $f(\mathcal{T} \cup \{s\}) - f(\mathcal{T}) \geq f(\mathcal{S} \cup \{s\}) - f(\mathcal{S})$  holds, which is the diminishing return property. Following theorem presents our established submodularity results.

**Theorem 3.** *Given a network  $G = (\mathcal{V}, \mathcal{E})$ , influence spread  $\sigma(\mathcal{S}, \infty)$  under the HC model is non-negative monotone submodular function.*

The greedy solution adds nodes to the seed set  $\mathcal{S}$  sequentially and maximizes a monotone submodular function with  $(1 - 1/e)$  factor approximation guarantee [15]. More formally the  $(k + 1)$ -th seed is the node with maximum **marginal gain**:  $(k + 1)$ -th-MIP $_t = \operatorname{argmax}_{s \in \mathcal{V} \setminus \{\mathcal{S}_k \cup \{n\}\}} \sigma(\mathcal{S}_k \cup \{s\}, t) - \sigma(\mathcal{S}_k, t)$ , where  $\mathcal{S}_k$  is the set of  $k$  seeds which have been picked already. Although we can compute the above objective function in closed form, for selecting the next seed we have to test all  $s$  to solve the problem which is the approach of all existing greedy based method in the literature. Previously a lazy greedy scheme have been introduced to reduce the number testing candidate nodes  $s$  [8]. In the next section we go one step further and show that under the HC model and for *infinite time horizon* we can solve the marginal gain in *closed form*.

### 4.3 GREEDY SELECTION

An important characteristic of the linear systems, like HC when  $t \rightarrow \infty$ , is the ‘‘superposition’’ principle. We leverage this principle to calculate the marginal gain of the nodes efficiently and pick the one with maximum gain for the greedy algorithm. Based on this principle, the value of each node in HC for infinite time, and for a given seed set  $\mathcal{S}$ , is equal to the algebraic sum of the values caused by each seed acting alone, while all other values of seeds have been kept zero. Therefore, when a node  $s$  is added to the seed set  $\mathcal{S}_k$ , its marginal gain can be calculated as the summation of values of the nodes when all of the values of  $\mathcal{S}_k$  have been turned to zero and node  $s$  is the only seed in the network, whose value is  $1 - v^{\mathcal{S}_k}(s)$ . In this new problem, the vector of boundary values  $v_{\mathcal{B}}^{\mathcal{S}_k \cup \{s\}}$  is a vector of all 0’s except the entry corresponding to the node  $s$  with value  $1 - v^{\mathcal{S}_k}(s)$ , and the value of interior node  $i$  is obtained from (7):

$$v_{\mathcal{I}}^{\mathcal{S}_k \cup \{s\}}(i) = Q_{is}^{\mathcal{S}_k \cup \{s\}}(1 - v^{\mathcal{S}_k}(s))$$

Substituting  $Q$  from lemma 3 result (see Supplementary), the  $k + 1$ -th seed is determined from the following closed

form equation:

$$\begin{aligned}
& (k+1)\text{th-MIP} \\
& = \operatorname{argmax}_{s \in \mathcal{V} \setminus \{\mathcal{S}_k \cup \{n\}\}} \sum_{i \in \mathcal{V} \setminus \{\mathcal{S}_k \cup \{n\}\}} \frac{F_{is}^{S_k}}{F_{ss}^{S_k}} (1 - v^{S_k}(s)), \\
& = \operatorname{argmax}(\mathbf{1} - v^{S_k})' \check{F}^{S_k} \tag{11}
\end{aligned}$$

Note that vector  $v^{S_k}$  is obtained in step  $k$  and is known, and matrix  $F^{S_k}$  can be calculated from  $F^{S_{k-1}}$  without any need for matrix inversion (see Supplementary, lemma 1). One may observe that equation (11) is the general form of Theorem 1, since  $v^{S_0} = v^\emptyset = 0$ . Notice that equation (11) intuitively uses two criteria for selecting the new seed: its current value should be far from 1 (higher value for  $(1 - v^{S_k}(s))$  term) which suggests that it is far from the previously selected seeds, and at the same time it should have a high network centrality (corresponding to the  $F_{is}^{S_k}/F_{ss}^{S_k}$  term). Algorithm 1 summarizes our C2GREEDY method for  $t \rightarrow \infty$ : a greedy algorithm with 2 closed form steps. Operator  $\otimes$  in step 10 denotes the Hadamard product.

## 5 DISCUSSION

In this section, we present the comprehensive view of the HC model and elaborate its (unifying) relation to the other models by providing multiple interpretations.

**Social interpretation.** HC can be simply extended to model many real cases that the other influence models fail to cover. As briefly mentioned in Section 2, the original HC (1), models both “social” and “non-social” influences which cover the observations from the real datasets [12]. The extension of HC which is more flexible in modeling real world cascades is as follows:

$$u(i, t+1) = m\alpha_i + r\gamma_i + (1 - \gamma_i - \alpha_i) \sum_{j \in \mathcal{N}(i)} \omega_{ij} u(j, t), \tag{12}$$

where,  $\sum_{j \in \mathcal{N}(i)} \omega_{ij} = 1$ ,  $\gamma_i, \alpha_i \in [0, 1]$ ,  $m = 1$ , and  $r = 0$ . Factor  $r$  models the “discouraging” factor like intrinsic *reluctance* of customers toward a new product, and  $m$  represents “encouraging” factor like *media* that promotes the new product. These two factors can explain cases

where all neighbors of a node are active but the node remains inactive, or when a node becomes active while none of her neighbors are active [12]. Note that all of the formulas and results stated so far is simply applicable to the general HC model (12).

**Unification of existing non-progressive models.** HC (1) unifies and extends many of the existing non-progressive models. In the Voter model, a node updates its choice at each time step by picking one of its neighbors randomly and adopting its choice. In other words, the choice rule of node  $i$  is the ratio of the number of her active neighbors to her total number of neighbors. Thus, Voter’s choice rule is the simplified form of HC’s choice rule (1) where  $\omega_{ij}$  is equal to  $\frac{1}{d_i}$  ( $d_i$  is the out-degree of node  $i$ ) and all  $\beta_i$ s are set to zero. Also, note that having  $\beta_i = 0$  indicates that the Voter does not cover the “non-social” influence.

In the *non-progressive* LT (NLT) [2], each node is assigned a random threshold  $\theta$  at each time step and becomes active if the weighted number of its active neighbors (at previous time step) becomes larger than its threshold:  $\sum_{j \in \mathcal{N}(i)} \omega_{ij} \delta_j(t) \geq \theta_i(t+1)$ , where the edge weights satisfy  $\sum_{j \in \mathcal{N}(i)} \omega_{ij} \leq 1$ . Thus, the choice rule of node  $i$  at time  $(t+1)$  under the NLT is obtained from the following equation:

$$\begin{aligned}
Pr(\delta_i(t+1) = 1 | \mathcal{N}(i)) &= Pr(\theta_i(t+1) \leq \sum_{j \in \mathcal{N}(i)} \omega_{ij}^{\text{NLT}} \delta_j(t)) \\
&= \sum_{j \in \mathcal{N}(i)} \omega_{ij}^{\text{NLT}} \delta_j(t), \tag{13}
\end{aligned}$$

where the second equality is the result of sampling  $\theta_i(t+1)$  from the *uniform distribution*  $U(0, 1)$ . Equation (13) is the simplified form of HC’s choice rule (1), where  $b = 0$  and  $(1 - \beta_i) \omega_{ij}^{\text{HC}} = \omega_{ij}^{\text{NLT}}$ . Note that since in the NLT  $b$  accepts only zero value, this influence model also cannot cover *encouraging* “non-social” influence. Moreover, if the edge weights’ gap in NLT, i.e.  $g_i = 1 - \sum_{j \in \mathcal{N}(i)} \omega_{ij}^{\text{NLT}}$ , is zero for all the nodes, it cannot model the “non-social” influence at all, since the corresponding  $\beta_i$ ’s in (1) would be equal to zero in that case.

Generalized linear threshold (GLT) is another non-progressive model proposed in [16] to model the adoption process of *multiple* products. Assigning a color  $c \in \mathcal{C}$  to each product, a node updates its color, at each time step, by randomly picking one of its neighbors based on its edge weights and adopts the selected neighbor’s color. For binary case  $|\mathcal{C}| = 2$ , where we only distinct between adoption of a desired product (active) and the rest of products (inactive), GLT’s choice rule reduces to the following equation:  $Pr(\delta_i(t+1) = 1 | \mathcal{N}(i)) = \frac{\beta}{2} + (1 - \beta) \sum_{j \in \mathcal{N}(i)} \omega_{ij} \delta_j(t)$ . It is easy to see that this is the restricted form of HC’s choice rule (1), where nodes are all connected to the bias node with equal weight of  $\beta$  and bias value  $b$  has to be  $\frac{\beta}{2}$ .

**Physical interpretation.** We showed that the existing non-progressive models are special cases of HC, and in this part we describe their equal heat conduction system

Table 1: Specifying the equal heat system for existing non-progressive influence models.

| Model | Non-Social influence | Weighted edges | Boundary     |             | Init. Cond. |          | Equivalent Physical Heat Conduction System    |
|-------|----------------------|----------------|--------------|-------------|-------------|----------|---|
|       |                      |                | High $T = 1$ | Low $T < 1$ | $= 0$       | $\neq 0$ |   |

which are uniquely specified by the initial and boundary conditions. Table 1 summarizes the heat interpretation of the influence models. We introduce four variants of non-progressive LT, based on two factors: seed and gap  $g_i$ . NLT1 and NLT2 support non-zero gaps, and NLT2 and NLT4 allows seeds, i.e. nodes in the network that always remain active. The non-progressive LT model presented in [2] is equivalent to NLT2. Reluctance factor and seeds in all models are equivalent to the low and high temperature boundaries respectively, and initial condition addresses the interiors’ initial values ( $z$  in (5)). The non-social influence and edge weights factors appear in the Laplacian matrix calculation of (5). The equivalent physical heat conduction systems are easy to understand, here we just briefly point out the equivalence of the Voter model and the isolated circular ring. Circular ring is a rod whose ends are connected to each other and do not have any energy exchange with outside [17] which explains why the Voter conserves the total initial heat energy, and reaches to an equilibrium with an equal temperature for all of the nodes, i.e., consensus.

**Random walk interpretation.** Beside the heat conduction view, the random walk prospect helps to gain a better understanding of the models and their relations. Assume that active and inactive nodes are colored black and white respectively. Consider the *original view* of any influence model which is the actual process that unfolds in time, so we look at the time-forward direction. We take a snapshot of the colored network at each time step  $t$ . Putting together the sequence of snapshots, the result is a random walk in the “colored graphs” state space with  $2^n$  states. On the other hand, the *dual view* looks at the time-reverse direction of influence models. It is known for both IC-based models (like IC [2] and ConTinEst [7]) and LT-based models (Table 1 as well as HC and LT) that a single node from  $\mathcal{N}(i)$  is responsible for  $i$ ’s color switch, which we name it as the parent of  $i$ . Now assuming that the process has advanced up to the time  $t$ , we reverse the process by starting from each node  $i$  and follow its ancestors. Here is the point where IC and LT based models separate from each other: due to  $\sum_{j \in \mathcal{N}(i)} \omega_{ij} \leq 1$  constraint, ancestors of  $i$  in the LT-based models form a random walk starting from node  $i$ , which is not the case in IC-based models. Note that we have  $n$  random walks that can meet and merge, thus they are known as *coalescing random walks* [18]. This view also helps us to demonstrate the essential difference between progressive

and non-progressive models. Dual view of progressive LT model is a *coalescing self-avoiding walks* which is the outcome of randomizing the threshold  $\theta$  only once at the beginning of the process for the nodes in each realization. This bounds the number of “live” edges [2] connected to each node by one which prevents the creation of “loop” in the influence paths. Note that both counting and finding the probability of self-avoiding walks are  $\#P$  hard [4].

## 6 EXPERIMENTS

In this section, we examine several aspects of C2GREEDY and compare it with state-of-the-art methods. Experiments mainly focus on influence maximization and timing aspects. Finally, we present one example of real non-progressive data and illustrate the result of C2GREEDY.

### 6.1 DATASET

Table 2 summarizes the statistics of the networks that we use throughout the experiments. We work with both synthetic and real networks which we briefly discuss next.

**Synthetic network generation.** We consider the following types of Kronecker network for extensive performance comparison of our method with the state-of-the-art methods: random [19] (parameter matrix [0.5, 0.5; 0.5, 0.5]), hierarchical [20] ([0.9, 0.1; 0.1; 0.9]), and core-periphery [21] ([0.9, 0.5; 0.5, 0.3]). We generate 10 samples from each network and report the average performance of each method. Edge weights are drawn uniformly at random from [0, 1] and weights of each node’s outgoing edges is normalized to 1. For timing experiment, we use ForestFire [20] (Scale-free) network with forward and backward burning probability of 0.35 and 0.25, respectively, and set the outgoing edge weights of node  $i$  to  $1/|\mathcal{N}(i)|$ . The expected density, i.e., number of edges per node, for the resulted ForestFire networks is 2.5.

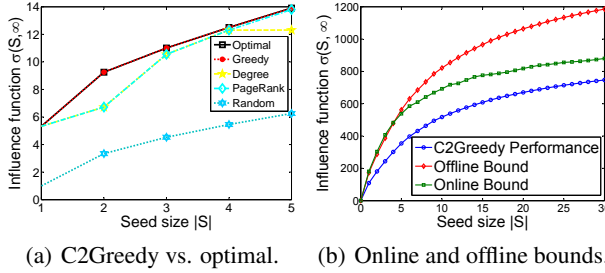

Figure 1: For small network (a) shows C2Greedy matches the optimal performance. For a larger network (b) compares performance of C2Greedy with online and offline bounds.

**Real Networks.** Zachary’s karate club network (KClub) is a small friendship network with 34 nodes and 501 edges [22]. The political blogs network (P Blogs) [23], is a moderate size directed network of hyperlinks between weblogs on US politics with 1490 nodes and 19087 edges. Wikipedia vote network (WikiVote), is the network of who-vote-whom from wikipedia administrator elections [24] with 7115 nodes and 103689 edges. Finally, MLFWF is the network of who-follow-whom in the machine learning research community which we extract from citation networks of combined ACM and DBLP citation network which is available as a part of ArnetMiner [25]. For more information about MLFWF refer to Section 6.4.

For all synthetic and real networks, after constructing the network, we add the bias node to the network and connect all nodes to it with weight  $\beta_i = 0.1$  and re-normalize the weight of the other edges accordingly.

## 6.2 INFLUENCE MAXIMIZATION

In this section we investigate the performance of C2GREEDY in the main task of influence maximization i.e., solving the set function optimization (9). Since finding the optimal solution for (9) is NP-hard, we compare C2GREEDY with optimal solution only for a small network, then for a large network we show that C2GREEDY result is close to the online bound [8]. We also compare the performance of C2GREEDY with the state-of-the-art methods proposed for solving (9) under different (mostly progressive) influence models.

**C2GREEDY vs. optimal.** For testing the quality of C2GREEDY method, we compare its performance with the best seed set (determined by brute force) on a small size network. We work with the KClub network for the brute-force experiment with  $K = 5$ . As Figure 1(a) shows C2GREEDY selects nodes that match the performance of the optimal seed set. In the next step, on a larger network, we show that the performance of C2GREEDY is close to the known online upper bound [8]. We compute the online and offline bounds of greedy influence maximization [8] with  $K = 30$  for P Blogs network. Figure 1(b) illustrates that C2GREEDY result is close to the online bound and therefore close to the optimal solution’s performance.

**C2GREEDY vs. state-of-the-art.** Next, we compare C2GREEDY with the state-of-the-art methods of influence maximization over three aforementioned synthetic networks and WikiVote real network. Among baseline methods PMIA [5] and LDAG [4] are approximation for IC and LT models respectively and SP1M [26] is a shortest-path based heuristic algorithm for influence maximization under IC. ConTinEst [27] is a recent method for solving continuous time model of [6] and PageRank is the well-known information retrieval algorithm [28]. Finally, Degree selects the nodes with highest degree as the most influential and Random picks the seed set randomly.

The comparison results are depicted in Figure 2. Interestingly, our algorithm outperformed all of the baselines. Strangely, ConTinEst performs close to Random (except in the random network). A closer look at the results for three synthetic networks reveal that except ConTinEst’s odd behavior all other methods have persistence rank in performance. C2GREEDY is the best method and is followed by PMIA and LDAG, both in second place, which are closely followed by SP1M. PageRank, Degree and Random are next methods in order. In WikiVote real network of Figure 2(d) surprisingly most of the state-of-the-art methods perform terribly poor and Degree (as the KMIP solution to the Voter model) is the only competitor of C2GREEDY. Result of experiment with WikiVote shows that most influential nodes in a progressive models are not necessary influential in non-progressive ones, and designing non-progressive-specific algorithms (like C2GREEDY) is required for influence maximization under non-progressive models.

## 6.3 SPEED AND SCALABILITY

In this part we illustrate the speed benefits of having two closed form updates in the greedy algorithm and also deal with the required single inverse computation of C2GREEDY to prove the scalability of our method.

**Closed form benefits.** As discussed in Section 4, our main algorithm C2GREEDY benefits from closed form computation for both influence spread (8) and greedy selection (11). To show the gain of these closed form solutions, we run the greedy algorithm in three different settings. First without using any of (8) and (11) which we call GREEDY and uses Monte Carlo simulation to estimate the influence spread. Second we only use (8) to have the closed form for influence spread without closed form greedy update of (11) which results in C1GREEDY, and finally C2GREEDY which uses both (8) and (11). Note that we can add lazy update of [8] (see Supplementary) to GREEDY and C1GREEDY to get LGREEDY and LC1GREEDY respectively. Finally we include the original greedy method [2] of solving LT model (progressive version of our model) and its lazy variant, with 100 iteration of Monte Carlo simulation. Note that for having a good approximation of influence spread in LT model, simulations are run for several thousand iterations, but here we just want to illustrate that

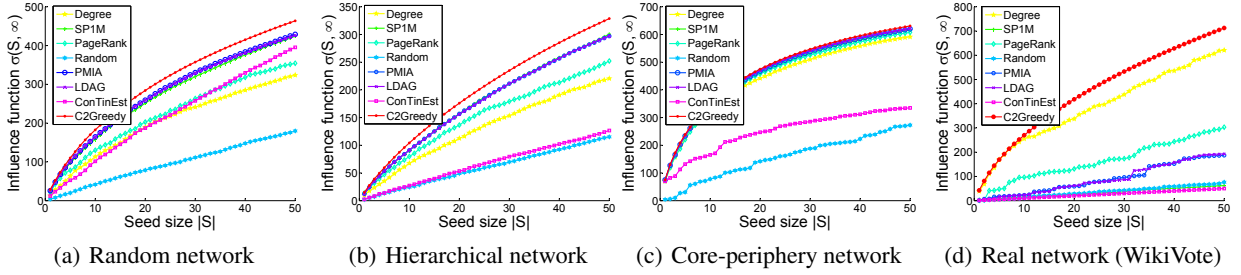

Figure 2: Comparing performance of C2Greedy with state-of-the-art influence maximization methods. Networks of (a), (b), and (c) are synthetic and (d) is a real network.

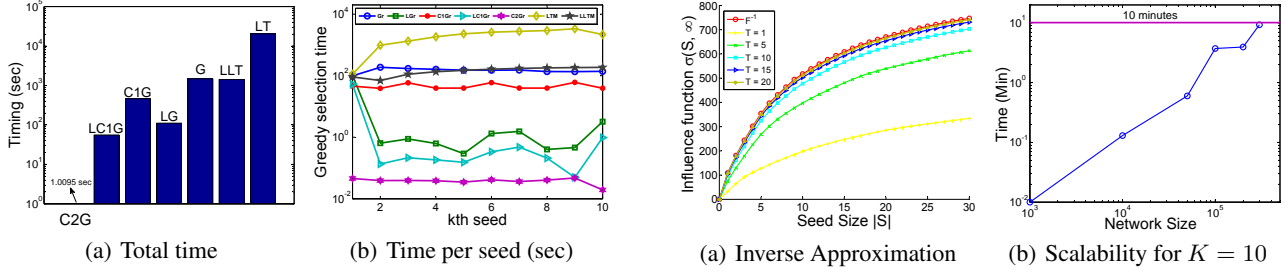

Figure 3: In (a) we compare the total timing of seven algorithms to investigate the effect of closed updates on speed and in (b) we show the per-seed required time for the same experiment.

Figure 4: Timing for inf. max. in large scale networks by exploiting (a) inverse approximation and (b) parallel programming. Results of (b) are on FF networks with edge density 2.5.

the greedy algorithm for HC is much faster than LT, for which 100 iterations is enough. Figure 3(a) illustrates the speed in log-scale of all seven algorithms for  $K = 10$  over the Pblogs dataset [23]. Note that the required time of inverse computation (7) is also included. The results confirm that both closed forms decrease the timing *significantly* (1 sec vs. 461 sec for the next best variation) and help the greedy algorithm far more than the lazy update.

**Per-seed selection time.** The major computational bottleneck of our algorithm is the inverse computation of (7). But fortunately this is needed once and at the beginning of the process. Here assuming offline inverse computation, we are interested in the cost of adding each seed. Figure 3(b) compares the cost of selecting  $k$ -th seed for the five variation of our algorithm, plus LT and LazyLT all described previously. As expected C2GREEDY requires the lowest computation time per seed. Also, the timing per seed for C2GREEDY is strictly decreasing over the size of  $\mathcal{S}$ , because the matrix  $N$  shrinks, while per seed selection time of LT is increasing on average, because more seeds probably lead to bigger cascades.

**Inverse approximation.** Going beyond networks of size  $10^4$  makes the inverse computation problematic, but fortunately we have a good approximation of the inverse through the following expansion:  $F = (I - R)^{-1} \approx I + R^1 + R^2 + \dots + R^T$ . Since all eigenvalues of  $R$  are less than or equal to 1 contribution of  $(R)^i$  to the summation drops very fast as  $i$  increases. The question is how many terms of the expansion,  $T$ , is enough for our application. Heuristically we choose the (effective) diameter of the graph as the number that provides us with a good approximation of  $F^{-1}$ . Note

that the  $i$ th term of the expansion pertains to the shortest paths of size  $i$  between any pair of nodes. Since the graph diameter is the longest shortest path between any pair of nodes, having that many terms gives us a good approximation of  $F^{-1}$ . This is also demonstrated by the experimental result of Figure 4(a) where we compare the result of the influence maximization on the WikiVote network with diameter 15, with actual  $F^{-1}$  and its approximation for different  $T$ 's. As discussed when  $T$  reaches to the diameter, the result of the algorithm that uses inverse approximation coincides with the algorithm that uses the exact inverse.

**Scalability.** Finally to show the scalability of C2GREEDY we perform influence maximization on networks with sizes up to  $3 \times 10^5$ . For speeding up the large scale matrix computation of the Algorithm 1 we developed an MPI version of our code which allows us to run C2GREEDY on computing clusters. Figure 4(b) shows the running time of C2GREEDY for ForestFire networks of sizes varying between 1K to 300K with edge density 2.5 (i.e. ratio of edges to nodes) and effective diameter of 10. The MPI code was run on up to 400 cores of 2.8 GHz. As Figure 4(b) indicates even for the largest tested network with 0.3 million nodes and 0.75 million edges C2GREEDY takes less than 10 minutes for  $K = 10$ .

To give a sense of our achievement in scalability we briefly mention the result of one of the state-of-the-art methods: The scalable ConTinEst [7] runs with 192 cores for almost 60 minutes on ForestFire network of size 100K and edge density of 1.5 to select 10 seeds, where our C2GREEDY finishes in less than 2 minutes for the similar ForestFire

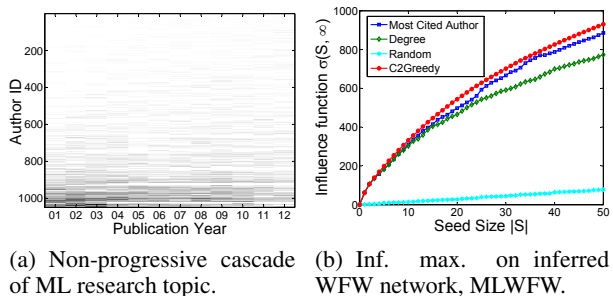

Figure 5: In (a) we show the existence of non-progressive cascade of ML research topic where white means all papers of the author is about ML. In (b) we compare C2Greedy result with other baselines such as most cited author.

network (100K nodes and density 1.8) with 200 cores.

#### 6.4 REAL NON-PROGRESSIVE CASCADE

Collaboration and citation networks are two well-known real networks that have been studied in social network analysis literature [2, 29]. Here we introduce a new network that represents who-follows-whom (WFW) in a research community. Note that the nodes in the collaboration and citation networks are authors and papers respectively but in WFW network nodes are authors and edges are inferred from citations. A directed edges  $(u, v)$  means that author  $u$  has cited one of the papers of author  $v$  which reveals that  $u$  follows/reads papers of  $v$ . Here we investigate the “research topic adoption” cascade. Researchers adopt new research topics during their careers and influence their peers along different research communities. The process starts with an arbitrary research topic for each author and they are influenced by the research topic of those they follow and switch to another topic. For example a data mining researcher that follows mostly the papers of machine learning authors is probably going to switch his research topic to machine learning.

For illustration, we consider only the authors who have published papers in Machine Learning (ML) conferences and journals in a given time period. For the list of ML related conferences and journal we use resources of Arnet-Miner project [25]. We consider each time step a year and study the years 2001 - 2012. An author is an *active* ML author in a given year if at least half of his publications in that year was published in ML venues. Figure 5(a) shows the change in the percentage of ML publication of ML authors who has more than 70 publication in years between 2001 and 2012. As Figure 5(a) suggests, cascade of ML research topic is a non-progressive process and researcher switch back and forth between ML and other alternatives. Among 1049 authors of Figure 5(a) about 400 of them are core ML authors who have rarely published in any other topic, but the non-progressive nature of the process is more visible in the rest (bottom part of Figure 5(a)).

Next we perform influence maximization on the inferred WFW network which we call MLFW network. We ex-

tract the MLFW network from the combined citation network of DBLP and ACM which is publicly available as a part of ArnetMiner project [25] and learn the edge weights similar to the weighted cascade model of [2]. The MLFW network of 2001 - 2012 time frame consists of 10604 authors and 168918 edges. Figure 5(b) compares the result of influence maximization using C2GREEDY and other baselines. Note that other than regular baselines in this specific domain we have another well-known method which is “most cited author” that is equal to selecting authors with highest weighted in-degree in MLFW network. As Figure 5(b) illustrates, C2GREEDY outperforms all of the other methods. Note that the list of  $K$  most influential authors in this experiment means that “if” those authors were switching to the ML topic completely (becoming a member of seed set  $S$ ) they would make the topic vastly popular. Therefore, although the seed set contains the familiar names of well-known ML authors (e.g., Michael I. Jordan and John Lafferty in first and second places), sometimes we encounter exceptions. For example, in the list of top 10 authors selected by C2GREEDY we have “Emery N. Brown” who is a renowned neuroscientist with publications in “Neural Computation” journal.

## 7 CONCLUSION

We introduced the Heat Conduction Model which is able to capture both social influence and non-social influence, and extends many of the existing non-progressive models. We also presented a scalable and provably near-optimal solution for influence maximization problem by establishing three essential properties of HC: 1) submodularity of influence spread, 2) closed form computation for influence spread, and 3) closed form greedy selection. We conducted extensive experiments on networks with hundreds of thousands of nodes and close to million edges where our proposed method gets done in a few minutes, in sharp contrast with the existing methods. The experiments also certified that our method outperforms the state-of-the-art in terms of both influence spread and scalability. Moreover, we exhibited the first real non-progressive cascade dataset for influence maximization. We believe that our method removes the computational barrier that prevented the literature from considering the non-progressive influence models. Studying other forms of non-progressive influence models, such as non-progressive IC, is an interesting future work.

## Abstract

We develop hierarchical Poisson matrix factorization (HPF), a novel method for providing users with high quality recommendations based on implicit feedback, such as views, clicks, or purchases. In contrast to existing recommendation models, HPF has a number of desirable properties. First, we show that HPF more accurately captures the long-tailed user activity found in most consumption data by explicitly considering the fact that users have finite attention budgets. This leads to better estimates of users' latent preferences, and therefore superior recommendations, compared to competing methods. Second, HPF learns these latent factors by only explicitly considering positive examples, eliminating the often costly step of generating artificial negative examples when fitting to implicit data. Third, HPF is more than just one method—it is the simplest in a class of probabilistic models with these properties, and can easily be extended to include more complex structure and assumptions. We develop a variational algorithm for approximate posterior inference for HPF that scales up to large data sets, and we demonstrate its performance on a wide variety of real-world recommendation problems—users rating movies, listening to songs, reading scientific papers, and reading news articles.

## 1 INTRODUCTION

Recommendation systems are a vital component of the modern Web. They help readers effectively navigate otherwise unwieldy archives of information and help websites direct users to items—movies, articles, songs, products—that they will like. A recommendation system is built from historical data about which items each user has consumed, be it clicked, viewed, rated, or purchased. First, it uncovers

the behavioral patterns that characterize various types of users and the kinds of items they tend to like. Then, it exploits these discovered patterns to recommend future items to its users.

In this paper, we develop Hierarchical Poisson factorization (HPF) for generating high-quality recommendations. Our algorithms easily scale to massive data and outperform several existing methods. We show HPF is tailored to real-world properties of user behavior data: the heterogeneous interests of users, the varied types of items, and a realistic distribution of the finite resources that users have to consume these items.

In more detail, HPF is a probabilistic model of users and items. It associates each user with a latent vector of preferences, each item with a latent vector of attributes, and constrains both sets of vectors to be sparse and non-negative. The model assumes that each cell of the observed behavior matrix is drawn from a Poisson distribution—an exponential family distribution over non-negative integers—whose parameter is a linear combination of the corresponding user preferences and item attributes. The main computational problem is posterior inference: given an observed matrix of user behavior, we would like to discover the latent attributes that describe the items and the latent preferences of the users, which we can then use to make predictions and recommendations.

This inferential computation is common to many variants of matrix factorization. We find, however, that HPF enjoys significant quantitative advantages over classical methods for a variety of *implicit feedback* data sets. Figure 4 shows that HPF performs better than competing methods—including the industry standard of matrix factorization with user and item biases (MF) fit using stochastic gradient descent—for large data sets of Netflix users watching movies, Last.FM users listening to music, scientists reading papers, and *New York Times* readers clicking on articles.

We review related work in detail in Section 4. We now discuss details of the Poisson factorization model, including

Figure 1: The hierarchical Poisson factorization model.

its statistical properties and methods for scalable inference.

## 2 POISSON RECOMMENDATION

In this section we describe the Poisson factorization model for recommendation, and discuss its statistical properties.

We are given data about users and items, where each user has consumed and possibly rated a set of items. The observation  $y_{ui}$  is the rating that user  $u$  gave to item  $i$ , or zero if no rating was given. In the “implicit” consumer data that we consider here,  $y_{ui}$  equals one if user  $u$  consumed item  $i$  and zero otherwise. User behavior data, such as purchases, clicks, or views, are typically sparse. Most of the values of the matrix  $y$  are zero.

We model these data with factorized Poisson distributions [4], where each item  $i$  is represented by a vector of  $K$  latent attributes  $\beta_i$  and each user  $u$  by a vector of  $K$  latent preferences  $\theta_u$ . The observations  $y_{ui}$  are modeled with a Poisson distribution, parameterized by the inner product of the user preferences and item attributes,  $y_{ui} \sim \text{Poisson}(\theta_u^\top \beta_i)$ . This is a variant of probabilistic matrix factorization [33] but where each user and item’s weights are positive [25] and where the Poisson replaces the Gaussian. While a Bernoulli distribution may seem more appropriate for modeling binary data, we demonstrate in Section 2.1 that the additivity of independent Poissons result in models that capture the marginal user, item distributions well.<sup>1</sup>

Beyond the basic data generating distribution, we place Gamma priors on the latent attributes and latent preferences, which encourage the model towards sparse representations of the users and items. Furthermore, we place additional priors on the user and item-specific rate parameter of those Gammas, which controls the average size of the representation. This hierarchical structure allows us to

<sup>1</sup>Our ongoing work considers censored Poisson distributions. Our initial results indicate that it is computationally expensive but does not give better performance.

capture the diversity of users, some tending to consume more than others, and the diversity of items, some being more popular than others. The literature on recommendation systems suggests that a good model must capture such heterogeneity across users and items [23].

Putting this together, the generative process of the hierarchical Poisson factorization model (HPF), illustrated in the graphical model in Figure 1, is as follows:

1. For each user  $u$ :
  - (a) Sample activity  $\xi_u \sim \text{Gamma}(a', a'/b')$ .
  - (b) For each component  $k$ , sample preference

$$\theta_{uk} \sim \text{Gamma}(a, \xi_u).$$

2. For each item  $i$ :
  - (a) Sample popularity  $\eta_i \sim \text{Gamma}(c', c'/d')$ .
  - (b) For each component  $k$ , sample attribute

$$\beta_{ik} \sim \text{Gamma}(c, \eta_i).$$

3. For each user  $u$  and item  $i$ , sample rating

$$y_{ui} \sim \text{Poisson}(\theta_u^\top \beta_i).$$

This process describes the statistical assumptions behind the model. We note that this contains, as a sub-class, a factorization model with fixed rate parameters for all users and items. We call this model Bayesian Poisson Factorization (BPF).

The central computational problem is posterior inference, which is akin to “reversing” the generative process. Given a user behavior matrix, we want to estimate the conditional distribution of the latent per-user and per-item structure,  $p(\theta_{1:N}, \beta_{1:M} | y)$ , termed the posterior, which is the key to recommendation. We estimate the posterior expectation of each user’s preferences, each items attributes and, subsequently, form predictions about which unconsumed items each user will like. We discuss posterior inference in Section 2.2.

Once the posterior is fit, we use HPF to recommend items to users by predicting which of the unconsumed items each will like. We rank each user’s unconsumed items by their posterior expected Poisson parameters,

$$\text{score}_{ui} = E[\theta_u^\top \beta_i | y]. \quad (1)$$

This amounts to asking the model to rank by probability which of the presently unconsumed items each user will likely consume in the future.

### 2.1 Properties of HPF

With the modeling details in place, we highlight several statistical properties of hierarchical Poisson factorization.

Figure 2: A posterior predictive check of the distribution of total ratings for the Netflix data set. The black squares show the empirical count of the number of users who have rated a given number of items, while the red and blue curves show the simulated totals from fitted Poisson and traditional matrix factorization models, respectively. The Poisson marginal closely matches the empirical, with the exception of users with very low activity, whereas classical matrix factorization fits a large mean to account for skew in the distribution and the missing ratings.

These properties provide advantages over *classical Gaussian matrix factorization*. Specifically, by classical MF we mean L2 regularized matrix factorization with bias terms for users and items, fit using stochastic gradient descent [23]. Without the bias terms, this corresponds to maximum a-posteriori inference under Probabilistic Matrix Factorization [33]. We generate negatives by randomly sampling from missing ratings in the training set [7, 8, 29].

**HPF captures sparse factors.** As mentioned above, the Gamma priors on preferences and attributes encourages sparse representations of users and items. Specifically, by setting the shape parameter to be small, most of the weights will be close to zero and only a few will be large. This leads to a simpler, more interpretable model.

**HPF models the long-tail of users and items.** One statistical characteristic of real-world user behavior data is the distribution of user activity (i.e., how many items a user consumed) and item popularity (i.e., how many users consumed an item). These distributions tend to be long-tailed: while most users consume a handful few items, a few “tail users” consume thousands of items. A question we can ask of a statistical model of user behavior data is how well it captures these distributions. We found that HPF captures them well, while classical matrix factorization does not.

To check this, we implemented a *posterior predictive check* (PPC) [31, 10], a technique for model assessment from the Bayesian statistics literature. The idea behind a PPC is to simulate a complete data set from the posterior predictive distribution—the distribution over data that the posterior

induces—and then compare the generated data set to the true observations. A good model will produce data that captures the important characteristics of the observed data.

We developed a PPC for matrix factorization algorithms on user behavior data. First, we formed posterior estimates of user preferences and item attributes for both classical MF and HPF. Then, from these estimates, we simulated user behavior by drawing values for each user and item. (For classical matrix factorization, we truncated these values at zero and rounded to one in order to generate a plausible matrix.) Finally, we compared the matrix generated by the posterior predictive distribution to the true observations.

Figure 2 illustrates our PPC for the Netflix data. In this figure, we illustrate three distributions over user activity: the observed distribution (squares), the distribution from a data set replicated by HPF (red line), and a distribution from a data set replicated by Gaussian MF with generated negatives using popularity-based sampling (blue line). HPF captures the truth much more closely than Gaussian MF, which overestimates the distribution of user activity. This indicates that HPF better represents real data when measured by its ability to capture distributions of user activity. In fact, this is encoded in its assumptions. We can rewrite the Poisson observation model as a two stage process where a user  $u$  first decides on a budget  $b_u$  she has to spend on items, and then spends this budget rating items that she is interested in:

$$b_u \sim \text{Poisson}(\theta_u^T \sum_i \beta_i)$$

$$[y_{u1}, \dots, y_{uM}] \sim \text{Mult}(b_u, \frac{\theta_u^T \beta_i}{\theta_u^T \sum_i \beta_i}).$$

This shows that learning a PF model for user-item ratings is effectively the same as learning a budget for each user while also learning how that budget is distributed across items.

**HPF downweights the effect of zeros.** Another advantage of HPF is that it implicitly down-weights the contribution of the items that each user did not consume. With an appropriate fit to user activity, the model has two ways of explaining an unconsumed item: either the user is not interested in it or she would be interested in if she the opportunity to consider it. In contrast, a user that consumes an item must be interested in it. Thus, the model benefits more from making latent factors for a consumed user/item pair more similar compared to making them less similar for an unconsumed user/item pair.

Classical MF is based on Gaussian likelihoods (i.e., squared loss), which gives equal weight to consumed and unconsumed items. Consequently, when faced with a sparse matrix and implicit feedback, i.e., binary consumption data, matrix factorization places more total emphasis on the unconsumed user/item pairs. (This too can be seen

to stem from classical MF’s overestimation of the distribution of user activity.) To address this, researchers have patched MF in complex ways, for example, by including per-observation confidences [23] or considering all zeroes to be hidden variables [29]. Poisson factorization naturally solves this problem with a realistic model of user activity.

As an example, consider two similar science fiction movies, “Star Wars” and “The Empire Strikes Back”, and consider a user who has seen one of them. The Gaussian model pays an equal penalty for making the user similar to these items as it does for making the user different from them—with quadratic loss, seeing “Star Wars” is evidence for liking science fiction, but not seeing “The Empire Strikes Back” is evidence for disliking it. The Poisson model, however, will prefer to bring the user’s latent weights closer to the movies’ weights because it favors the information from the user watching “Star Wars”. Further, because the movies are similar, this increases the Poisson model’s predictive score that a user who watches “Star Wars” will also watch “The Empire Strikes Back”.

**Fast inference with sparse matrices.** Finally, the likelihood of the observed data under HPF depends only on the consumed items, that is, the non-zero elements of the user/item matrix  $y$ . This facilitates computation for the kind of sparse matrices we observe in real-world data.

We can see this property from the form of the Poisson distribution. Given the latent preferences  $\theta_u$  and latent attributes  $\beta_i$ , the Poisson distribution of the rating  $y_{ui}$  is

$$p(y_{ui} | \theta_u, \beta_i) = (\theta_u^\top \beta_i)^{y_{ui}} \exp\{-\theta_u^\top \beta_i\} / y_{ui}! \quad (2)$$

Recall the elementary fact that  $0! = 1$ . With this, the log probability of the complete matrix  $y$  can be written as

$$\log p(y | \theta, \beta) = \sum_{\{y_{ui} > 0\}} y_{ui} \log(\theta_u^\top \beta_i) - \log y_{ui}! - (\sum_u \theta_u)^\top (\sum_i \beta_i).$$

This avoids the need for sub-sampling [7], approximation [17], or stochastic optimization [27] that complicate other approaches.

## 2.2 INFERENCE WITH VARIATIONAL METHODS

Using HPF for recommendation hinges on solving the posterior inference problem. Given a set of observed ratings, we would like to infer the user preferences and item attributes that explain these ratings, and then use these inferences to recommend new content to the users. In this section we discuss the details and practical challenges of posterior inference for HPF, and present a mean-field variational inference algorithm as a scalable approach. Our algorithm easily accommodates data sets with millions of users and hundreds of thousands of items on a single CPU.

Given a matrix of user behavior, we would like to compute the posterior distribution of user preferences  $\theta_{uk}$ , item attributes  $\beta_{ik}$ , user activity  $\xi_u$  and item popularity  $\eta_i$ . As for many Bayesian models, however, the exact posterior is computationally intractable. We show how to efficiently approximate the posterior with mean-field variational inference.

Variational inference is an optimization-based strategy for approximating posterior distributions in complex probabilistic models [21, 35]. Variational algorithms posit a family of distributions over the hidden variables, indexed by free “variational” parameters, and then find the member of that family that is closest in Kullback-Liebler (KL) divergence to the true posterior. (The form of the family is chosen to make this optimization possible.) Thus, variational inference turns the inference problem into an optimization problem. Variational inference has previously been used for large-scale recommendation [29].

We will describe a simple variational inference algorithm for HPF. To do so, however, we first give an alternative formulation of the model in which we add an additional layer of latent variables. These auxiliary variables facilitate derivation and description of the algorithm [11, 16].

For each user and item we add  $K$  latent variables  $z_{uik} \sim \text{Poisson}(\theta_{uk}\beta_{ik})$ , which are integers that sum to the user/item value  $y_{ui}$ . A sum of Poisson random variables is itself a Poisson with rate equal to the sum of the rates. Thus, these new latent variables preserve the marginal distribution of the observation,  $y_{ui} \sim \text{Poisson}(\theta_u^\top \beta_i)$ . These variables can be thought of as the contribution from component  $k$  to the total observation  $y_{ui}$ . Note that when  $y_{ui} = 0$ , these auxiliary variables are not random—the posterior distribution of  $z_{uik}$  will place all its mass on the zero vector. Consequently, our inference procedure need only consider  $z_{uik}$  for those user/item pairs where  $y_{ui} > 0$ .

With these latent variables in place, we now describe the algorithm. First, we posit the variational family over the hidden variables. Then we show how to optimize its parameters to find an approximation to the posterior.

The latent variables in the model are user weights  $\theta_{uk}$ , item weights  $\beta_{ik}$ , and user-item contributions  $z_{uik}$ , which we represent as a  $K$ -vector of counts  $z_{ui}$ . The *mean-field family* considers these variables to be independent and each governed by its own distribution,

$$q(\beta, \theta, \xi, \eta, z) = \prod_{i,k} q(\beta_{ik} | \lambda_{ik}) \prod_{u,k} q(\theta_{uk} | \gamma_{uk}) \prod_u q(\xi_u | \kappa_u) \prod_i q(\eta_i | \tau_i) \prod_{u,i} q(z_{ui} | \phi_{ui}).$$

Though the variables are independent, this is a flexible family of distributions because each variable is governed by its own free parameter. The variational factors for preferences  $\theta_{uk}$ , attributes  $\beta_{ik}$ , activity  $\xi_u$ , and popularity  $\eta_i$  are

For all users and items, initialize the user parameters  $\gamma_u, \kappa_u^{\text{rte}}$  and item parameters  $\lambda_i, \tau_i^{\text{rte}}$  to the prior with a small random offset. Set the user activity and item popularity shape parameters:

$$\kappa_u^{\text{shp}} = a' + Ka; \quad \tau_i^{\text{shp}} = c' + Kc$$

Repeat until convergence:

1. For each user/item such that  $y_{ui} > 0$ , update the multinomial:

$$\phi_{ui} \propto \exp\{\Psi(\gamma_{uk}^{\text{shp}}) - \log \gamma_{uk}^{\text{rte}} + \Psi(\lambda_{ik}^{\text{shp}}) - \log \lambda_{ik}^{\text{rte}}\}.$$

2. For each user, update the user weight and activity parameters:

$$\begin{aligned} \gamma_{uk}^{\text{shp}} &= a + \sum_i y_{ui} \phi_{uik} \\ \gamma_{uk}^{\text{rte}} &= \frac{\kappa_u^{\text{shp}}}{\kappa_u^{\text{rte}}} + \sum_i \lambda_{ik}^{\text{shp}} / \lambda_{ik}^{\text{rte}} \\ \kappa_u^{\text{rte}} &= \frac{a'}{b'} + \sum_k \frac{\gamma_{uk}^{\text{shp}}}{\gamma_{uk}^{\text{rte}}} \end{aligned}$$

3. For each item, update the item weight and popularity parameters:

$$\begin{aligned} \lambda_{ik}^{\text{shp}} &= c + \sum_u y_{ui} \phi_{uik} \\ \lambda_{ik}^{\text{rte}} &= \frac{\tau_i^{\text{shp}}}{\tau_i^{\text{rte}}} + \sum_u \gamma_{uk}^{\text{shp}} / \gamma_{uk}^{\text{rte}} \\ \tau_i^{\text{rte}} &= \frac{c'}{d'} + \sum_k \frac{\lambda_{ik}^{\text{shp}}}{\lambda_{ik}^{\text{rte}}} \end{aligned}$$

Figure 3: Variational inference for Poisson factorization. Each iteration only needs to consider the non-zero elements of the user/item matrix.

all Gamma distributions, with freely set scale and rate variational parameters. The variational factor for  $z_{ui}$  is a free multinomial, i.e.,  $\phi_{ui}$  is a  $K$ -vector that sums to one. This form stems from  $z_{ui}$  being a bank of Poisson variables conditional on a fixed sum  $y_{ui}$ , and the property that such conditional Poissons are distributed as a multinomial [20, 5].

After specifying the family, we fit the variational parameters  $\nu = \{\lambda, \gamma, \kappa, \tau, \phi\}$  to minimize the KL divergence to the posterior, and then use the corresponding variational distribution  $q(\cdot | \nu^*)$  as its proxy. The mean-field factorization facilitates both optimizing the variational objective and downstream computations with the approximate posterior, such as the recommendation score of Equation 1.

We optimize the variational parameters with a coordinate ascent algorithm, iteratively optimizing each parameter while holding the others fixed. The algorithm is illustrated

in Figure 3. We denote shape with the superscript “shp” and rate with the superscript “rte”. We provide a detailed derivation in the Appendix.

Note that our algorithm is efficient on sparse matrices. In step 1, we need only update variational multinomials for the non-zero user/item observations  $y_{ui}$ . In steps 2 and 3, the sums over users and items need only to consider non-zero observations. This efficiency is thanks the likelihood of the full matrix only depending on the non-zero observations, as we discussed in the previous section. Both HPF and BPF enjoy this property and have the same computational overhead, but HPF allows for more flexibility in modeling the variation in activity and popularity across users and items, respectively.

We terminate the algorithm when the variational distribution converges. Convergence is measured by computing the prediction accuracy on a validation set. Specifically, we approximate the probability that a user consumed an item using the variational approximations to posterior expectations of  $\theta_u$  and  $\beta_i$ , and compute the average predictive log likelihood of the validation ratings. The HPF algorithm stops when the change in log likelihood is less than 0.0001%. We find that the algorithm is largely insensitive to small changes in the hyper-parameters. To enforce sparsity, we set the shape hyperparameters  $a', a, c$  and  $c'$  to provide exponentially shaped prior Gamma distributions—we fixed each hyperparameter at 0.3. We set the hyperparameters  $b'$  and  $d'$  to 1, fixing the prior mean at 1.

### 3 EMPIRICAL STUDY

We evaluate the performance of the Hierarchical Poisson factorization (HPF) algorithm on a variety of large-scale user behavior data sets: users listening to music, users watching movies, users reading scientific articles, and users reading the newspaper. We find that HPF provides significantly better recommendations than competing methods. We provide an exploratory analysis of preferences and attributes on the New York Times data set in the appendix.<sup>2</sup>

**Data Sets.** We study the HPF algorithm in Figure 3 on several data sets of user behavior:

- The **Mendeley** data set [19] of scientific articles is a binary matrix of 80,000 users and 260,000 articles, with 5 million observations. Each cell indicates the presence or absence of an article in a user’s library.
- The **Echo Nest** music data set [2] is a matrix of 1 million users and 385,000 songs, with 48 million observations. Each observation is the number of times a user played a song.

<sup>2</sup>Our source code is available from <https://github.com/premgopalan/hgaprec>

- The **New York Times** data set is a matrix of 1,615,675 users and 103,390 articles, with 80 million observations. Each observation is the number of times a user viewed an article.
- The **Netflix** data set [23] contains 480,000 users and 17,770 movies, with 100 million observations. Each observation is the rating (from 1 to 5 stars) that a user provided for a movie.

The scale and diversity of these data sets enables a robust evaluation of our algorithm. The Mendeley, Echo Nest, and New York Times data are sparse compared to Netflix. For example, we observe only 0.001% of all possible user-item ratings in Mendeley, while 1% of the ratings are non-zero in the Netflix data. This is partially a reflection of large number of items relative to the number of users in these data sets.

Furthermore, the intent signaled by an observed rating varies significantly across these data sets. For instance, the Netflix data set gives the most direct measure of stated preferences for items, as users provide a star rating for movies they have watched. In contrast, article click counts in the New York Times data are a less clear measure of how much a user likes a given article—most articles are read only once, and a click through is only a weak indicator of whether the article was fully read, let alone liked. Ratings in the Echo Nest data presumably fall somewhere in between, as the number of times a user listens to a song likely reveals some indirect information about their preferences.

As such, we treat each data set as a source of implicit feedback, where an observed positive rating indicates that a user likes a particular item, but the rating value itself is ignored. The Mendeley data are already of this simple binary form. For the Echo Nest and New York Times data, we consider any song play or article click as a positive rating, regardless of the play or click count. As in previous work, we consider an implicit version of the Netflix data where only 4 and 5 star ratings are retained as observations [29].

**Competing methods.** We compare Poisson factorization against an array of competing methods:

- **NMF:** Non-negative Matrix Factorization [25]. In NMF, user preferences and item attributes are modeled as non-negative vectors in a low-dimensional space. These latent vectors are randomly initialized and modified via an alternating multiplicative update rule to minimize the Kullback-Leibler divergence between the actual and modeled rating matrices. We use the GraphLab implementation of NMF [24] to scale to our large data sets.
- **LDA:** Latent Dirichlet Allocation [3]. LDA is a Bayesian probabilistic generative model where user

preferences are represented by a distribution over different topics, and each topic is represented by a distribution over items. Interest and topic distributions are randomly initialized and updated using stochastic variational inference [16] to approximate these intractable posteriors. We used the default setting of the hyperparameters in the Vowpal Wabbit package [37].

- **MF:** Probabilistic Matrix Factorization with user and item biases. We use a variant of matrix factorization popularized through the Netflix Prize [23], where a linear predictor—comprised of a constant term, user activity and item popularity biases, and a low-rank interaction term—is fit to minimize the mean squared error between the predicted and observed rating values, subject to L2 regularization to avoid overfitting. Weights are randomly initialized and updated via stochastic gradient descent using the Vowpal Wabbit package [37]. This corresponds to maximum a-posteriori inference under Probabilistic Matrix Factorization [33]. We selected hyperparameters using grid search with a small validation set.
- **ClIMF:** Collaborative Less-is-More filtering [34] maximizes mean reciprocal rank to improve the top- $n$  predictive performance on binary relevance data sets. We use the GraphLab implementation of ClIMF [24] to scale to our large data sets, and use the default parameter settings in the package.

We note that while HPF and LDA take only the non-zero observed ratings as input, traditional matrix factorization requires that we provide explicit zeros in the ratings matrix as negative examples for the implicit feedback setting. In practice, this amounts to either treating all missing ratings as zeros (as in NMF) and down-weighting to balance the relative importance of observed and missing ratings [17], or generating negatives by randomly sampling from missing ratings in the training set [8, 7, 29]. We take the latter approach for computational convenience, employing a popularity-based sampling scheme: we sample users by activity—the number of items rated in the training set—and items by popularity—the number of training ratings an item received to generate negative examples.<sup>3</sup>

Finally, we note that a few candidate algorithms failed to scale to our data sets. The fully Bayesian treatment of the Probabilistic Matrix Factorization [32], uses a MCMC algorithm for inference. The authors [32] report that a single Gibbs iteration on the Netflix data set with 60 latent factors, requires 30 minutes, and that they throw away the first 800 samples. This implies at least 16 days of training, while the HPF variational inference algorithm converges within

<sup>3</sup>We also compared this to a uniform random sampling of negative examples, but found that the popularity-based sampling performed better.

Figure 4: Predictive performance on data sets. The top and bottom plots show normalized mean precision and mean recall at 20 recommendations, respectively. While the relative performance of the competing methods varies across data sets, HPF consistently outperforms each of them.

13 hours on the Netflix data. Another alternative, Bayesian Personalized Ranking (BPR) [30, 8], optimizes a ranking-based criteria using stochastic gradient descent. The algorithm performs an expensive bootstrap sampling step at each iteration to generate negative examples from the vast set of unobserved. We found time and space constraints to be prohibitive when attempting to use BPR with the data sets considered here. Finally, the GraphChi implementation of CLiMF [24] failed with an error on the Netflix and New York Times data sets.

**Evaluation.** Prior to training any models, we randomly select 20% of ratings in each data set to be used as a held-out test set comprised of items that the user has consumed. Additionally, we set aside 1% of the training ratings as a validation set and use it to determine algorithm convergence and to tune free parameters. We used the HPF settings described in Section 2.2 across all data sets, and set the number of latent components  $K$  to 100.

During testing, we generate the top  $M$  recommendations for each user as those items with the highest predictive score under each method. For each user, we compute a variant of precision-at- $M$  that measures the fraction of relevant items in the user’s top- $M$  recommendations. So as not to artificially deflate this measurement for lightly active users who have consumed fewer than  $M$  items, we compute *normalized* precision-at- $M$ , which adjusts the denominator to be at most the number of items the user has in the test set. Likewise, we compute recall-at- $M$ , which captures the fraction of items in the test set present in the top  $M$  recommendations.

Figure 4 shows the normalized mean precision at 20 recommendations for each method and data sets. We see that

HPF outperforms other methods on all data sets by a sizeable margin. Poisson factorization provides high-quality recommendations—a relatively high fraction of items recommended by HPF are found to be relevant, and many relevant items are recommended. While not shown in these plots, the relative performance of methods within a data set is consistent as we vary the number of recommendations shown to users. We also note that while Poisson factorization dominates across all of these data sets, the relative quality of recommendations from competing methods varies substantially from one data set to the next. For instance, LDA performs quite well on the Echo Nest data, but fails to beat classical matrix factorization for the implicit Netflix data set.

We also study precision and recall as a function of user activity to investigate how performance varies across users of different types. In particular, Figure 5 shows the mean difference in precision and recall to HPF, at 20 recommendations, as we look at performance for users of varying activity, measured by percentile. For example, the 10% mark on the x-axis shows mean performance across the bottom 10% of users, who are least active; the 90% mark shows the mean performance for all but the top 10% of most active users. Here we see that Poisson factorization outperforms other methods for users of all activity levels.

## 4 RELATED WORK

The roots of Poisson factorization come from nonnegative matrix factorization [25], where the objective function is equivalent to a factorized Poisson likelihood. The original NMF update equations have been shown to be an expectation-maximization (EM) algorithm for maximum

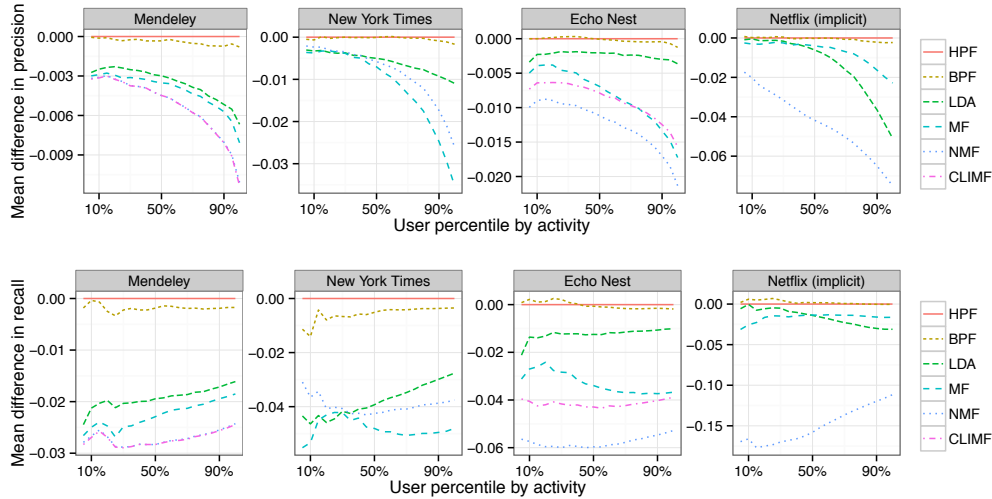

Figure 5: Predictive performance across users. The top and bottom plots show the mean difference in precision and recall to HPF at 20 recommendations, respectively, by user activity.

likelihood estimation of a Poisson model [5].

Placing a Gamma prior on the user weights results in the GaP model [4], which was developed as an alternative text model to latent Dirichlet allocation (LDA) [3, 18]. The GaP model is fit using the expectation-maximization algorithm to obtain point estimates for user preferences and item attributes. The Probabilistic Factor Model (PFM) [26] improves upon GaP by placing a Gamma prior on the item weights as well, and using multiplicative update rules to infer an approximate maximum a posteriori estimate of the latent factors. Our model uses a hierarchical prior structure of Gamma priors on both user and item weights, and Gamma priors over the rate parameters from which these weights are drawn. Furthermore, we approximate the full posterior over all latent factors using a scalable variational inference algorithm.

Independently of GaP and user behavior models, Poisson factorization has been studied in the context of signal processing for source separation [5, 15] and for detecting community structure in network data [1, 13]. This research includes variational approximations to the posterior, though the issues and details around these data differ significantly from user data we consider and our derivation in the supplement (based on auxiliary variables) is more direct.

When modeling implicit feedback data sets, researchers have proposed merging factorization techniques with neighborhood models [22], weighting techniques to adjust the relative importance of positive examples [17], and sampling-based approaches to create informative negative examples [8, 7, 29]. In addition to the difficulty in appropriately weighting or sampling negative examples, there is a known selection bias in provided ratings that causes further complications [28]. HPF does not require such special

adjustments for negative examples and scales linearly in the observed ratings.

**Comparison to Gaussian MF.** Many of the leading MF methods are based on Gaussian likelihoods (i.e., squared loss). When applied to explicit data, Gaussian models are fit only to the observed ratings [23] and infer distributions over user preferences. For each user, the items she did not consume, i.e., the zero observations, are treated as missing. Gaussian models make up the state of the art in this setting [32, 33, 23].

In implicit data sets of user consumption, there is a fundamental asymmetry that allows one to infer which items a user consumed, and therefore liked, but not which items a user did not like [17]. In this setting, Gaussian MF applied to all observations gives equal weight to consumed and unconsumed items. Consequently, when faced with a sparse matrix and implicit feedback, matrix factorization places more total emphasis on the unconsumed user/item pairs.

To address this limitation of Gaussian MF, researchers have proposed two main approaches. The first approach, proposed by [17], is to treat the unconsumed items with greater uncertainty and increase confidence as the rating for an item increases. This converts the raw observations into two separate quantities with distinct interpretations: user preferences and confidence levels. Hu et al. [17] present an alternating least squares algorithm that considers all observations but whose per-iteration complexity is still linear in the number of non-zero observations.

The second approach is to randomly synthesize negative examples [7, 8, 29]. In this approach, unconsumed items are subsampled for each user to balance out the consumed items. As Dror et al. [7] note, it is unclear how to bal-

ance these two sets of items. Do we use an equal number of consumed and unconsumed items, or do we use the full set of unconsumed items [6, 17]? Further, the subsampling of negative or unconsumed items is often expensive, and can account for a substantial fraction of resources devoted to model fitting. An issue that we found in Gaussian MF with subsampled zeros, fit using SGD, is that it systematically overestimates the users' budgets. We confirmed this in Section 3 using a posterior predictive check [10]. Poisson factorization does not require synthesizing negative examples and is better able to capture distributions of users' budgets.

Further, the HPF algorithm retains the linear-scaling of Gaussian MF with downweighted zeros [17]. HPF algorithms only need to iterate over the consumed items in the observed matrix of user behavior. This follows from the mathematical form of the Poisson distribution. In contrast, the subsampling-based Gaussian MF methods [7, 8, 29] must iterate over both positive and negative examples in the implicit setting. This makes it difficult to take advantage of data sparsity to scale to massive data sets.

Finally, unlike Gaussian MF which typically provides dense latent representations of users and items, PF models provide sparse latent representations. This property arises from the PF log-likelihood which can be shown to minimize the information (Kullback-Leibler) divergence under NMF [5], and from the Gamma priors in the HPF model.

**Recent extensions.** Building on the HPF model and algorithm we presented in a preprint, recent extensions have been proposed. One extension is a combined model of article text and reader preferences [14]. This model takes advantage of the sparse, non-negative representations in PF, which are useful in capturing different types of discrete data, such as word counts and user ratings. Further, they exploit the additive properties of independent Poisson random variables to capture dependencies between discrete data, for example, the dependence of user ratings of an article on its content. Another recent work proposes a Bayesian nonparametric model [12] that adapts the dimensionality of the latent representations, learning the preference patterns (and their number) that best describe the users. Both models exploit the scalability of PF algorithms to study massive data sets. These extensions testify to the modeling flexibility of PF models.

## 5 DISCUSSION

We have demonstrated that Poisson factorization is an efficient and effective means of generating high quality recommendations across a variety of data sets ranging from movie views to scientific article libraries. It significantly outperforms a number of leading methods in modeling implicit behavior data without the need for ad hoc modifications. Variational inference for HPF scales to massive data

and differs from traditional methods in its ability to capture the heterogeneity amongst users and items, accounting for the wide range of activity and popularity amongst them, respectively. The HPF algorithm is a robust, off-the-shelf tool, providing high accuracy even with fixed hyperparameter settings.

Finally, we emphasize that HPF is more than just one method—it is the simplest in a class of probabilistic models with these properties, and has already been extended to a combined model of article content and reader ratings [14], and a Bayesian nonparametric model that adapts the dimensionality of the latent representations [12].

A notable innovation in Gaussian MF is the algorithm of [17] that explicitly downweights zeros using confidence parameters. We presented the empirical study in this paper comparing to the Gaussian MF with subsampled zeros [23]. We attempted to compare to a GraphChi implementation [24] of [17], but it gave unexpectedly poor results. We found another implementation [36], and these comparisons are ongoing work. Another piece of ongoing work includes bringing the confidence-weighting of [17] into HPF. This will allow downweighting of the zeros beyond that provided implicitly by Poisson factorization.

## Abstract

Given a discrete time finite state hidden Markov model (HMM) and a sequence of observations, there are different ways to estimate the hidden behavior of the system. In this paper, the problem of finding the most probable state sequence is considered. The state sequence, as opposed to the state trajectory, specifies the sequence of states that the HMM visits but does not specify the dwelling times in these states. This inference problem is relevant in a variety of domains, like text analysis, speech recognition, or behavior recognition, where the exact timing of hidden state transitions is not nearly as important as the sequence of states visited. No existing algorithm addresses this inference question adequately. Leveraging previous work on continuous time Markov chains, we develop a provably correct algorithm, called *state sequence analysis*, that addresses this inference question in HMMs. We discuss and illustrate empirically the differences between finding the most probable state sequence directly and doing so through running the Viterbi algorithm and collapsing repetitive state visitations. Experimental results in two synthetic domains demonstrate that the Viterbi-based approach can be significantly suboptimal compared to state sequence analysis. Further, we demonstrate the benefits of the proposed approach on a real activity recognition problem.

## 1 INTRODUCTION

Hidden Markov models are a powerful and widely-used formalism for analyzing sequential information in a variety of domains, including speech recognition [Bahl et al., 1986, Rabiner, 1989], text analysis [Blei and Moreno, 2001], behavior recognition [Yamato et al., 1992, Nguyen et al., 2005], protein struc-

ture prediction [Sonnhammer et al., 1998], genomics [Haussler and Eeckman, 1996, Wang et al., 2007], and so on. As with graphical models generally, much of the utility of HMMs derives from our ability to use them to make estimates about hidden/unobserved variables based on observable variables. HMMs are often used as models of dynamical systems. In this context, the unobserved variables would be the true (underlying) state of the dynamical system. The observed variables would be something that we “see” when we observe or measure the system. The observations typically have some relationship to the underlying state, but the relationship may be imperfect or noisy. A typical task would then involve receiving some kind of observations of the system, and estimating the underlying states that generated those observations. Of course, an HMM can model sequential information that is not dynamical in nature, as seen for instance in applications in text analysis, genome annotation, etc. Regardless, the most common task is to estimate underlying states based on observations.

There are several different types of hidden state estimation problems for HMMs. Although we define HMMs formally in the next section, to distinguish different types of inference problems it is useful to introduce a small amount of notation here. We let  $X_t$  be a random variable denoting the underlying state at time  $t$ , and  $x_t$  a realization of that variable. Similarly, we let  $o_t$  be the observation at time  $t$ . Further, we let  $X_{1:t} = (X_1, X_2, \dots, X_t)$  be a random variable describing possible system *trajectories*, a realization of which is denoted  $\mathbf{x}_{1:t} = (x_1, x_2, \dots, x_t)$ . Similarly, a series of observations is denoted  $\mathbf{o}_{1:t} = (o_1, o_2, \dots, o_t)$ .

One of the fundamental HMM inference problems is to compute the probabilities of different underlying system states based on observations. More formally, if we receive a stream of observations,  $o_1, o_2, o_3, \dots$  then at each time  $t = 1, 2, 3, \dots$  we may want to compute the probabilities of different states  $x$  conditional on the observations:  $P(X_t = x | \mathbf{o}_{1:t})$ . This can be done by the forward algorithm [Rabiner, 1989], which is very efficient, and indeed allows us to readily compute  $P(X_t = x | \mathbf{o}_{1:t})$  incremen-

tally based on  $P(X_{t-1} = x' | \mathbf{o}_{1:t-1})$ . If we are given an entire sequence of observations,  $\mathbf{o}_{1:t}$ , and we want to estimate the underlying state probabilities at all times, namely  $P(X_{t'} = x | \mathbf{o}_{1:t})$  for all  $x$  and  $1 \leq t' \leq t$ , then the forward-backward algorithm [Rabiner, 1989] gives us an efficient solution. From those probabilities, one can easily compute the most probable state at each time:  $x_{t'}^{\max} = \arg \max_x P(X_{t'} = x | \mathbf{o}_{1:t})$ .

Each of these problems give us some information about underlying states based on observations, but they do not explicitly give us any pathway information. The forward and forward-backward algorithms, for example, give us only state probabilities. The sequence of most probable states,  $x_1^{\max}, x_2^{\max}, x_3^{\max}, \dots$ , may or may not comprise a valid system path. That is, some transition  $x_{t'}^{\max} \rightarrow x_{t'+1}^{\max}$  may not even be allowed under the dynamics. Thus, while these approaches are useful for estimating underlying states or “classifying” time points into different states, they are not directly useful for reconstructing underlying system paths.

For path reconstruction, by far the most common approach is the Viterbi algorithm [Rabiner, 1989], which is an efficient means for computing the maximum probability trajectory underlying a given sequence of observations:  $\arg \max_{\mathbf{x}_{1:t}} P(\mathbf{x}_{1:t} | \mathbf{o}_{1:t})$ . Despite the many successes of the Viterbi approach (e.g., in speech recognition, activity recognition and bioinformatics, as described above), it has been critiqued on a few different grounds. For one, like any *maximum a posteriori* (MAP) estimator, there is a question of how “representative” the maximum is. Intuitively, if the bulk of the posterior distribution contains trajectories that are “unlike” the MAP trajectory in some way, then the MAP trajectory can be misleading in our attempt to interpret observational data (see, e.g., [Lember and Koloydenko, 2014] and references therein). As a simple example, imagine the underlying state system is a series of independent flips of a biased coin that comes up heads with probability  $p > 0.5$ , and suppose we receive totally non-informative observations. Then the MAP trajectory is a series of all heads. But this path is “atypical” in a number of senses. For instance, we do expect some tails—in particular, about  $n(1-p)$  of them where  $n$  is the number of flips. This and a great many other statistics about the series of coin flips are not represented in the MAP path. This is not a criticism of Viterbi per se, but merely of the practice of thinking or hoping that the MAP path is somehow representative of other probable paths as well.

In some other work, the authors have pointed out problems with MAP paths for stochastic continuous-time discrete-state systems [Perkins, 2009, Levin et al., 2012]. Such systems dwell in a state for random period of time, before moving on to a randomly-chosen next state. Although MAP paths can be efficiently computed [Perkins, 2009], solutions are non-typical in that they involve “instant” transitions through low latency states and dwells in high latency

states. Similar issues can arise in discrete time HMMs, particularly, but not exclusively, when analyzing an HMM that arises from discretizing a continuous-time process.

A second problem with MAP paths is that they constitute an overly-specific inference. For example, in a simple speech recognition scenario, a MAP path might assign a word or phoneme to every timestep underlying the speech signal. However, transitions between words are not truly so crisp. Moreover, there is usually no point in assigning precise start and end times to each word or phoneme. If we hear, “The quick brown fox . . .”, what is the value of estimating that the word “The” ends and the word “quick” begins precisely 0.823 seconds into a spoken signal? It is the sequence of words spoken, and not their exact timing, that is important. Similarly for gesture recognition, activity recognition, etc.

Motivated by these criticisms of MAP trajectories, an alternative inference method, called *state sequence analysis*, was proposed earlier [Levin et al., 2012]. In this inference problem, the objective is to find the maximum a posteriori *sequence* of states, but averaging away (i.e. marginalizing over) the transition times between those states—essentially treating them as nuisance variables. In that work, however, the inference problem is solved for systems modeled as continuous-time Markov chains with initial and/or terminal probabilities; no observations during the time period of interest are allowed. In the present work, we study state sequence analysis for HMMs: the focus is on discrete time setting, where a series of noisy observations is allowed. We describe a provably-correct algorithm that finds the most probable state sequence given a trajectory of observations. Then, we demonstrate how state sequence analysis differs from Viterbi path inference on synthetic and real examples, and in particular (as it is designed to do) how state sequence analysis provides more accurate estimates of the sequence of states underlying a noisy series of observations.

## 2 BACKGROUND

Let  $\mathcal{X}$  be a discrete finite state space and  $\mathcal{O}$  the observation space of a hidden Markov model [Rabiner, 1989]. Let  $\mathbf{T}$  be the transition matrix of this HMM, with  $\mathbf{T}_{x,y}$  representing the probability of transitioning from state  $x \in \mathcal{X}$  to state  $y \in \mathcal{X}$ , and  $p_x(o)$  be the emission probability of observation  $o \in \mathcal{O}$  in state  $x \in \mathcal{X}$ .

For a possible trajectory of states visited by a discrete time HMM we are interested in identifying what is the corresponding duration-free sequence of states, i.e. sequence of states with self-loops removed. For example, given the trajectory of states  $\langle x, x, x, y, y, y, x \rangle$ , the corresponding *state sequence* will be  $\langle x, y, x \rangle$ . We denote the probability that HMM trajectory follows the state sequence  $\mathbf{s}$  given the se-

quence of  $n$  observations, as

$$P(X_{1:n} \in \text{seq}_n(\mathbf{s}) | \mathbf{o}_{1:n}),$$

where  $\text{seq}_n(\mathbf{s})$  is a set of all length  $n$  trajectories whose duration-free sequence equals to  $\mathbf{s}$ . Where possible, we will use  $P(\mathbf{s} | \mathbf{o}_{1:n})$  as a shortcut to the above notation.

### 3 THE STATE SEQUENCE INFERENCE PROBLEM

Finding the most probable state sequence, which we call *state sequence analysis* (SSA), can be seen as a search problem that requires evaluation of probabilities of state sequences. Recall that, to find the most probable trajectory of states, a naive exhaustive enumeration quickly becomes infeasible because the number of possible trajectories grows exponentially with the length of observation sequence. Similarly, a naive implementation of the search for the most probable state sequence does not scale well. Even a single evaluation of a probability of a state sequence involves the summation over possibly large number of terms. Specifically, the number of terms in the set  $\text{seq}_n(\mathbf{s})$  is equal to  $\binom{n-1}{|\mathbf{s}|-1}$  for the state sequence  $\mathbf{s}$ .

Nevertheless, inferring the most probable trajectory can be done efficiently by a well-known Viterbi algorithm that uses dynamic programming to do the search and evaluation simultaneously. Although a Viterbi-like approach does not appear to be possible to address the question we pose, in what follows we develop search and evaluation algorithms that make the problem tractable. First, we identify a particular structure within the search space that allows us to prune large parts of the space as the search progresses. Second, we provide a recursive relation that is used to efficiently evaluate probabilities of new state sequences using dynamic programming. However, prior to delving into the algorithmic details, we begin with a little discussion about the similarities and differences between most probable state sequence and most probable state trajectory.

#### 3.1 THE MOST PROBABLE STATE SEQUENCE AND TRAJECTORY

The definition of a state sequence presented in an earlier section leaves little doubt that the most probable state trajectory is not necessarily the same as the most probable state sequence, given a sequence of observations. Yet, to better understand the nature of their differences it might be helpful to pinpoint the cases where those two will, in fact, be equal. In the first case, consider a HMM in which probabilities of staying in any state are zero. Any state trajectory generated by this HMM will have no repetitive states, and therefore the only state sequences that have non zero probability of happening must be of the same length as the observation sequence. Hence, the most probable state tra-

jectory and the most probable state sequence will be the same.

In the second case, suppose that the observations identify the underlying hidden states exactly (observation sequence is also Markov). It implies that there is only one state trajectory that could generate a given sequence of observations. Hence, there is only one state sequence explaining a given observation sequence; that state sequence can be computed by collapsing repetitive states appearing in the only possible state trajectory.

Of course, both of these cases are rather extreme, and in their exact form can rarely be found in practice. However, one can expect that the ‘‘closer’’ the given HMM is to one of those extremes, the less evident will the difference be between the most probable state sequence and state trajectory (in its collapsed form). This intuition is also backed up, to some extent, by the experimental results presented in later sections.

#### 3.2 DOMINATION OF SEQUENCES

In [Levin et al., 2012], the authors develop a structural relation between state sequences of a continuous time Markov chain that allows them to avoid searching all of the space of sequences. In this section, we develop a similar relation between sequences in the setting of discrete time HMMs. The following derivation, which serves as a basis for this development, enables us to express the probability of longer state sequences in terms of shorter state sequences. Let  $\mathbf{s}_x$  be a state sequence that ends with state  $x$ , and let  $\mathbf{u}_y$  be a one step shorter subsequence of  $\mathbf{s}_x$  such that  $\mathbf{s}_x = \langle \mathbf{u}_y, x \rangle$ . Then,

$$\begin{aligned} P(\mathbf{s}_x | \mathbf{o}_{1:n}) &= \sum_{i=1}^{n-1} P[X_{1:i} \in \text{seq}_i(\mathbf{u}_y); X_{i+1:n} = x | \mathbf{o}_{1:n}] \\ &= \sum_{i=1}^{n-1} P[X_{1:i} \in \text{seq}_i(\mathbf{u}_y) | \mathbf{o}_{1:n}] \\ &\quad \cdot P[X_{i+1:n} = x | \mathbf{o}_{1:n}; X_i = y] \\ &= \sum_{i=1}^{n-1} \frac{P[\mathbf{o}_{1:n} | X_{1:i} \in \text{seq}_i(\mathbf{u}_y)] \cdot P[X_{1:i} \in \text{seq}_i(\mathbf{u}_y)]}{P(\mathbf{o}_{1:n})} \\ &\quad \cdot P[X_{i+1:n} = x | \mathbf{o}_{i+1:n}; X_i = y] \\ &= \sum_{i=1}^{n-1} \frac{P[\mathbf{o}_{1:i} | X_{1:i} \in \text{seq}_i(\mathbf{u}_y)] \cdot P[X_{1:i} \in \text{seq}_i(\mathbf{u}_y)]}{P(\mathbf{o}_{1:i})} \\ &\quad \cdot \frac{P[\mathbf{o}_{i+1:n} | X_i = y]}{P[\mathbf{o}_{i+1:n} | \mathbf{o}_{1:i}]} \\ &\quad \cdot P[X_{i+1:n} = x | \mathbf{o}_{i+1:n}; X_i = y] \\ &= \sum_{i=1}^{n-1} P[X_{1:i} \in \text{seq}_i(\mathbf{u}_y) | \mathbf{o}_{1:i}] \\ &\quad \cdot \frac{P[X_{i+1:n} = x; \mathbf{o}_{i+1:n} | X_i = y]}{P[\mathbf{o}_{i+1:n} | \mathbf{o}_{1:i}]} \\ &= \sum_{i=1}^{n-1} P(\mathbf{u}_y | \mathbf{o}_{1:i}) \cdot \frac{\mathbf{T}_{y,x} \mathbf{T}_{x,x}^{n-i-1} \prod_{j=i+1}^n p_x(o_j)}{P[\mathbf{o}_{i+1:n} | \mathbf{o}_{1:i}]} \end{aligned} \quad (1)$$

Eq. (1) makes the separation between the parameters of the problem (HMM, observation sequence) and the shorter state sequence explicit. Specifically, the probability of

longer state sequence equals to convolution of probabilities of shorter state sequence and the probability of staying in new state, normalized appropriately by the emission probabilities. As a result, the following definition of dominance between sequences turns out to be useful in speeding up the search.

**Definition 1.** Given a sequence of observations  $\mathbf{o}_{1:n}$ , let  $\mathbf{s}$  and  $\mathbf{v}$  be sequences that start from the same state and end with the same state. Then we say that  $\mathbf{s}$  dominates  $\mathbf{v}$ , and denote it by  $\mathbf{s} \gg_n \mathbf{v}$ , if

$$\forall i \in \{1, \dots, n\} : P(\mathbf{s} | \mathbf{o}_{1:i}) \geq P(\mathbf{v} | \mathbf{o}_{1:i}).$$

The dominance relation assures us that extensions of dominated sequences should never be explored within the search space, as the following lemma suggests.

**Lemma 1.** Let  $\mathbf{v}_y$  and  $\mathbf{s}_y$  be two state sequences that start with the same state and end with state  $y$ . If  $\mathbf{v}_y$  is dominated by  $\mathbf{s}_y$  given an observation sequence  $\mathbf{o}_{1:n-1}$  for some  $n > 1$ , then a one step extension of state sequence  $\mathbf{v}_y$  will be dominated by some other state sequence, given an observation sequence  $\mathbf{o}_{1:n}$ .

*Proof.* Observe that if  $\mathbf{v}_y$  is dominated by  $\mathbf{s}_y$  for an observation sequence  $\mathbf{o}_{1:n-1}$ , then the same holds for shorter observation sequences, e.g.  $\forall i \in \{1, \dots, n-1\} : \mathbf{o}_{1:i}$ , simply following the definition of the dominance. Now, let  $\langle \mathbf{v}_y, x \rangle$  be a one step extension of a state sequence  $\mathbf{v}_y$ . Since  $\mathbf{v}_y$  is dominated by  $\mathbf{s}_y$  for observation sequences  $\mathbf{o}_{1:i}$  ( $\forall i < n$ ), following equation (1) we get that

$$\forall i \leq n : P(\langle \mathbf{v}_y, x \rangle | \mathbf{o}_{1:n}) \leq P(\langle \mathbf{s}_y, x \rangle | \mathbf{o}_{1:n}).$$

□

Based on the above result, similarly to [Levin et al., 2012], we devise the algorithm that performs the search within the space of sequences by maintaining sets of non-dominated sequences only. The pseudo-code of the algorithm is provided in Algorithm 1 box. Each new sequence is checked against existing non-dominated sequences (line 6). If it appears to be non-dominated by any of those sequences, it is added to the set on non-dominated sequences (line 7). All sequences that are dominated by the new sequence in this set are removed (line 8), and all one step extensions of the new sequence will be checked by the algorithm later on (line 9).

### 3.3 COMPUTING THE PROBABILITY OF A STATE SEQUENCE

As mentioned above, performing the search within the space of state sequences will rely on evaluation of probabilities of those sequences. One approach to do so is based on implementing the recursive relation between sequences

given in Eq. (1) using dynamic programming. Following this route it requires  $O(n^2k)$  operations to evaluate the probability of a state sequence of length  $k$  given  $n$  observations. On the other hand, the following recursive relation can be used to evaluate probabilities in just  $O(nk)$  operations. As previously, let  $\mathbf{s}_x = \langle \mathbf{u}_y, x \rangle$  be a state sequence that consists of a shorter state sequence  $\mathbf{u}_y$  and a last state  $x$ .

$$\begin{aligned} P(\mathbf{s}_x | \mathbf{o}_{1:n}) &= \frac{P(\mathbf{o}_{1:n-1}, o_n | X_{1:n} \in \mathbf{seq}_n(\mathbf{s}_x)) \cdot P[X_{1:n} \in \mathbf{seq}_n(\mathbf{s}_x)]}{P(o_n | \mathbf{o}_{1:n-1}) \cdot P(\mathbf{o}_{1:n-1})} \\ &= \frac{P(\mathbf{o}_{1:n-1} | X_{1:n} \in \mathbf{seq}_n(\mathbf{s}_x)) \cdot P[X_{1:n} \in \mathbf{seq}_n(\mathbf{s}_x)]}{P(\mathbf{o}_{1:n-1})} \\ &\quad \cdot \frac{P(o_n | X_n = x)}{P(o_n | \mathbf{o}_{1:n-1})} \\ &= P[X_{1:n} \in \mathbf{seq}_n(\mathbf{s}_x) | \mathbf{o}_{1:n-1}] \\ &\quad \cdot \frac{p_x(o_n)}{P(o_n | \mathbf{o}_{1:n-1})}. \end{aligned} \quad (2)$$

Now, the first term in the product of Eq. (2) can be expanded as follows:

$$\begin{aligned} P[X_{1:n} \in \mathbf{seq}_n(\mathbf{s}_x) | \mathbf{o}_{1:n-1}] &= P[X_{1:n} \in \mathbf{seq}_n(\mathbf{s}_x); X_{n-1} = y | \mathbf{o}_{1:n-1}] \\ &\quad + P[X_{1:n} \in \mathbf{seq}_n(\mathbf{s}_x); X_{n-1} = x | \mathbf{o}_{1:n-1}] \\ &= P[X_{1:n-1} \in \mathbf{seq}_{n-1}(\mathbf{u}_y); X_n = x | \mathbf{o}_{1:n-1}] \\ &\quad + P[X_{1:n-1} \in \mathbf{seq}_n(\mathbf{s}_x); X_n = x | \mathbf{o}_{1:n-1}] \\ &= P(\mathbf{u}_y | \mathbf{o}_{1:n-1}) \mathbf{T}_{y,x} + P(\mathbf{s}_x | \mathbf{o}_{1:n-1}) \mathbf{T}_{x,x}. \end{aligned} \quad (3)$$

Combining Eq. (2) and Eq. (3) we get,

$$\begin{aligned} P(\mathbf{s}_x | \mathbf{o}_{1:n}) &= \frac{p_x(o_n)}{P(o_n | \mathbf{o}_{1:n-1})} \\ &\quad \cdot [P(\mathbf{u}_y | \mathbf{o}_{1:n-1}) \mathbf{T}_{y,x} + P(\mathbf{s}_x | \mathbf{o}_{1:n-1}) \mathbf{T}_{x,x}]. \end{aligned} \quad (4)$$

## 4 EMPIRICAL EVALUATION

### 4.1 SYNTHETIC EVENT-DETECTION EXAMPLES

To demonstrate state sequence analysis, and its difference compared to the Viterbi algorithm, consider the HMM in Figure 1A. Trajectories begin in state  $S$  and can remain there through self-looping or move on either to state  $B$  or state  $E$ . State  $E$  is absorbing. When the system is in state  $B$  it can remain there through self-looping or proceed to state  $E$ . All states emit normal-distributed observations with standard deviation 1. However, the mean observation is zero in states  $S$  and  $E$ , and  $\mu_B$  in state  $B$ . Thus, states  $S$  and  $E$  appear the same, whereas state  $B$  may appear different if  $\mu_B \neq 0$ .

At a high level, this example models event detection problems—for instance, detecting a security intrusion [Qiao et al., 2002], detecting specific gestures [Dardas and Georganas, 2011], detecting molecular events [Schreiber and Karplus, 2015], etc. Essentially, there is a series of noisy but harmless or uninteresting events, punctuated, rarely and for a short time, with relevant activity. But that relevant activity may still be subtle to detect, depending on how different it is from the background.

We simulated state-observation trajectories of 100 steps from the HMM. Because the chance of following the self-loop on state  $S$  is 0.95, the chance that a trajectory remains in that state for all 100 steps is  $0.95^{99} \approx 0.0062$ . Thus, almost all trajectories move on from the initial state, and they do so on average after 20 steps. From  $S$ , trajectories are equally likely to proceed to  $E$  or  $B$ , thus approximately half of all trajectories will contain a visit to state  $B$ , and half will not. Because the self-loop probability on state  $B$  is  $2/3$ , trajectories remain there on average for just three steps before moving on to state  $E$ . Figure 1B shows example observation trajectories that respectively do not and do include a visit to state  $B$  with  $\mu_B = 4.5$ . In the second trajectory, the visit to  $B$  happens on steps 15 and 16, as indicated by the black bar below.

We simulated 10,000 state-observation trajectories, and for each observation series applied the Viterbi algorithm and state sequence analysis. We “collapsed” the simulated state trajectory into the sequence of states visited, and likewise for the Viterbi solution. Then, we counted on how many of the 10,000 simulations Viterbi and/or state sequence analysis inferred the correct state sequence from the observation series. Figure 1C shows the fraction of correct state sequence inferences for each algorithm as a function of  $\mu_B$ . When  $\mu_B = 0$ , there is no information to distinguish any of the states and so, unsurprisingly, both algorithms are right approximately half the time. Conversely, when  $\mu_B$  is large, a brief visit to state  $B$  is so obvious that the sequence is clear, and both algorithms get nearly 100% of

state sequence correct. In between, both algorithms have intermediate performance, but state sequence analysis is correct a greater fraction of the time. Figure 1D reports in greater detail the frequencies of simulated and inferred state sequences when  $\mu_B = 5$ . Both algorithms are correct more than 90% of the time, but state sequence analysis demonstrates substantially fewer “false positive” detections of state  $B$  than Viterbi does (66 versus 467), although it incurs a greater number of “false negatives” (inferring no  $B$  visit when there was one, 115 versus 36).

Figure 2A shows a similar problem where more than one event (visit to state  $B$ ) can occur in a given trajectory, with a sample observation trajectory displayed in Figure 2B with  $\mu_B = 4$ . Again, we ran 10,000 simulations of 100 time steps to generate observation trajectories, and then applied Viterbi and state sequence analysis to estimate the underlying state sequences. Figure 2C shows the results. Similar to the previous example, when  $\mu_B$  is high, so that events are clearly observed, both algorithms predict the number of events correctly. However, when  $\mu_B$  is lower, state sequence analysis outperforms Viterbi. Unlike the previous example, state sequence analysis predicts correctly more often than Viterbi even when  $\mu_B = 0$ , so that observations are uninformative. With uninformative observations, state sequence analysis predicts the sequence with the highest a priori probability, which turns out to be  $SBSBSBSBS$ . By contrast, Viterbi computes the maximum probability trajectory to be  $SS \dots S$ , but this corresponds to the state sequence  $S$ , which is of much lower probability. So, even with non-informative observations, state sequence analysis “guesses” correctly a greater fraction of the time. In part, this advantage extends to partially-informative observations. Figure 2D shows a heatmap of true numbers of events versus predicted numbers of events by the two algorithms, across our 10,000 simulations when  $\mu_B = 2$ . In this domain, we see that Viterbi tends to underestimate the number of events, whereas state sequence analysis appears much less biased.

### 4.2 ACTIVITY RECOGNITION DATASET

The increasing availability of various kinds of sensors allows us to collect and analyze data that was previously unthinkable. One place where sensors invade our lives is houses and apartments. The data collected from those sensors is the basis for designing various intelligent environments [Cook and Das, 2004, Augusto and Nugent, 2006] and several healthcare applications [Abowd et al., 2002, Suzuki et al., 2004]. In [van Kasteren et al., 2011], activity data was collected from several individuals living in an apartment/house. The data consists of sensor readings and activity annotations made either manually or automatically. The sensors installed around the house report, for example, open-close states of doors and cupboards, and pressure measurements on the couch, while the activities might in-

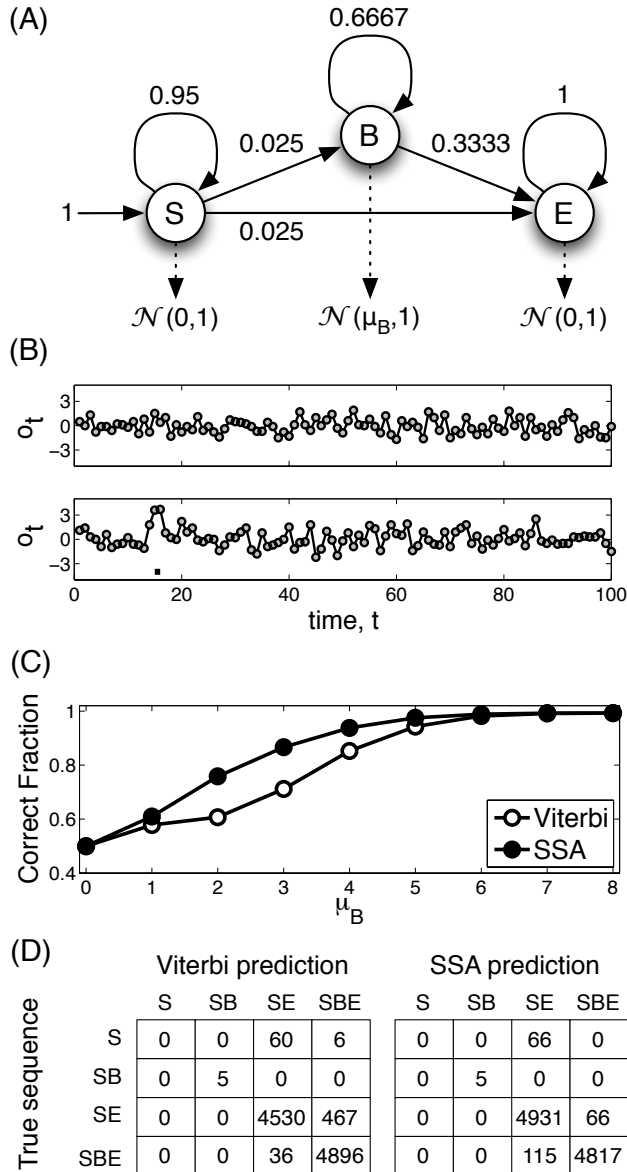

Figure 1: Demonstration of State Sequence Analysis, and comparison with the Viterbi algorithm, on a simple detection problem. Based on a noisy time series, the problem is to infer the underlying sequence of states, which is approximately equivalent to determining whether the sequence contains a visit to the state  $B$ .

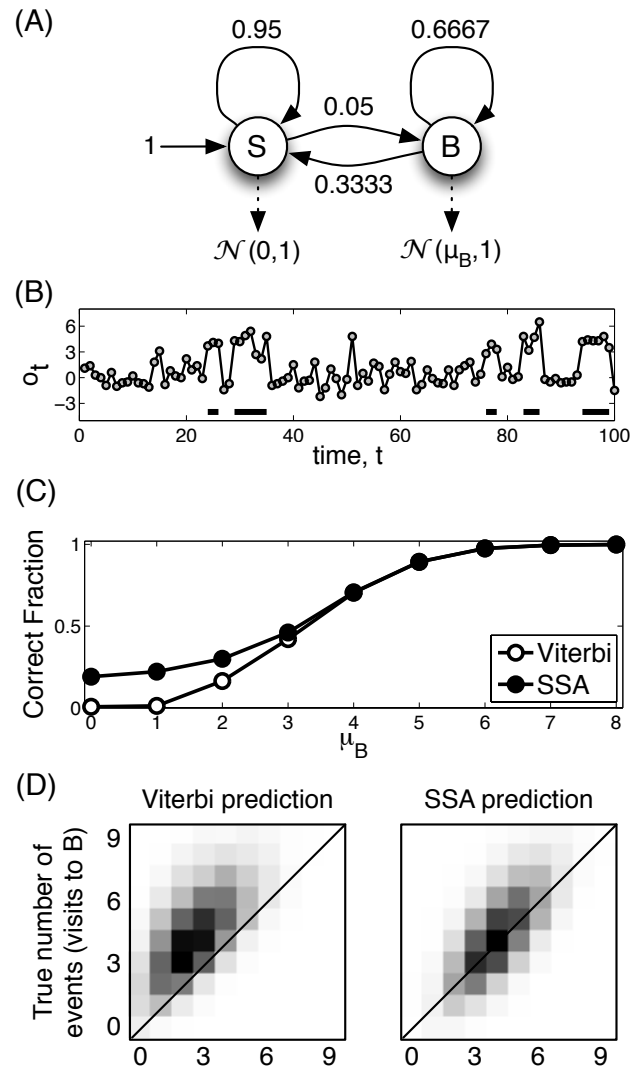

Figure 2: Comparison of State Sequence Analysis and Viterbi on a detection problem where multiple events per trajectory are possible.

clude cooking, eating, taking a shower, etc. The authors trained several models that identify past activities given a time series of sensor readings. Modeling the data with an HMM and using the Viterbi algorithm to identify the activities was among the options that demonstrated competitive recognition performance. The reported results offer a useful benchmark to evaluate new methods of activity recognition in this setting.

Interestingly, the current problem formulation for activity recognition task around the house does not necessarily reflect the type of questions that the user is interested to find answers to. In particular, it is easy to imagine that what really matters to the user is the sequence of activities performed in a period of time, regardless of their duration. If an intelligent system is able to identify the activity perfectly at each point of time, one can obtain the sequence of activities simply by collapsing repetitive activities into a single value. Clearly, sensor readings do not always help to identify activities perfectly. As seen from the synthetic problem described earlier, when observations provide limited information about the underlying state, collapsing repetitive activities identified by the most probable state trajectory (Viterbi output) is often inferior to finding the most probable state sequence directly.

To illustrate the potential benefits of state sequence analysis on a realistic problem, we evaluate it on the largest out of three available datasets collected in [van Kasteren et al., 2011]. This dataset, named *House A*, contains 592 hours (nearly 25 days) of recorded activities and sensor readings of a single individual living in a one floor apartment. There are 14 sensors with binary outputs reporting different states of objects and 10 possible activities that the person can do at any single time period (see Table 1). A single record of activity and sensor readings was recorded every minute. To compare Viterbi and SSA approaches, 25 HMMs were trained, each on data from different sets of 24 days. These HMMs were then used, in combination with Viterbi or SSA, to make predictions on 24 trajectories (one hour each) taken from the remaining single day. For more details about the dataset see [van Kasteren et al., 2011].

As previously, we compared the performance of SSA to the results obtained by collapsing repetitive activities in the most probable state trajectory computed using the Viterbi algorithm. Out of 592 sample trajectories, Viterbi and SSA disagreed on 25 ( $\approx 5\%$ ) of those. Further, we measured how well the produced state sequences match the true state sequences using the insert-delete string comparison<sup>1</sup>. On 7 trajectories the results of Viterbi produced a better score, while on 13 trajectories SSA performed better (for the other

<sup>1</sup>This is similar to the well known edit/Levenshtein string distance, except that the replace operation is not directly allowed. In the context of activity recognition problems, it is better not to report a particular activity at all than to report a wrong activity.

|   |
|---|
| Activities: <i>idle, leave house, use toilet, take shower, brush teeth, go to bed, prepare breakfast, prepare dinner, get snack, get drink.</i> |
|---|

|   |
|---|
| Sensors: <i>microwave, hall-toilet door, hall-bathroom door, cups cupboard, fridge, plates cupboard, front door, toilet flush, freezer, pans cupboard, groceries cupboard, hall-bedroom door.</i> |
|---|

Table 1: House A: activities and sensors.

5 the scores were equal). Although the difference might appear not very meaningful at first glance, there are several factors about the problem that need to be understood. First, some sensors identify the activities rather precisely, e.g., using toilet flush indicates that the toilet was used at that time, or opening the front door means that the person is leaving/coming back to the apartment. Second, most of the true state sequences are short (see Table 2, first line). In fact, around 75% of those contain only a single state, the majority of which are either *idling* (unidentified activity), *go to bed* or *leave house*. However, hours that include 3 activities or more are much more likely to produce sequences of observations on which Viterbi and SSA differ (see Table 2, second line). Considering that, it is expected to have a small number of trajectories on which Viterbi and SSA disagree. Among those, SSA provided a better prediction on nearly twice the number of trajectories on which Viterbi performed better. An example of a one hour trajectory where SSA improves over Viterbi inference is given in Figure 3. This is a typical example where sensor readings provide only indirect information about an activity that happens, which Viterbi algorithm fails to identify. From the computational perspective, it took about 5 minutes to run SSA algorithm on the entire dataset using a 3.40GHz CPU with 16GB memory machine, and a fraction of a second to find the most probable state trajectories (Viterbi).

To further establish the fact that SSA performs better as compared to Viterbi algorithm on this domain, we trained an HMM on the entire dataset and sampled a large number of state and observation trajectories. Specifically, for each starting state of an HMM we sampled 1000 one-hour-long trajectories and evaluated SSA and Viterbi on this simulated dataset. The results are presented in Figure 4. As expected, depending on the initial state of the HMM, there will be a different number of trajectories on which SSA and Viterbi state sequences are not equal. Moreover, depending on the initial state, the general performance of SSA and Viterbi, compared to each other, can be different. Nevertheless, in most cases SSA performed significantly better than Viterbi. In total, Viterbi scored better on 286 trajectories while SSA scored better on 494 trajectories, which amounts to more than 70% improvement in performance.

| length $\geq 1$ | length $\geq 2$ | length $\geq 3$ | length $\geq 4$ |
|-----------------|-----------------|-----------------|-----------------|
| 100% (592)      | $\approx 25\%$  | $\approx 20\%$  | $\approx 12\%$  |
| 100% (25)       | 96%             | 92%             | 52%             |

Table 2: House A: the percentage of state sequences of different length appearing in the dataset (line 1), and those whose Viterbi and SSA scores were different (line 2).

Figure 3: Example of a one hour trajectory of observations. Y axis enumerates binary sensor readings, and points on the plot identify active sensors. Note that we use the sensor readings representation that continues to be active until there is any change in other sensor readings (see more details in [van Kasteren et al., 2011]). Vertical dashed lines on the plots show the time of true activity change. The true underlying activity sequence is: *idle*, *brush teeth*, *use toilet*, *go to bed*. SSA outputs the true activity sequence, whose probability equals to 0.53. However, Viterbi’s output omits the *brush teeth* activity, and the probability of resulting activity sequence is only 0.34.

## 5 CONCLUSION

Inference problem in Hidden Markov Models have received considerable attention, and several algorithms have been used in a variety of domains to infer the behavior of the underlying system this HMM represents, given a sequence of noisy observations. Typically, these algorithms estimate different quantities involving hidden variables (e.g., Viterbi, posterior decoder, most probable annotation sequence, etc. [Brejová et al., 2007, Lember and Koloydenko, 2014]) and therefore, at their core, address different inference problems. In this work, we point out that in a variety of domains none of these techniques is adequate enough to answer our question of interest, which is to find the most probable state sequence. Naturally, the closest existing approach that can be used to find the most probable state sequence is to find the most probable state trajectory using the Viterbi algorithm and collapse repetitive state visitations. However, by doing so, the recovered state sequence is not guaranteed to be the

Figure 4: Comparison of SSA and Viterbi evaluated on simulated trajectories from *House A* dataset. X axis identifies the initial state of an HMM that the trajectories were sampled from. For each state, 1000 trajectories were sampled, and the performance of SSA was compared to Viterbi. As previously, trajectories on which the outputs of SSA and Viterbi differ were used to measure the performance by means of insert-delete string distance (Viterbi/SSA vs. true state sequence). Each bar in a category represents the number of trajectories on which the corresponding method scored better.

most probable state sequence. Moreover, the resulting state sequence might actually have a much lower probability of happening compared to the most probable one, as our experimental results suggest. In fact, those discrepancies are not surprising since, using Bayesian networks terminology, the Viterbi algorithm for HMMs produces *most probable explanation* (MPE) solution, while we are seeking to find a MAP solution different from MPE as we ignore dwelling time (variables) [Darwiche, 2009].

Building on earlier work where an algorithm to find the most probable state sequence in continuous time Markov chains was proposed [Levin et al., 2012], in this work we developed a state sequence analysis algorithm that finds the most probable state sequence of an HMM given a sequence of observations. The algorithm performs a search in the space of state sequences by evaluating those sequences and pruning parts of the search space by carefully maintaining a domination relationship between the sequences. We evaluated the algorithm on synthetic event-detection problems first to highlight its advantages over a Viterbi-based approach. Then, we used state sequence analysis to find the most probable sequence of activities based on a real activity recognition dataset collected from individuals performing different duties at home [van Kasteren et al., 2011]. Although the Viterbi algorithm performed reasonably well on this problem, the advantages of using state sequence analysis were nevertheless apparent.

Much remains to be done with respect to the analysis and evaluation of our proposed approach. One of the topics that

requires further attention is the computational complexity of the algorithm. Although we did not experience difficulties running the algorithm on the problems presented in this paper, it is still not clear whether the problem of finding the most probable state sequence is polynomial or NP hard in general. Further, in many real dynamical systems that involve hidden variables, the model of choice is Hidden Semi-Markov Models (HSMM) [Yu, 2010]. It seems rather straightforward to adapt our algorithm to HSMMs, however experimental results are needed to verify its benefits and computational cost.

# Multitasking: Efficient Optimal Planning for Bandit Superprocesses

---

Dylan Hadfield-Menell and Stuart Russell

## Abstract

A bandit superprocess is a decision problem composed from multiple independent Markov decision processes (MDPs), coupled only by the constraint that, at each time step, the agent may act in only one of the MDPs. Multitasking problems of this kind are ubiquitous in the real world, yet very little is known about them from a computational viewpoint, beyond the observation that optimal policies for the superprocess may prescribe actions that would be suboptimal for an MDP considered in isolation. (This observation implies that many applications of sequential decision analysis in practice are technically incorrect, since the decision problem being solved is often part of a larger, unstated bandit superprocess.) The paper summarizes the state-of-the-art in the theory of bandit superprocesses and contributes a novel upper bound on the global value function of a bandit superprocess, defined in terms of a direct relaxation of the arms. The bound is equivalent to an existing bound (the Whittle integral), but is defined constructively, as the value of a related multi-armed bandit. We provide a new method to compute this bound and derive the first practical algorithm to select optimal actions in bandit superprocesses. The algorithm operates by repeatedly establishing dominance relations between actions using upper and lower bounds on action values. Experiments indicate that the algorithm's run-time compares very favorably to other possible algorithms designed for more general factored MDPs.

## 1 INTRODUCTION

Multitasking is no doubt an activity familiar to the reader: one faces several decision problems but can act on only one (or perhaps a bounded number) at a time. Such prob-

lems are ubiquitous for individuals, corporations, armies, and governments.

Multitasking problems are expressed by the class of *bandit superprocesses* [Nash, 1973] or BSPs. A  $k$ -armed BSP  $M$  consists of  $k$  independent Markov decision processes  $M_1, \dots, M_k$ ; the MDPs are coupled by a common discount factor and by the constraint that at each time step the agent can act in only one MDP.

Since the MDPs are independent of each other, one might imagine that the optimal policy for  $M$  is obtained by solving each MDP—turning the BSP into a multi-armed bandit—and then using Gittins indices to choose a sequence of arms. In fact, *the optimal policy for a BSP may include actions that are suboptimal from the point of view of the constituent MDP in which they are taken*. The reason for this is that the availability of other MDPs in which to act changes the balance between short-term and long-term rewards in a component MDP; in fact, it tends to lead to greedier behavior in each MDP because aiming for long-term reward in one MDP would delay rewards in all the other MDPs. The globally and locally optimal policies necessarily coincide only when the discount factor is 1.

Hence, in addition to their general importance in the real world, a second reason to study multitasking problems is that they undermine an assumption implicit in practical applications of sequential decision analysis: the assumption that an optimal solution for the user's decision problem is optimal for a user who faces multiple decision problems.

Despite these considerations, there has been remarkably little research on bandit superprocesses and almost none in AI. Section 2 summarizes what is known. Obviously, there are connections to multi-armed bandits (MABs), which are a special case of BSPs in which each arm only allows one choice of action rather than several. Unfortunately, the index theorems that simplify the computation of optimal MAB policies are not valid for BSPs. There are also strong connections—hitherto unexplored—between BSPs and *sums of games* as studied in combinatorial game theory [Conway, 2000]. The principal question we address in

this paper is whether an algorithm exists that is substantially more efficient than applying a standard MDP solver to the “cross-product” MDP obtained by combining the states spaces of the constituent MDPs.

The sole known case where planning for a BSP is provably more efficient is the case where a *dominating* policy exists: if a single policy is optimal across the family of *retirement processes* associated with each arm then a BSP can be reduced to an equivalent MAB [Whittle, 1980]. (Retirement processes provide a measure of how the optimal policy depends on context and are defined in Section 3.) However, this condition is seldom satisfied in practice.

This paper provides three contributions. First, we give a concise survey of the bandit superprocess literature tailored to the AI community. Second, we provide a novel upper bound on the global value function of a BSP. For a BSP,  $M$ , with arms  $\{M_1, \dots, M_k\}$  we relax each arm to obtain an MAB  $M' = \{M'_1, \dots, M'_k\}$  by adding actions to ensure that dominating policies exist. We show that this upper bound is equivalent to the *Whittle integral*, an existing upper bound for BSPs [Brown and Smith, 2013]. Because our bound is defined in terms of an explicit relaxation, it provides insight into the nature of the bound and opens an avenue to extend this work to more general MDPs. Finally, we describe a practical computational approach for solving BSPs: we derive a simple method for computing the Whittle integral upper bound that can use an arbitrary MDP solver as a black box; then we combine this upper bound with a lower bound to derive an efficient algorithm for  $\epsilon$ -optimal decision making in a BSP. We present empirical results to show that it substantially improves over more general optimal factored MDP algorithms; we use it to compute provably optimal actions for problems with upwards of  $10^{30}$  states in the full state space.

## 2 RELATED WORK

Robbins [1952] provided the first formulation of multi-armed bandits (MABs) in their modern form. The famous Gittins index theorem [Gittins, 1979] showed that optimal MAB policies are obtained by ranking the arms according to an index function defined on each separately. An immediate corollary is that optimal decision making in an MAB is *linear* in the number of arms. Problems with this property are said to be *indexable*.

Bandit superprocesses (BSPs) were introduced by Nash [1973] as a generalization of multi-armed bandits to study allocation of resources among research projects. Whittle [1980] provided an alternate proof of the Gittins index theorem that extends to bandit superprocesses with dominating policies. His proof utilized a construction called the *Whittle integral*, which allows one to compute the value of a composite state in an MAB. Glazebrook [1982] provides a proof that bandit superprocesses are *not* indexable

in general. Glazebrook [1993] considers bandit superprocesses where the arms can exert limited influence on each other and shows a result analogous to Whittle’s.

Brown and Smith [2013] were the first to identify the significance of the Whittle integral for sequential decision making. They developed a version of policy iteration to compute it, and recognized that it upper bounds the value function of a BSP,<sup>1</sup> but did not derive an algorithm for solving BSPs. Our work provides two further contributions regarding the Whittle integral: a short proof that it is an upper bound and a simpler algorithm to compute it.

Within the AI community, there has been limited study of loosely coupled Markov decision processes. Singh and Cohn [1998] consider optimal solutions to *simultaneous MDPs*, where an agent can take actions in a number of MDPs. Their formulation is more general than ours, as it is possible to act in multiple MDPs at once. They derive bounds for this problem and give an algorithm that combines a form of real-time dynamic programming with pruning steps to remove provably suboptimal actions. However, their bounds are substantially looser than ours, and our experiments show that the corresponding algorithm can be impractical for simple BSPs with many arms.

Meuleau et al. [1998] examine MDPs that are coupled by constraints on the use of shared resources. BSPs fit within this class if we view the restriction to a single MDP at a time as a constraint on the agent’s attention. Interestingly, their heuristics are also defined in terms of a parameterized value function for the component MDPs—it would be interesting to attempt to generalize the approaches considered here to their problem domain. In this work, we leverage the particular structure of our resource to compute optimal solutions; Meuleau et al. construct a heuristic policy.

## 3 TECHNICAL BACKGROUND

### MARKOV DECISION PROCESSES

**Definition 1.** (*Markov Decision Process [Puterman, 2009]*) A (finite-state, discounted) MDP,  $M$ , is a tuple  $M = \langle \mathcal{S}, \mathcal{A}, T, R, \gamma \rangle$ .  $\mathcal{S}$  is a set of states.  $\mathcal{A}$  is a set of actions.  $T : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \rightarrow [0, 1]$  is a function that assigns probability to state transitions for each state–action pair.  $R$  is a (bounded) reward function that maps state–action pairs to (positive) rewards  $R : \mathcal{S} \times \mathcal{A} \rightarrow \mathbb{R}^+$ .  $\gamma \in [0, 1)$  is a discount factor.

A solution to  $M$  is a policy,  $\pi$ , that maps states to actions. The value of a state,  $s$ , under  $\pi$  is the sum of expected discounted rewards received by starting in  $s$  and selecting ac-

<sup>1</sup>This result first appears in the literature as an intermediate step in a larger proof from Whittle [1980]. It went unnoticed or unappreciated in the intervening 30+ years.

tions according to  $\pi$ :

$$V^\pi(s) = \mathbb{E} \left[ \sum_{t=0}^{\infty} \gamma^t R(s_t) | s_0 = s, \pi \right].$$

The optimal policy,  $\pi^*$ , maximizes this value. In the above definition, and the ones that follow, we use superscripts to indicate dependence on the agent’s policy. To simplify notation, we will omit these superscripts when the policy referred to is the optimal policy (e.g.,  $V(s) = V^{\pi^*}(s)$ ). The  $Q$ -function for the state–action pair,  $(s, a)$ , is the value of taking  $a$  in  $s$  and selecting future actions according to  $\pi^*$ .

## RETIREMENT PROCESSES

Given an MDP, Whittle defines a family of optimal stopping problems:

**Definition 2.** (*Retirement Process [Whittle, 1980]*) Let  $M$  be an MDP. For  $\rho \geq 0$ , the retirement process for  $M$  with retirement reward,  $\rho$ , is an MDP,  $M_\rho$ , with a single additional state,  $s_R$ , and action,  $a_R$ .  $a_R$  transitions deterministically to  $s_R$  and receives reward  $\rho$ .  $s_R$  is a sink state that accrues zero reward.

We refer to a decision to select  $a_R$  as a decision to retire. We denote the retirement process value function as a function of a state and retirement reward,  $V(s, \rho)$ . We let the optimal policy for retirement reward  $\rho$  be  $\pi_\rho^*$ . We write the set of states where the policy,  $\pi$ , retires as  $\tau_\rho^\pi$ . We use  $\rho_-(\pi)$  and  $\rho_+(\pi)$  to denote the interval of retirement rewards so that  $\pi$  is optimal:

$$\rho' \in [\rho_+(\pi), \rho_+(\pi)] \Rightarrow V^\pi(s, \rho) = V(s, \rho).$$

We adopt the convention from the MAB/BSP literature and abuse notation to denote the (random) number of steps prior to retirement as  $\tau_\rho^\pi(s)$ . For  $s' \in \tau_\rho^\pi$  we let  $P_{retire}(s'|s, \rho, \pi)$  be the probability that  $s'$  is the first state in  $\tau_\rho^\pi$  the agent will reach given that it is in state  $s$  and executes policy  $\pi$ . We denote the expected discounted reward accrued prior to retirement, starting in  $s$ , as  $R_\rho^\pi(s)$ . In regions of retirement reward where the optimal policy and stopping rule do not change,  $\frac{\partial V}{\partial \rho}(s, \rho)$  is defined and is equal to the expected value of the discount parameter at retirement. This allows us to write the following expression for the retirement process value function:

$$V(s, \rho) = R_\rho(s) + \mathbb{E}[\gamma^{\tau_\rho(s)}] \rho. \quad (1)$$

$V(s, \rho)$  is piecewise linear in  $\rho$ . Figure 1 shows  $V(s, \rho)$  for the example BSP in Ex. 1. A policy that is optimal for every setting of  $\rho$  is called a *dominating policy*.

**Definition 3.** (*Dominating Policy*) Let  $\pi$  be a policy for an MDP,  $M$ .  $\pi$  is a dominating policy iff

$$\forall \rho \geq 0 \forall s \notin \tau_\rho \pi(s) = \pi_\rho^*(s).$$

## MULTI-ARMED BANDITS AND BANDIT SUPERPROCESSES

Multi-armed bandits (MAB) are a restricted class of MDPs that have received extensive study. Of particular interest are the form of the optimal policy and its utility in modelling “exploration vs exploitation” trade-offs.

An MAB consists of a set of Markov reward processes (MRPs), where an MRP is an MDP with a single action. Each MRP is referred to as an *arm* of the problem. At each time-step, the agent selects an arm, that arm transitions according to its transition distribution, and the agent receives the corresponding reward. We adopt a summation notation to indicate the combination of several MRPs into an MAB. For example, if  $X$  and  $Y$  are MRPs and  $Z$  is the MAB with arms  $X$  and  $Y$ , we will write  $Z = X + Y$ .

A famous result is that the optimal policy for any MAB is an *index policy* [Gittins, 1979]. Each state,  $s_i$ , in the individual arms is assigned an index,  $I_{s_i}$ . In joint state  $s = \{s_1, \dots, s_k\}$ , the optimal action is to select  $\text{argmax}_i I_{s_i}$ . For MAB arm  $M_i$  in state  $s_i$ , the index is defined as the value of retirement reward such that the agent is indifferent between immediate retirement and following the optimal stopping policy [Whittle, 1980]:

$$I_{s_i} = \min_{\rho} \{ \rho ; V_i(s_i, \rho) = \rho \}.$$

This means that, in a sense, context for a multi-armed bandit can always be summarized by a single number.

To model a multi-tasking problem, we consider a generalization of multi-armed bandits: bandit superprocesses (BSPs). Bandit superprocesses allow arms that are arbitrary MDPs (and so are a generalization of MABs); at each time step, the agent selects both an arm *and* an action to take within that arm.

**Definition 4.** (*Bandit Superprocess [Nash, 1973]*) Given  $k$  MDPs,  $\{M_i = \langle \mathcal{S}_i, \mathcal{A}_i, T_i, R_i, \gamma \rangle\}$ , we define

$$M = \sum_i M_i = \langle \mathcal{S}, \mathcal{A}, T, R, \gamma \rangle$$

to be the bandit superprocess with arms  $\{M_i\}$ .  $\mathcal{S} = \times_i \mathcal{S}_i$  and  $\mathcal{A} = \cup_i \mathcal{A}_i$ . The transition distribution is stationary for arms that are not selected and follows the identical reward and transition distributions for the selected arm.

Naturally, this makes planning more difficult. To see how, consider the following proposal:

**Conjecture 1.** Let  $X = \langle \mathcal{S}_X, \mathcal{A}_X, T_X, R_X, \gamma \rangle$  be an MDP. Define  $Y$  similarly and let  $Z = X + Y$  be the bandit superprocess that is their sum. Let  $a \in \mathcal{A}_X$ ,  $s_X \in \mathcal{S}_X$  be a state–action pair from  $X$ . Suppose that this transition is suboptimal in every retirement process:  $\forall \rho \geq 0, V_X(s_X, \rho) > Q_X((s_X, a), \rho)$ . Then a is

suboptimal for any state in  $Z$  with  $s_X$  as one of the components:

$$\forall s_Y \in \mathcal{S}_Y, V_Z(\{s_X, s_Y\}) > Q_Z(\{s_X, s_Y\}, a).$$

This conjecture essentially proposes that state–action pairs can be safely ignored if they are suboptimal for all settings of a constant alternative. Unfortunately, as the following example illustrates, this is not the case.

**Example 1.** Define  $X$  to be a deterministic reward chain and  $Y$  to be an initial choice between three reward chains  $(y_0, y_1, y_2)$  defined as follows:

$$X = 28, 28, 28, 28, 28, 28, 0, 0, \dots$$

$$Y = \begin{cases} y_0 = 100, 100, 100, 0, 0, 0, \dots \\ y_1 = 99, 99, 99, 1.4, 1.4, 1.4, \dots \\ y_3 = 28, 28, 28, \dots \end{cases}$$

The retirement process value function for each reward chain can be computed by simulating the Gittins index policy:<sup>2</sup>

$$V(y_0, \rho) = \max \left\{ 100 \left( \sum_{t=0}^2 \gamma^t \right) + \gamma^3 \rho, \rho \right\}$$

$$V(y_1, \rho) = \max \left\{ 99 \left( \sum_{t=0}^2 \gamma^t \right) + \gamma^3 \max \left\{ \frac{1.4}{1-\gamma}, \rho \right\}, \rho \right\}$$

$$V(y_2, \rho) = \max \left\{ \frac{28}{1-\gamma}, \rho \right\}.$$

If we let  $\gamma = .9$ , then we have

$$\forall 280 > \rho \geq 0 \max\{V(y_0, \rho), V(y_2, \rho)\} > V(y_1, \rho).$$

Thus, any policy for a retirement process retirement process derived from  $Y$  that initially selects  $y_1$  is suboptimal. We can apply the same strategy to compute the value of each combination of reward streams:

$$V(y_0 + X) = 100 \left( \sum_{t=0}^2 \gamma^t \right) + \gamma^3 \left( 28 \sum_{t'=0}^5 \gamma^{t'} \right)$$

$$V(y_1 + X) = 99 \left( \sum_{t=0}^2 \gamma^t \right) + \gamma^3 \left( 28 \sum_{t'=0}^5 \gamma^{t'} + \gamma^6 \frac{1.4}{1-\gamma} \right)$$

$$V(y_2 + X) = \frac{28}{1-\gamma}$$

From this we can see that the optimal policy for the BSP that combines these MDPs,  $Z = X + Y$ , initially collects reward from  $y_1$ . This contradicts Conjecture 1.

<sup>2</sup>Here we use the fact that the Gittins index of a non-increasing reward sequence is equal to the instantaneous reward.

## 4 AN UPPER BOUND FOR BANDIT SUPERPROCESSES

In this section we show a bound on the value function of a bandit superprocess. We derive this bound by adding actions to a BSP so that it is equivalent to an MAB. The value function of our relaxed BSP is equivalent to the Whittle integral bound derived in Brown and Smith [2013] and so it yields insight into that computation. We begin by defining the Whittle integral and show some basic results in order to motivate our relaxation.

**Definition 5.** (Whittle Integral [Brown and Smith, 2013]) Let  $M$  be a BSP. Let  $i$  index the arms of  $M$ . For any state,  $s = \{s_i\}$ , and  $\rho \geq 0$ , the Whittle integral of  $s$  is defined as

$$\hat{V}(s, \rho) = I - \int_{x=\rho}^I dx \prod_i \frac{\partial V_i}{\partial \rho}(s_i, x). \quad (2)$$

Where  $I \geq \max_i I_{s_i}$ .

When the arms of a BSP admit a dominating policy the Whittle integral is equal to the value function:

**Theorem 1.** (Whittle Condition [Whittle, 1980]) Let  $M$  be a  $k$ -armed BSP with components  $\{M_i\}$  and state space  $\mathcal{S}$ . If each  $M_i$  has a dominating policy, then

$$\forall s \in \mathcal{S}, \forall \rho \geq 0, \hat{V}(s, \rho) = V(s, \rho).$$

MRPs have a single action per state, so the Whittle condition is trivially satisfied for all multi-armed bandits.  $V(s, 0) = V(s)$ , so  $\hat{V}(s, 0)$  provides an efficient method to compute the value of an MAB. For BSPs an arm that satisfies the Whittle condition can be replaced with an MRP that selects actions according to  $\pi^*$ .

The formula in Eq. 2 lends itself to a straightforward implementation, but is very challenging to interpret. We show below that this is equivalent to evaluating the retirement process value function for a single arm with a set of rewards determined by the other arms<sup>3</sup>. We refer to this set of rewards as the *critical points* of those arms.

**Definition 6.** (Critical Points of an MDP) Let  $M$  be a Markov decision process. The critical points of  $M$ ,  $\mathcal{C}(M) = \{\rho_i\}$ , are the values of retirement reward such that the optimal stopping rule or policy changes.

These are points where there is a discontinuity in  $\frac{\partial V}{\partial \rho}$ . We let

$$\Delta^M(s, \rho) = \lim_{\delta \rightarrow 0} \frac{\partial V_M}{\partial \rho}(s, \rho + \delta) - \frac{\partial V_M}{\partial \rho}(s, \rho - \delta)$$

be the size of the corresponding discontinuities. This is equivalent to the expected increase in  $\mathbb{E}[\gamma^\tau]$  under the new stopping rule. Theorem 2 shows that  $\Delta$  and  $\mathcal{C}$  characterize the interaction between arms of an MAB.

<sup>3</sup>Our result is a small extension on a related result in Brown and Smith [2013]; it is primarily included to provide intuition.

**Theorem 2.** Let  $X, Y$  be Markov reward processes. Let  $Z = X + Y$  be the 2-armed bandit.  $\forall s = \{s_X, s_Y\} \in \mathcal{S}_Z$ ,

$$V_Z(s) = \sum_{\rho \in \mathcal{C}(Y)} V_X(s_X, \rho) \Delta^Y(s_Y, \rho). \quad (3)$$

*Proof.* (sketch) As a first step, we follow the steps in Whittle [1980] and integrate Equation 2 by parts. This expresses  $\hat{V}$  as the following integral:

$$\hat{V}_Z(s) = \int_{\rho'=\rho}^{I_{s_X}} V_X(s_X, \rho') \frac{\partial^2 V_Y(s_Y, \rho')}{\partial \rho^2} d\rho'.$$

$V_Y$  is piecewise linear with respect to  $\rho$  so  $\frac{\partial^2 V_Y}{\partial \rho^2}$  is a weighted sum of delta functions centered at  $V_Y$ 's kinks.  $\mathcal{C}(Y)$  and  $\Delta^Y$  respectively characterize these kinks and weights. Thus,  $\hat{V}_Z(s)$  is equal to the rhs of Eq. 3.  $X$  and  $Y$  are MRPs, so an appeal to Theorem 1 shows the result.  $\square$

A similar property holds for arbitrary  $k$ -armed bandits. This shows that we can summarize the context for an arm as a collection of weighted retirement rewards. Turning to BSPs, this lends insight into the approximation the Whittle integral introduces.

To see how, we reconsider Ex. 1. Recall that this example consists of the BSP  $Z = X + Y$  and that  $Y$  is a choice between three reward chains,  $\{y_0, y_1, y_2\}$ . Theorem 2 allows us to write the gap between the Whittle integral upper bound and the value of selecting  $y_1$  as

$$\sum_{\rho \in \mathcal{C}(X)} \left( \max_i V_{y_i}(s_i, \rho) - V_{y_1}(s_1, \rho) \right) \Delta^X(s_X, \rho)$$

Figure 1 shows the retirement process value functions for this example. While the retirement process value of  $y_1$  is always less than that of either  $y_0$  or  $y_2$ , it is close enough to their maximum that choosing  $y_1$  essentially achieves the upper bound. The Whittle integral for  $Z$  is a weighted combination of distinct retirement process value functions ( $V_{y_0}, V_{y_2}$ ) but, in reality, the agent will be forced to pick a single policy of the two.

## DOMINATED RELAXATION OF AN MDP

In this section, we introduce our primary theoretical result: a relaxation for the arms of a BSP so that a dominating policy exists. This reduces the BSP to an MAB whose value upper bounds the value of states in the BSP. We can show that the Whittle integral computes the value of states in this MAB and arrive at a straightforward proof that the Whittle integral is an upper bound. We call the result the *dominated relaxation* of an MDP. Before providing the details, we illustrate the main ideas with an example. The relaxed MDP is actually a *Semi-MDP* (SMDP): a generalization of an MDP where each action,  $a$ , has a duration,  $\delta(a) \in \mathbb{R}_+$ .

**Example 2.** Let MDP  $M$  be an initial choice between MRPs:

$$M = \begin{cases} 15, 0, 0, 0 \dots \\ 10, 10, 10, 3, 3, 3, \dots \end{cases}.$$

Let  $T(B)$  be the top (bottom) MRP. Let  $\pi_T$  ( $\pi_B$ ) be the policy that selects  $T(B)$  in  $s_0$ . We can relax  $M$  with the addition of a single durative action,  $a'$ , that transitions from the sink state in  $T$  to the sink state  $B$ . We set  $\delta(a') = 2$ . We take  $\rho$  such that  $V^{\pi_T}(s_0, \rho) = V^{\pi_B}(s_0, \rho)$  and set the rewards associated with  $a'$  to be

$$R_{\rho}^{\pi_B}(s_0) - R_{\rho}^{\pi_T}(s_0) = 10 \sum_0^2 \gamma^t - 15 = 12.1.$$

With this change, at low settings of retirement reward, the agent is indifferent between a policy that opts for the top chain then selects  $a'$  and the bottom reward chain. For high settings of retirement reward, the optimal policy retires immediately or retires after collecting the reward of 15. This SMDP satisfies the Whittle condition and can be replaced by an MRP in any bandit superprocess. Fig. 1 (c) shows an illustration of the state space and the introduced action.

In this example, we connected the state where  $\pi_T$  retires to the state where  $\pi_B$  retires. This lets the agent collect short-term and long-term rewards with the same policy. To do this in general, we introduce multiple copies of the state space, one for each policy that is optimal for some  $\rho$ .

**Definition 7.** (*Dominated Relaxation of an MDP*) Let  $M$  be an MDP with discount factor  $\gamma$  and state space  $\mathcal{S}$ . Let  $s$  be a state in  $M$ . The dominated relaxation of  $M$  for  $s$ ,  $M_D(s)$ , is a semi-Markov decision process that fixes  $s$  as an initial state. Let  $\{\pi_i\}$  be the policies that are optimal for some  $\rho$ :  $\{\pi_{\rho}^* | \rho \in \mathcal{C}(M)\}$ . This sequence is ordered so that  $\rho_-(\pi_i)$  is increasing in  $i$ <sup>4</sup>.

For each  $i$ , we introduce a copy of the state space,  $\mathcal{S}_i$ , where the agent is restricted to following  $\pi_i$ . Let  $s'_i$  be the analogue of  $s'$  in  $\mathcal{S}_i$ . For  $s'_i \in \tau_{\rho_-(\pi_i)}$ , we introduce a single durative action,  $a_i$ , that takes the agent from  $\mathcal{S}_i$  to  $\mathcal{S}_{i-1}$  and characterize it as follows:

- $R(s'_i) = R_{\rho_+(\pi_{i-1})}(s) - R_{\rho_-(\pi_i)}(s)$
- $T(s'_i, a_i, s''_{i-1}) = P_{retire}(s'' | \pi_{i-1}, \rho_+(\pi_{i-1}), s)$
- $\delta(a_i) = \log_{\gamma} \mathbb{E} \left[ \gamma^{\tau_{\rho_+}^{\pi_{i-1}}(s)} \right] - \log_{\gamma} \mathbb{E} \left[ \gamma^{\tau_{\rho_-}^{\pi_i}(s)} \right]$

For each  $i$ , we introduce an action that transitions from  $s$  to  $s_i$  with  $\delta = 0$ . Let  $V_D(s)$  represent the value of  $s$  in  $M_D(s)$ .

**Theorem 3.** Let  $M$  be an MDP with state space  $\mathcal{S}$ . The following statements are true for  $s \in \mathcal{S}$  and  $\rho \geq 0$ :

<sup>4</sup>Recall that  $[\rho_-(\pi), \rho_+(\pi)]$  is the interval of retirement rewards where  $\pi$  is optimal.

1.  $M_D(s)$  satisfies the Whittle condition.
2.  $V_D(s, \rho) = \hat{V}(s, \rho)$ .
3.  $\hat{V}(s, \rho) \geq V(s, \rho)$

*Proof.* See supplementary materials □

## 5 AN $\epsilon$ -OPTIMAL ALGORITHM FOR BANDIT SUPERPROCESSES

In this section, we present two algorithms related to BSPs. The first is a novel algorithm to compute  $V(s, \rho)$  that can use any method to solve the underlying MDP. The second is an efficient algorithm to compute optimal actions for a BSP. Our approach, *Branch-and-Bound Value Iteration* (BBVI), uses Whittle integrals to compute upper and lower bounds on value. Then, we apply a modified Branch-and-Bound search to find provably optimal actions.

### COMPUTING A RETIREMENT PROCESS VALUE FUNCTION

Before we present BBVI, we give a simple algorithm to compute a retirement process value function that uses an (arbitrary) MDP solver as a black box. Brown and Smith [2013] describe an algorithm to compute retirement process value functions, but their approach requires custom implementation of a modified simplex algorithm. Our approach is simple and based on an algorithm that initially appeared in the solutions manual for Russell and Norvig [2010].

Our goal is to identify each component of  $V(\cdot, \rho)$ , so our output will be a list of critical points and the associated slopes. First, we will need the following result.

**Lemma 1.** *Let  $M$  be an MDP with state space  $\mathcal{S}$ . Let  $\rho_0 < \rho_1$ . Consider a retirement reward in the interior of this interval,  $\rho \in (\rho_0, \rho_1)$ . If,  $\forall s \in \mathcal{S}$*

$$V(s, \rho) = V(s, \rho_0) + \frac{V(s, \rho_1) - V(s, \rho_0)}{\rho_1 - \rho_0}(\rho - \rho_0), \quad (4)$$

*then there is at least one policy and stopping rule that is optimal for every  $\rho' \in [\rho_0, \rho_1]$ . The expected value of the discount factor at retirement is the slope between those points:*

$$\mathbb{E} \left[ \gamma^{\tau^*(s)} \right] = \frac{V(s, \rho_1) - V(s, \rho_0)}{\rho_1 - \rho_0}. \quad (5)$$

*Proof.* This follows from the form of Equation 1 and the fact that  $V(s, \rho)$  is piecewise linear, increasing, and convex. □

(a)

(b)

(c)

Figure 1: (a-b) Retirement process value functions for the reward chains in Ex. 1. The slope of the lines is the expected value of the discount parameter at retirement:  $\mathbb{E}[\gamma^\tau]$ . Flat sections indicate regions of retirement rewards where retirement is always suboptimal. The kink in the green curve at  $\rho = 280$  indicates that it has become optimal to retire immediately. The kink in the black curve at  $\rho = 14$  increases the slope to  $\gamma^6 < 1$ ; for  $\rho > 14$ , it is optimal to retire after collecting a prefix of the reward stream from  $y_2$ . (c) Dominated relaxation of the MDP in Ex. 2. We add additional durative actions to the state space to ensure that a dominating policy exists. Note that the original MDP does not admit a dominating policy.

This test allows us to implement a binary search over retirement rewards. Our approach relies on a given MDP solution method, SOLVE, that returns the vector of values for a given MDP. We initialize an interval that contains all critical points and make a call to SOLVE to compute the retirement process value at each endpoint. Then we call SOLVE to compute the retirement process value for the midpoint of our interval and apply the test in Eq. 4. If it succeeds, we return the lower endpoint and the corresponding slope. If this does not, we sub-divide our interval and recurse. We can concatenate the results to get the breakpoints and slopes for the retirement process value function over this interval. Algorithm 1 shows pseudocode for this algorithm.

**BRANCH-AND-BOUND VALUE ITERATION**

Now, we present a practical algorithm to compute optimal actions in a bandit superprocess. While a BSP is not indexable, we would like to be able to plan efficiently when the arms are ‘close’ to indexable—when there are only a few states where the optimal policy changes in response to the opportunity cost of delayed rewards in other arms.

Our approach is based on envelope dynamic programming methods to solve MDPs: we compute value estimates for a given initial state by solving a dynamic program defined over a reachable subset of the state space [Gardiol, Natalia H and Kaelbling, Leslie P, 2003, Hansen and Zilberstein, 2001]. The primary difference between our approach and standard envelope methods is that we use dynamic programming

on our envelope to update an upper bound and a lower bound on the value. This is useful in a BSP because the Whittle integral allows efficient calculation of both bounds.

Our goal is to compute the optimal action for a given state  $s$  in a BSP,  $M = \langle M_1, \dots, M_K \rangle$ . We can obtain an upper bound on  $V(s)$  with a Whittle integral. We use a Whittle integral for the MAB that solves each arm independently to compute a lower bound. Our algorithm maintains upper and lower bounds on the  $Q$ -function for each action that could be executed from  $s$ . We write these bounds as  $Q^+(s, a)$  and  $Q^-(s, a)$  respectively. If there is a pair of actions  $a, a'$  such that  $Q^+(s, a') < Q^-(s, a) + \epsilon$ , then we can conclude that  $a'$  is at least  $\epsilon$ -suboptimal. If this test removes all but a single action, then we have found a  $\epsilon$ -optimal action and return it.

In the event that more than one action remains, we do a partial expansion of the state space around  $s$ . We keep track of a set of expanded states,  $\mathcal{E}$ , and a set of boundary states,  $\mathcal{B}$ . States in the boundary set,  $\mathcal{B}$ , are states that some expanded state can transition to but have not yet been added to  $\mathcal{E}$ . We can use these states to update the bounds on  $Q(s, \cdot)$  by solving a related MDP. This is formalized in the following theorem.

**Theorem 4.** *Let  $M$  be an MDP with state space  $\mathcal{S}$  and action space  $\mathcal{A}$ . Let  $\mathcal{S}' \subseteq \mathcal{S}$  where  $\mathcal{S}' = \mathcal{B} \cup \mathcal{E}$  and  $\forall s \in \mathcal{E}, T(s, a, s') \neq 0 \Rightarrow s' \in \mathcal{S}'$ . Let  $M^+$  be an MDP with state space  $\mathcal{S}' \cup \{\alpha\}$ .  $M^+$ ’s transition distribution and rewards are identical for states in  $\mathcal{E}$  (expanded states). Each state  $s \in \mathcal{B}$  transitions deterministically to  $\alpha$  and receives a reward that is an upper bound on  $V_M(s)$ .  $\alpha$  is a sink state that accrues 0 reward. Then the value of a state in  $M^+$  is an upper bound on its value in  $M$ :*

$$V_{M^+}(s) \geq V_M(s).$$

*Proof.* See supplementary materials. □

It is straightforward to show that an updated lower bound can be computed by fixing boundary states to have value equal to a lower bound. Our approach alternates between pruning actions based on dominance relations, adding states to  $\mathcal{E}$ , and computing the value of an MDP defined over  $\mathcal{E}$ . We interleave value iteration with a branch-and-bound search, so we call it Branch-and-Bound Value Iteration (BBVI). Algorithm 2 shows pseudocode to implement this method. At termination, the action we return is guaranteed to be at most  $\epsilon$ -suboptimal.

**Theorem 5.** *Let  $M$  be a BSP and let  $s$  be a state in  $M$ . Let  $a$  be the action returned by BBVI( $M, s, \epsilon$ ).*

$$V(s) - Q(s, a) < \epsilon.$$

*Proof.* See supplementary materials. □

Large regions of the state space are irrelevant to our objective so we use a heuristic to guide node expansion. Our heuristic is a measure of the sensitivity of values at the root to change in the upper and lower bounds of unexpanded nodes. Similar heuristics have been applied in many settings [Rivest, 1987, Smith and Simmons, 2004]. In BBVI, these values are the expected discounted visitation rates in the bounding MDPs and are computed as the dual variables from a value iteration LP. The backup procedure is slower than node expansions, so we perform backups in batches. In between backups and heuristic computations, we approximate the state space as a tree and push new states onto the agenda with their parent’s heuristic value weighted by the transition probability.

---

**Algorithm 2** Branch-and-Bound Value Iteration

---

**Define:** BBVI( $\langle M_0, \dots, M_K \rangle, s_0, \epsilon$ )

**Input:** BSP arms,  $M_k$ ; Initial state,  $s_0$ ; Tolerance,  $\epsilon$

# Lower bound  $M$  by fixing a policy for each arm  
 $LB_k \leftarrow \text{toMRP}(M_k)$   
 Compute critical points for  $M_k, LB_k$   
 Compute bounds on  $Q(s_0, \cdot)$  with Whittle integrals for  $M$  and  $LB$ .

# Keep track of expanded region of state space  
 $\mathcal{E} \leftarrow \emptyset$

# Keep track of states at boundary of  $M^+, M^-$   
 $\mathcal{B} \leftarrow \{s_0\}$   
 $a^* \leftarrow \operatorname{argmax}_a Q^-(s_0, a)$

**while**  $\exists a' \neq a^* \text{ s.t. } Q^+(s_0, a') \geq Q^-(s_0, a^*)$  **do**  
    $s \leftarrow \text{pop}(\mathcal{B})$   
    $\mathcal{E} \leftarrow \mathcal{E} \cup \{s\}$   
   **for**  $a \in \mathcal{A}$  **do**  
     **for**  $s' \in \text{successors}(s)$  **do**  
       Compute upper and lower bounds for  $Q(s', \cdot)$   
        $\mathcal{B} \leftarrow \mathcal{B} \cup \{s'\}$   
     **end for**  
   **end for**  
    $Q^+ \leftarrow \text{SOLVE}(\text{BOUNDMDP}(\mathcal{E}, \mathcal{B}, Q^+))$   
    $Q^- \leftarrow \text{SOLVE}(\text{BOUNDMDP}(\mathcal{E}, \mathcal{B}, Q^-))$   
    $a^* \leftarrow \operatorname{argmax}_a Q^-(s_0, a)$

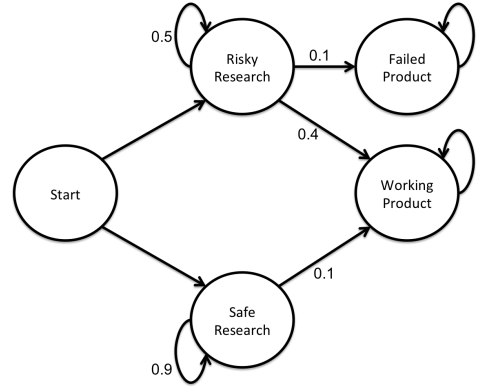

**end while**  
**return**  $\epsilon$ -optimal action  $a^*$

## 6 EMPIRICAL EVALUATION

We implemented BBVI in Python and use the linear programming solver Gurobi to compute value functions. Our experiments were run on an Intel i7 with 16 GB of RAM. In our first experiments, we compare the scalability of BBVI with that of standard MDP algorithms. In particular we compare the following algorithms:

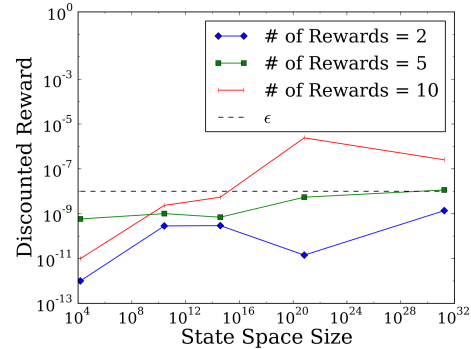

- SPUDD: the baseline factored MDP algorithm in the 2011 IPPC [Hoey et al., 1999].

(a) State Space for R & D BSP

(b) Runtime vs. Problem Size

(c) Solution Quality vs. Problem Size

Figure 2: (a) the state space for an arm of a R & D BSP. All states accrue 0 reward except for the ‘Working Product’ state, which collects a fixed reward per time step. (b) shows runtime (log-scale) vs problem size for BBVI and several alternatives on an R & D BSP. SPUDD [Hoey et al., 1999] and LRTDP (with the heuristic from Singh and Cohn [1998]) scale poorly compared with algorithms that leverage the Whittle integral. BBVI’s additional improvement over LRTDP stems from the use of an efficient, exact lower bound to check convergence. (c) BBVI’s bound on suboptimality after 10,000 node expansions (measured in units of discounted reward). Changing the number of rewards in each arm allows us to measure BBVI’s performance as arms become more sensitive to context.

- LRTDP(Merge): Labeled Real-Time Dynamic Programming [Bonet and Geffner, 2003] with the upper bound from Singh and Cohn [1998] as a heuristic.
- LRTDP(WI): LRTDP with the Whittle integral as an upper bound.
- BBVI: Branch-and-Bound Value Iteration.

We evaluate performance on a simple BSP designed to model allocation of research resources to product research and development. Each arm in this problem corresponds to a potential product that our agent could sell in the market. However, before we sell a product we must devote effort to R&D. This can be done in one of two ways, a safe research approach that is slow but reliable, and a risky approach that is fast, but runs a risk of producing a defective product.

After at least one product has been researched, the agent can opt to spend a round to produce and sell that product or continue research on a different project. Because taking a product to market does not change the state of the BSP, it is straightforward to show that any stationary policy (including  $\pi^*$ ) will only ever produce a single product. We define a distribution over these problems by selecting a random market value for each product uniformly from  $[0, 1]$  and random durations for the safe and risky research strategies (although we ensure that safe research is at least 3x as slow as risky research). Figure 2 (a) shows the state space for an example arm with typical parameters.

Figure 2 (b) shows the results of our comparison. We used a timeout of 1000s and set a memory limit of 4 GB. We ran our experiments in an online setting and running times reflect the amount of time to select an optimal action from scratch. While this is a natural setting for LRTDP and BBVI, it is admittedly a little unfair to SPUD (which computes a full policy). This is mitigated by the fact that BBVI's improvement over SPUD, which is a little under 5 orders of magnitude with  $10^8$  states, is such that an agent would need to be planning over an immense horizon before SPUD presents a reasonable alternative.

The factored MDP bounds from Singh and Cohn [1998] are quite ill-suited to this problem. This is because its upper bound (the sum of the independent value for each arm) is very loose and it essentially forces LRTDP to enumerate the state space. In contrast, LRTDP performs quite well when it has good heuristic information. However, its performance degrades faster than that of BBVI, because it does not effectively leverage a lower bound on value. Even for very large problem instances, BBVI computes optimal solutions in well under a second.

BBVI's performance in the R&D domain is largely explained by the structure of the arms and the short horizon within each arm. Although there may be a large number of arms, BBVI reduces each individual arm to an equivalent MRP after a small number of node expansions. This

means that running time is essentially linear in the number of arms. Note that, in this domain, the solution that solves each MDP independently and executes the corresponding index policy will just opt for conservative research on the most valuable option. This policy is essentially always sub-optimal: as long as there are reasonable alternatives it is usually a good idea to try some risky projects.

Our next experiment uses a synthetic domain to explore the performance of BBVI as the structure and number of arms changes. In this BSP, each arm is a 20x20 grid world. The actions in this world correspond to moving in the 4 cardinal directions. Rewards are 0 everywhere except at randomly chosen locations and after receiving a reward, the agent transitions to a random location.

In this experiment we vary the number of rewards that are available in each arm. Adding rewards will typically cause the optimal policy for an arm to be more sensitive to context. This means that the dominated relaxation will produce a looser upper bound, because it will need to add more actions. We evaluate this difficulty by measuring the convergence criterion of BBVI after 10,000 node expansions. Figure 2 (c) shows the results of this experiment. We can see that BBVI's solution quality decreases with the number of states, but the primary variation comes from changes in the properties of the arms.

## 7 CONCLUSION AND FUTURE WORK

In summary, we presented a model of highly decoupled decision making: bandit superprocesses. A BSP presents an agent with the opportunity to act in one of several Markov decision processes. The key constraint is that the agent can only act in a single process at a time. We provided a summary of BSP research, including an upper bound for the value function of a BSP in the form of the Whittle integral. We derived an equivalent relaxation and thus gave a novel proof that the Whittle integral is an upper bound. Finally we presented and evaluated algorithmic solutions for this class of decision problems.

In future work, we plan to extend these ideas in three directions. The first is algorithmic improvements for BSPs. A potential direction here is to leverage factored dynamics in the bounding MDPs themselves. A search over sequences of MDPs that only consider states where the current policy stops could be more efficient. Next, also plan to explore generalizations of the bounds used for BSPs to more general cases of global resource constraints (e.g., those considered in Meuleau et al. [1998]). Finally, the similarity to sums of games studied in Conway [2000] suggests an unexplored connection between BSPs and combinatorial game theory.

{shadjis, ermon}@cs.stanford.edu

## Abstract

Computing expectations in high-dimensional spaces is a key challenge in probabilistic inference and machine learning. Monte Carlo sampling, and importance sampling in particular, is one of the leading approaches. We propose a generalized importance sampling scheme based on randomly selecting (exponentially large) subsets of states rather than individual ones. By collecting a small number of extreme states in the sampled sets, we obtain estimates of statistics of interest, such as the partition function of an undirected graphical model. We incorporate this idea into a novel maximum likelihood learning algorithm based on cutting planes. We demonstrate empirically that our scheme provides accurate answers and scales to problems with up to a million variables.

## 1 INTRODUCTION

Probabilistic inference is one of the key computational challenges in statistical machine learning and Bayesian statistics. The key computational bottleneck for many statistical inference problems of interest lies in the computation of high-dimensional integrals. Examples include computing posterior probabilities, model averaging, and evaluating partition functions of undirected graphical models. The field is dominated by two main paradigms tracing their roots to statistics and physics: Monte Carlo sampling methods [1, 15, 19] and variational techniques [16, 29]. Monte Carlo sampling is an extremely influential idea leveraged by numerous algorithms which have found an enormous number of applications in many fields of scientific computation, with application ranging from machine learning, statistics, and physics. It is often ranked among the most important algorithms of all time in polls and surveys [4]. The basic idea is to estimate properties of a high-dimensional space (e.g., the integral of a function) by look-

ing at a small number of representative states. The major difference between Monte Carlo schemes lies in how these representative states are selected and weighted.

Importance sampling (IS) is one of the most popular Monte Carlo sampling schemes. It is a simple and elegant idea, which is at the core of other widely used techniques such as Markov Chain Monte Carlo, Annealed Importance Sampling [21], and others [10]. The approach is very general: one can choose the samples randomly according to any desired *proposal distribution* (some mild restrictions have to be met), and IS provides a recipe to properly weight the samples and obtain an estimate for the original high-dimensional integral. The choice of the proposal distribution affects the variance of the estimate, and the number of samples required to obtain a statistically reliable estimate can grow exponentially in the problem size if the proposal distribution is poorly chosen. Unfortunately, designing a good proposal distribution is generally hard.

We introduce a more general scheme which we call importance sampling over sets (ISS) where we randomly select (large) subsets of states (rather than individual samples) using a generalized notion of proposal distribution called set-proposal distribution. Like traditional importance sampling, we provide a way to re-weight the samples and obtain an unbiased estimator for the original high-dimensional integral of interest. Intuitively, the idea is that by considering a very large (potentially, even exponential in the dimensionality of the problem) number of samples, one can significantly reduce the variance. Unfortunately, simply enumerating the samples would take exponential space. We therefore consider specially structured set-proposal distributions such that the set of samples can be represented in an *implicit* and *compact* way. The second main obstacle to overcome is that it is no longer possible to do enumeration-based inference on the samples. We therefore propose an approximation based on the importance weight of the heaviest configuration in the sampled set. For many classes of probabilistic models, e.g. log-supermodular [6], we can compute these statistics efficiently, e.g. using graphcuts. Surprisingly, we can show some strong formal guarantees

for this approximation. In particular, we identify a natural link between our scheme and some recently introduced probabilistic inference schemes based on randomized hashing and optimization [7, 8]. By reformulating these prior results within our framework, we show that there exists set-proposal distributions that are in some sense *universal*—they are guaranteed to give accurate answers using a small number of samples no matter what the underlying probabilistic model is.

We improve the accuracy and efficiency of our approach by developing a class of *adaptive* set-proposal distributions that can be tailored to the specific target probabilistic model leveraging the samples we draw from the model. We show that this approach provides very accurate estimates for the partition function of undirected graphical models on a range of benchmark problems. Our method is also extremely scalable: we are able to estimate the partition function for models with *up to one million variables* in a matter of minutes. Finally, we develop a new maximum likelihood parameter learning scheme based on our probabilistic inference framework. Our technique is very different from standard gradient descent approaches, and resembles structured prediction schemes such as structured SVM learning. We empirically show the effectiveness of our technique on the standard MNIST handwritten digits dataset.

## 2 SETUP

Given an undirected graphical model with  $n$  binary variables, let  $\mathcal{X} = \{0, 1\}^n$  be the set of all possible configurations (variable assignments or possible states of the world). Define a weight function  $w : \mathcal{X} \rightarrow \mathbb{R}^+$  that assigns to each configuration  $x$  a score proportional to its probability  $p(x)$ :  $w(x) = \prod_{\alpha \in \mathcal{I}} \psi_{\alpha}(\{x\}_{\alpha})$ . The weight function is compactly represented as a product of factors or potentials. The *partition function* of the model  $Z$  is defined as  $Z = \sum_{x \in \mathcal{X}} w(x) = \sum_{x \in \mathcal{X}} \prod_{\alpha \in \mathcal{I}} \psi_{\alpha}(\{x\}_{\alpha})$ . It is a normalization constant used to guarantee that  $p(x) = w(x)/Z$  sums to one. Computing  $Z$  is typically intractable because it involves a sum over an exponential number of configurations, and is often the most challenging inference task for many families of graphical models. Computing  $Z$  is required for many inference and learning tasks, such as evaluating the likelihood of data for a given model, computing marginal probabilities, and comparing competing models of data [29, 17].

Given that probabilistic inference problems are intractable in the worst case [23], a number of approximate inference algorithms have been developed. There are two main families of algorithms: Monte Carlo sampling techniques and variational approximations. Variational methods are based on approximating the target distribution  $p$  using a family of tractable approximating distributions, and minimizing a notion of divergence. Sampling techniques are randomized

approaches where the key idea is to estimate statistics of interest by looking at a small number of representative states.

## 3 IMPORTANCE SAMPLING

The simplest (naive) approach is to sample  $x_1, \dots, x_M$  uniformly from  $\mathcal{X}$ , and estimate  $\hat{Z} = \frac{1}{M} \sum_{i=1}^M w(x_i) 2^n$ . This is an unbiased estimator of  $Z$  as  $\mathbb{E}[\hat{Z}] = \frac{1}{M} \sum_{i=1}^M \sum_{x \in \mathcal{X}} \frac{1}{2^n} 2^n w(x) = Z$ . The variance of this estimator can be very large since we are limited to a small number of samples  $M$ , while the number of possible configurations  $|\mathcal{X}|$  is exponential in  $n$ . The variance can be reduced using *importance sampling* (IS) techniques, i.e. sampling using a proposal distribution (which is closer to  $p(x)$ ) rather than uniformly [1, 15, 19]. Here,  $x_1, \dots, x_M$  are sampled from  $\mathcal{X}$  according to some proposal distribution  $q(x)$ , and weighted by their inverse likelihood,  $\hat{Z} = \frac{1}{M} \sum_{i=1}^M \frac{w(x_i)}{q(x_i)}$ . This is also an unbiased estimator for  $Z$ .

Unfortunately, it is usually the case that the closer the proposal distribution  $q$  is to the original intractable  $p(x)$ , the harder it gets to sample from it. Markov Chain Monte Carlo sampling is one of the leading approaches for sampling from arbitrary distributions [1, 15, 19]. The key idea is to draw proper representative samples from  $p(x)$  by setting up a Markov Chain over the entire state space which has to reach an equilibrium distribution. For many statistical models of interest, reaching the equilibrium distribution will require simulating the chain for a number of steps which is exponential in  $n$ . Unless there are special regularity conditions, if the random walk does not visit all the possible states it might miss some important parts. In practice, the approach will therefore only give approximate answers. There is generally little or no information on the quality of the approximation. In fact, the Markov Chain may get trapped in less relevant areas and completely miss important parts of the state space.

Most similar to our approach is Greedy Importance Sampling (GIS) [27], a reformulation of IS which achieves variance reduction by sampling blocks of variables from a proposal distribution and then searching for highly weighted regions in the target distribution. The blocks of points are non-overlapping and points within a block are ordered, allowing points in a block to be selected using a greedy search. This search increases the probability of blocks containing highly weighted points and outperforms naive methods which are unlikely to observe such points by chance. These blocks can be seen as a special-case of sets in the ISS technique, in which the sets are selected through search. Whereas GIS blocks are likely to contain highly weighted points due to explicit search, sets in ISS more generally contain highly weighted points by sampling any exponentially large subset of points and extracting statistics of interest. For example ISS allows the use of order-statistics (MAP/MPE estimation) which can often be com-

puted efficiently (e.g. using graphcuts, Viterbi), although the search method of GIS is another approach. The methods are orthogonal and future work can investigate incorporating explicit search or other techniques such as analytic marginalization within ISS to further reduce variance. Another key generalization of ISS is that sets of points can overlap, which grants additional freedom in selecting set-proposal distributions. For example when sets are defined by parity constraints, set-proposal distributions implement a strongly universal hash function, providing strong theoretical guarantees on the accuracy of the estimates.

## 4 IMPORTANCE SAMPLING OVER SETS

We propose a generalized importance sampling procedure, in which instead of randomly selecting a single configuration  $\mathbf{x}$  we randomly select a (large) subset of configurations  $S \subseteq \mathcal{X}$ . Let  $P(\mathcal{X})$  denote the power set of  $\mathcal{X} = \{0, 1\}^n$ , i.e. the set of all subsets of  $\mathcal{X}$ . We define a probability distribution  $q$  over  $P(\mathcal{X})$  as a **set-proposal distribution**. A set-proposal distribution induces the following function  $\gamma : \mathcal{X} \rightarrow [0, 1]$

$$\gamma(\mathbf{x}, q) = \sum_{S \in P(\mathcal{X})} \mathbf{1}(\mathbf{x} \in S)q(S) \quad (1)$$

Intuitively,  $\gamma(\mathbf{x}, q)$  is the probability of  $\mathbf{x}$  being contained in a set  $S$  sampled from  $q$ . We omit the dependency on  $q$  when the set-proposal distribution used is clear from the context. Standard proposal distributions used in Importance Sampling are a special case of set-proposal distributions, assigning zero probability to all subsets  $S \subseteq \mathcal{X}$  such that  $|S| \neq 1$ . The following results generalizes the standard importance sampling result to our more general case.

**Proposition 1.** *Let  $q$  be any set-proposal distribution such that  $w(\mathbf{x}) > 0$  implies  $\gamma(\mathbf{x}, q) > 0$ . Let  $S \sim q$  denote a random sample from the set-proposal distribution  $q$ . Then  $\sum_{\mathbf{x} \in S} \frac{w(\mathbf{x})}{\gamma(\mathbf{x}, q)}$  is an unbiased estimator for the partition function  $Z$ .*

*Proof.*

$$\begin{aligned} Z &= \sum_{\mathbf{x} \in \mathcal{X}} w(\mathbf{x}) = \sum_{\mathbf{x} \in \mathcal{X}} w(\mathbf{x}) \frac{\gamma(\mathbf{x})}{\gamma(\mathbf{x})} \\ &= \sum_{\mathbf{x} \in \mathcal{X}} \frac{w(\mathbf{x})}{\gamma(\mathbf{x})} \sum_{S \in P(\mathcal{X})} \mathbf{1}(\mathbf{x} \in S)q(S) \\ &= \sum_{S \in P(\mathcal{X})} q(S) \sum_{\mathbf{x} \in \mathcal{X}} \frac{w(\mathbf{x})}{\gamma(\mathbf{x})} \mathbf{1}(\mathbf{x} \in S) \\ &= \sum_{S \in P(\mathcal{X})} q(S) \sum_{\mathbf{x} \in S} \frac{w(\mathbf{x})}{\gamma(\mathbf{x})} = E_{S \sim q} \left[ \sum_{\mathbf{x} \in S} \frac{w(\mathbf{x})}{\gamma(\mathbf{x})} \right] \end{aligned}$$

□

Note that when the set-proposal distribution  $q$  is a standard proposal distribution (over singletons), one recovers the standard importance sampling result. There are three main aspects to consider for the practical usability of Proposition 1. We need to 1) sample a subset  $S$  from  $q$  efficiently, 2) evaluate the importance weight  $\gamma(\mathbf{x})$  tractably, 3) when  $S$  is (exponentially) large, represent  $S$  compactly and evaluate the summation. The first two considerations apply to traditional importance sampling as well. The third one is new. For example, if  $q$  deterministically chooses  $S = \mathcal{X}$ , then evaluating the estimator is just as hard as computing the partition function. As this extreme example suggests, the advantage is that by considering larger sets, one can significantly reduce the variance. The following corollary is very useful,

**Corollary 1.** *Let  $q$  be any set-proposal distribution such that  $w(\mathbf{x}) > 0$  implies  $\gamma(\mathbf{x}) > 0$ . Let  $S \sim q$  denote a random sample from the set-proposal distribution  $q$ . Then  $E_{S \sim q} \left[ \max_{\mathbf{x} \in S} \frac{w(\mathbf{x})}{\gamma(\mathbf{x})} \right]$  is a lower bound for the partition function  $Z$ .*

*Proof.* Since the weights are non-negative  $w(\mathbf{x}) \geq 0$ , it follows that  $\max_{\mathbf{x} \in S} \frac{w(\mathbf{x})}{\gamma(\mathbf{x})} \leq \sum_{\mathbf{x} \in S} \frac{w(\mathbf{x})}{\gamma(\mathbf{x})}$  and the claim follows from Proposition 1 by linearity of expectation. □

Notice that if  $q$  is a standard proposal distribution, i.e.  $q(S) = 0$  if  $|S| \neq 1$ , the estimators  $\sum_{\mathbf{x} \in S} \frac{w(\mathbf{x})}{\gamma(\mathbf{x})}$  and  $\max_{\mathbf{x} \in S} \frac{w(\mathbf{x})}{\gamma(\mathbf{x})}$  coincide. In general, the value of  $\max_{\mathbf{x} \in S} \frac{w(\mathbf{x})}{\gamma(\mathbf{x})}$  can be exponentially far from  $\sum_{\mathbf{x} \in S} \frac{w(\mathbf{x})}{\gamma(\mathbf{x})}$ , for example in the case of a constant (uniform) weight function  $w(\cdot)$ . The upside is that the max statistic, i.e. computing the mode of the distribution, is often more tractable. For example, there are numerous classes of probabilistic models, such as attractive Ising models, where one can find the mode of the distribution (MAP/MPE query) in polynomial time, while computing the partition function is NP-hard [11, 14].

### 4.1 EXAMPLES OF SET-PROPOSAL DISTRIBUTIONS

In both examples below, let  $m \leq n$ , let  $v_m(\mathbf{x}) = \{v_i(x_i), i = 1, \dots, m\}$  be a family of marginal distributions over individual variables. Let  $b_i$  be independent samples from  $v_i(x_i)$  for  $i = 1, \dots, m$ .

#### 4.1.1 Constraining Variables

We can define a set-proposal distribution  $q$  where to sample a set we define  $S = \{\mathbf{x} \in \mathcal{X} : x_i = b_i, \forall i \in \{1, \dots, m\}\}$ . Note that  $\gamma(\mathbf{x}) = \prod_{i=1}^m q(x_i) = \prod_{i=1}^m v_i(x_i)^{b_i} (1 - v_i(x_i))^{1-b_i}$ . The set can be represented compactly using  $m$  equations (equivalently, additional factors to be added

to the graphical model that clamp some variables to certain values). Intuitively, this approach samples a set  $S$  where  $|S| = 2^{n-m}$  by constraining or "clamping" variables  $x_1, \dots, x_m$  to fixed binary values.

### 4.1.2 Parity Constraints

As a second example of a set-proposal distribution, let  $A \in \{0, 1\}^{m \times n}$  be a binary matrix with rows  $a_i$ . We define a set-proposal distribution  $q$  according to the following generative process. To sample a set  $S$  from  $q$ , we define  $S = \{\mathbf{x} \in \mathcal{X} : a_i \mathbf{x} = b_i \pmod{2}, \forall i \in \{1, \dots, m\}\}$ . It can be seen that given any  $\mathbf{x} \in \mathcal{X}$ , the probability that  $\mathbf{x}$  belongs to a randomly chosen  $S \sim q$  is again  $\gamma(\mathbf{x}) = \prod_{i=1}^m q(x_i)$ . This is the probability that  $\mathbf{x}$  satisfies  $m$  parity equations with randomly chosen right-hand side coefficients. The set can be represented compactly using  $m$  linear equations modulo 2. Parity constraints can be represented compactly as a product of factors, using a linear number of extra variables [7].

## 5 MULTIPLE PROPOSAL DISTRIBUTIONS

As noted earlier, the lower bound obtained with Corollary 1 given by  $L(S, q) = \max_{\mathbf{x} \in S} \frac{w(\mathbf{x})}{\gamma(\mathbf{x}, q)}$  might be loose compared to  $A(S, q) = \sum_{\mathbf{x} \in S} \frac{w(\mathbf{x})}{\gamma(\mathbf{x}, q)}$ , which is an unbiased estimator of  $Z$  by Proposition 1. Here we are making explicit the dependence of  $\gamma(\mathbf{x}, q)$  on the set-proposal distribution  $q$ . Intuitively, this approximation is accurate when the weight distribution over  $S$  is peaked, i.e. the mode is a good approximation of the "total area". On the other hand, the lower bound is loose when there are "many" configurations in  $S$  that have a weight comparable to the one of the heaviest assignment. If that is the case, it is intuitively possible to randomly subsample the set  $S$  and obtain a smaller set  $S' \subseteq S$  such that  $\max_{\mathbf{x} \in S} w(\mathbf{x}) \approx \max_{\mathbf{x} \in S'} w(\mathbf{x})$ . Since  $|S'| < |S|$ , the gap between the approximation introduced by considering only the mode of the weight distribution on  $S'$  yields a smaller error. This suggests the use of another set-proposal distribution  $q'$  that is more likely to propose smaller sets  $S'$  compared to  $q$ . Because we do not know a priori if the bound is tight or not, this discussion motivates a more general scheme that relies on multiple set-proposal distributions. By letting the typical size of a sampled set change, e.g. from 1 to  $|\mathcal{X}| = 2^n$ , we can sample from a wide variety of configurations and accurately predict  $\log Z$  for distributions which are peaked to various degrees.

**Proposition 2.** Let  $\mathcal{Q} = (q_1, \dots, q_k)$  be a family of set-proposal distributions. Let  $S_1 \sim q_1, S_2 \sim q_2, \dots, S_k \sim q_k$ . Suppose that for all  $i$ ,  $w(\mathbf{x}) > 0$  implies  $\gamma(\mathbf{x}, q_i) > 0$ . Then  $\frac{1}{k} \sum_{i=1}^k \sum_{\mathbf{x} \in S_i} \frac{w(\mathbf{x})}{\gamma(\mathbf{x}, q_i)}$  is an unbiased estimator for the partition function  $Z$ .

*Proof.*

$$E_{S_1 \sim q_1, \dots, S_k \sim q_k} \left[ \frac{1}{k} \sum_{i=1}^k \sum_{\mathbf{x} \in S_i} \frac{w(\mathbf{x})}{\gamma(\mathbf{x}, q_i)} \right] = \frac{1}{k} \sum_{i=1}^k E_{S_i \sim q_i} \left[ \sum_{\mathbf{x} \in S_i} \frac{w(\mathbf{x})}{\gamma(\mathbf{x}, q_i)} \right] = Z$$

where the last step follows from Proposition 1.  $\square$

The following corollary follows, and is implemented by Algorithm 1 with input  $T = 1$ .

**Corollary 2.** Let  $\mathcal{Q} = (q_1, \dots, q_k)$  be a family of set-proposal distributions. Let  $S_1 \sim q_1, S_2 \sim q_2, \dots, S_k \sim q_k$ . Suppose that for all  $i$ ,  $w(\mathbf{x}) > 0$  implies  $\gamma(\mathbf{x}, q_i) > 0$ . Then  $\frac{1}{k} \sum_{i=1}^k \max_{\mathbf{x} \in S_i} \frac{w(\mathbf{x})}{\gamma(\mathbf{x}, q_i)}$  is in expectation a lower bound for the partition function  $Z$ .

*Proof.* Follows immediately from Corollary 1.  $\square$

**Input** :  $w : \mathcal{X} \rightarrow \mathbb{R}^+, T, k, q_i$  for  $i = 1, \dots, k$

**Output**: Estimate of  $\log Z = \log \sum_{\mathbf{x} \in \mathcal{X}} w(\mathbf{x})$

```

1 for  $i = 1, \dots, k$  do
2   Sample  $S_i^1 \dots S_i^T$  according to  $q_i$ 
3   for  $t = 1, \dots, T$  do
4      $\mathbf{m}_i^t = \max_{\mathbf{x} \in S_i^t} \frac{w(\mathbf{x})}{\gamma(\mathbf{x}, q_i)}$ 
5   end
6    $M_i \leftarrow \text{Median}(\mathbf{m}_i^1 \dots \mathbf{m}_i^T)$ 
7 end
8 Return  $\frac{1}{k} \sum_{i=1}^k M_i$ 

```

**Algorithm 1:** Set importance sampling

If we now let the typical size of a sampled set change, e.g. from  $|S| = 1$  to  $|S| = |\mathcal{X}| = 2^n$ , the magnitude of the various  $\gamma(\mathbf{x}, q_i)$  varies exponentially. Therefore it is often the case that many terms in the sum  $\sum_{i=1}^k \max_{\mathbf{x} \in S_i} \frac{w(\mathbf{x})}{\gamma(\mathbf{x}, q_i)}$  will not contribute significantly to the overall estimate of  $Z$ . In practice, a sufficiently accurate lower bound is obtained by  $T$  samples of only the highest weighted sets,

$$\max_{i=1}^k \max_{\mathbf{x} \in S_i} \frac{w(\mathbf{x})}{\gamma(\mathbf{x}, q_i)} \quad (2)$$

The main advantage of this approach is computational, as we have now reduced the inference procedure to a *single* optimization problem. The following result shows that this still provides a valid lower bound:

**Corollary 3.** Let  $\mathcal{Q} = (q_1, \dots, q_k)$  be a family of set-proposal distributions. Suppose that for all  $i$ ,  $w(\mathbf{x}) > 0$  implies  $\gamma(\mathbf{x}, q_i) > 0$ . Let  $S_i^1, \dots, S_i^T \sim q_i$  be i.i.d samples from the  $i$ -th set-proposal distribution  $q_i$ . Then  $\max_{i=1}^k \text{Median} \left( \max_{\mathbf{x} \in S_i^1} \frac{w(\mathbf{x})}{\gamma(\mathbf{x}, q_i)}, \dots, \max_{\mathbf{x} \in S_i^T} \frac{w(\mathbf{x})}{\gamma(\mathbf{x}, q_i)} \right)$  is with high probability an approximate lower bound for the partition function  $Z$ .

*Proof.* For every  $i$ , let us denote  $L(S_i) = \max_{\mathbf{x} \in S_i} \frac{w(\mathbf{x})}{\gamma(\mathbf{x}, q_i)}$ . Then by Proposition 1,  $E_{S_i \sim q_i} [L(S_i)] \leq Z$ . Therefore by Markov's inequality,  $P \left[ \max_{\mathbf{x} \in S_i} \frac{w(\mathbf{x})}{\gamma(\mathbf{x}, q_i)} \geq 4Z \right] \leq \frac{1}{4}$ . Let  $S_i^1, \dots, S_i^T$  be samples from  $q_i$ . It follows from Chernoff's inequality that

$$P[\text{Median}(L(S_i^1), \dots, L(S_i^T)) \geq 4Z] \leq \exp\left(-\frac{T}{24}\right)$$

therefore from the union bound

$$P[\cup_{i=1}^k \text{Median}(L(S_i^1), \dots, L(S_i^T)) \geq 4Z] \leq k \exp\left(-\frac{T}{24}\right)$$

Therefore

$$P[\max_{i=1}^k \text{Median}(L(S_i^1), \dots, L(S_i^T)) \leq 4Z] \geq 1 - k \exp\left(-\frac{T}{24}\right)$$

□

Corollary 3 is implemented in Algorithm 1 with line 8 changed to return the maximum  $M_i$  instead of the mean.

To make the procedure of Corollary 3 clear, consider again a family of set-proposal distributions  $q_i$  constructed by constraining variables as in the example of section 4.1.1. This can be implemented in Algorithm 1 by setting  $k = n + 1$  and selecting  $q_i$  to constrain the first  $i - 1$  variables: The outer-loop (line 1) searches for the  $q_i$  which contributes most towards the estimate of  $\log Z$  by, in each iteration, enforcing  $i$  "hard" variable constraints which limit the set of possible configurations by defining sets  $S_i^t$  where  $|S_i^t| = 2^{n+1-i}$ . Notice under this setup that if the maximum iteration is  $i = 1$  (no variables constrained,  $|S| = |\mathcal{X}| = 2^n$ ), then this is equivalent to approximating  $\log Z$  by the MAP/MPE configuration. Conversely, if the maximum is at  $i = n + 1$ , then this is equivalent to naive importance sampling based on proposal distribution  $q_{n+1}$  (all variables constrained,  $|S| = 1$ ). If the heaviest weighted set is not one of these two special cases, then the set importance sampling method will produce a more accurate estimate of  $\log Z$ . Also note that since empirically most of the iterations do not contribute significantly to the overall estimate of  $\log Z$ , the outer loop in Algorithm 1 over all  $n$  variables can search with a larger granularity or logarithmically for the heaviest  $i$ . In practice, fixing the number of iterations in the outer loop to 10 (sampling sets with a granularity of  $\frac{n}{10}$  constrained variables) is both accurate and fast to run. In fact, this can be taken a step further by skipping the loop altogether and searching for the heaviest weighted set as a *single* optimization problem: rather than a loop which incrementally adds "hard" variable constraints, we can add all the variable constraints at once as "soft" constraints which an optimization oracle may choose to satisfy. The reward for satisfying these constraints matches the scaling  $\frac{1}{\gamma(\mathbf{x}, q_i)}$ . Formulating the estimate of  $\log Z$  as a single optimization problem is useful for learning, see section 7.

## 5.1 RELATIONSHIP WITH RANDOMIZED HASHING

The advantage of using multiple proposal distributions is that one might be able to reduce the variance of the estimator, in accordance with the intuitive motivation presented earlier. In fact, it can be shown that there exists set-proposal distributions (based on universal hash functions) such that a polynomial number of samples is sufficient to obtain concentration of the estimate around the mean. The surprising result is that these proposal distributions are "universal", in that they are guaranteed to give accurate estimates (constant factor approximations) for *any* weight function  $w(\cdot)$ , i.e., any underlying graphical model.

Let  $\mathcal{S} \subseteq P(\mathcal{X})$  be a family of sets defined as  $\mathcal{S} = \{\{\mathbf{x} \in \mathcal{X} : \mathbf{A}\mathbf{x} = \mathbf{b} \bmod 2\}, A \in \{0, 1\}^{i \times n}, b \in \{0, 1\}^i\}$ . Let  $q_i$  be a set-proposal distribution where to sample from  $q_i$  we randomly choose each entry of  $A, b$  uniformly at random (independently). Then it can be shown that  $\gamma(\mathbf{x}) = 2^{-i}$ . For a state space  $\mathcal{X} = \{0, 1\}^n$ , let us consider a family of  $n$  proposal distributions  $\mathcal{Q}_P = (q_0, \dots, q_n)$ . These set-proposal distributions can be interpreted as implementing a strongly universal hash function, where each element  $\mathbf{x} \in \mathcal{X}$  is sampled by the  $i$ -th proposal distribution  $q_i$  with probability  $2^{-i}$ , and elements are sampled pairwise independently [9, 3, 12, 7, 8, 13]. As noted above, we can sample from  $q_i$  tractably, and represent sets  $S \in \mathcal{S}$  in a compact way. Theorem 1 from [8] implies the following remarkable result

**Corollary 4.** *Let  $\mathcal{Q}_P = (q_0, \dots, q_n)$  be defined as above. Let  $L(S_i) = \max_{\mathbf{x} \in S_i} \frac{w(\mathbf{x})}{\gamma(\mathbf{x}, q_i)}$  for every  $i$ . Then for any weight function  $w(\cdot)$  and  $1 > \delta > 0$ ,  $\sum_{i=1}^n \text{Median}(L(S_i^1), \dots, L(S_i^T))$  is with probability at least  $1 - \delta$  a constant factor approximation of  $Z$  when  $T = \Theta(n \ln n / \delta)$ .*

Reinterpreted in our set-proposal distribution framework, Corollary 4 is important because it shows that there exists a family of universal set-proposal distributions that are guaranteed to work well for any underlying target probability distribution  $p$ .

Although sets  $S \in \mathcal{S}$  defined by parity constraints can be represented compactly, the resulting optimization problems  $\max_{\mathbf{x} \in S_i} \frac{w(\mathbf{x})}{\gamma(\mathbf{x}, q_i)}$  are generally difficult to solve, even when  $w(\cdot)$  can be tractably optimized, i.e.,  $\max_{\mathbf{x} \in \mathcal{X}} w(\mathbf{x})$  can be solved efficiently. Rather than take a worst-case approach and consider a proposal distribution that is guaranteed to work for any weight function  $w$  as in [9, 3, 12, 7, 8, 13], in this paper we consider a more general class of set-proposal distributions. In particular, we construct proposal distributions that are tailored to particular probabilistic models (and weight function  $w$ ). The main advantage of this approach is that we can leverage the structure of the original problem, and the corresponding optimization problems

will be easier to solve, leading to massive improvements in scalability. This is similar in spirit to traditional importance sampling, where one typically uses some prior knowledge on the underlying probabilistic model to construct good proposal distributions.

## 6 ADAPTIVE SET IMPORTANCE SAMPLING SCHEME

Similarly to standard adaptive importance sampling schemes (e.g. [22]), we propose an adaptive procedure where set-proposal distributions are adapted based on the samples collected. This is an enhancement of Algorithm 1 in that its iterative procedure can be exploited to adaptively improve the input set-proposal distributions.

Recall from section 4.1.1 that a set-proposal distribution can be defined in which sets  $S_i$  are sampled by constraining variables  $x_1, \dots, x_i$ . For a fixed  $i$  there are  $2^i$  such sets  $S_i$  (where  $|S_i| = 2^{n-i}$ ), and as in the previous section for each  $i$  we sample  $T$  such sets  $S_i^t$ . Next, let  $\mathbf{e}_i^t = \arg \max_{\mathbf{x} \in S_i^t} \frac{w(\mathbf{x})}{\gamma(\mathbf{x}, q_i)}$ . We define empirical marginal distributions  $\hat{v}_{i+1}(\mathbf{x})$  based on the fraction of samples  $\mathbf{e}_i^t$  that have variables  $x_1$  to  $x_{i+1}$  set to one (with Laplace smoothing). Intuitively, the adaptive set importance algorithm performs the same iteration as Algorithm 1, sampling sets by incrementally constraining variables  $x_1$  to  $x_i$ , except that it interpolates the *input* proposal distribution with the empirical marginal distributions from the previous iteration to define a new set-proposal distribution for the current iteration. The full details of the algorithm are shown in Algorithm 2. During each iteration, as in Algorithm 1, generate  $T$  sets  $S_i^1 \dots S_i^T$  where each represents a set of configurations  $\mathbf{x}$  in which the first  $i$  binary variables are "clamped" to 0 or 1. The solutions  $\mathbf{e}_i^t = \arg \max_{\mathbf{x} \in S_i^t} \frac{w(\mathbf{x})}{\gamma(\mathbf{x}, q_i)}$  produce  $T$  samples which define the empirical marginal distribution  $\hat{v}_{i+1}(\mathbf{x})$ , and this empirical marginal distribution is used to sample sets in iteration  $i+1$ . For the first iteration, the variable  $x_1$  is sampled according to any proposal distribution (uniformly by default). Note also that when obtaining the MAP configuration of many variables is intractable, the iteration can begin with any number of variables constrained according to any proposal distribution (not just  $x_1$ ). ISS is still guaranteed to perform at least as well (and often much better) as IS by selecting subsets small enough that calculating the mode by brute force enumeration is tractable.

## 7 LEARNING

Because set importance sampling provides fast and scalable partition function estimates, it can be used for learning. We consider the standard problem of maximum likelihood learning of the parameters of an undirected graphical model. Given samples  $\mathbf{x}_1, \dots, \mathbf{x}_M$  from a parameterized probability distribution  $p_\theta(\mathbf{x}) = \frac{1}{Z(\theta)} \exp(\theta \phi(\mathbf{x}))$ ,

**Input** :  $w : \mathcal{X} \rightarrow \mathbb{R}^+, T$

**Output**: Estimate of  $\log Z = \log \sum_{\mathbf{x} \in \mathcal{X}} w(\mathbf{x})$

- 1  $M_0 \leftarrow \arg \max_{\mathbf{x} \in \mathcal{X}} w(\mathbf{x})$
- 2 Define  $\hat{v}_1(\mathbf{x})$  as uniform marginal over  $x_1$
- 3 **for**  $i = 1, \dots, n$  **do**
- 4     Sample  $S_i^1 \dots S_i^T$  using marginals  $\hat{v}_i(\mathbf{x})$  as in 4.1.1
- 5     **for**  $t = 1, \dots, T$  **do**
- 6          $\mathbf{m}_i^t, \mathbf{e}_i^t = \max, \arg \max_{\mathbf{x} \in S_i^t} \frac{w(\mathbf{x})}{\gamma(\mathbf{x}, q_i)}$
- 7     **end**
- 8      $M_i \leftarrow \text{Median}(\mathbf{m}_i^1 \dots \mathbf{m}_i^T)$
- 9     Compute  $\hat{v}_{i+1}(\mathbf{x})$  based on  $\mathbf{e}_i^1 \dots \mathbf{e}_i^T$  (with Laplace smoothing). This is the fraction of argmax results  $\mathbf{e}_i^t$  with  $x_j = 1$ , for  $j \in \{1, \dots, i+1\}$ .
- 10 **end**
- 11 Return  $\frac{1}{n+1} \sum_{i=0}^n M_i$

**Algorithm 2:** Adaptive set importance sampling

find maximum likelihood estimate of the parameters

$$\max_{\theta} \sum_{i=1}^M \log p_{\theta}(x_i) \quad (3)$$

which can be equivalently written as  $\max_{\theta} \theta \frac{1}{M} \sum_{i=1}^M \phi(x_i) - \log Z(\theta)$ . It is well known that solving this parameter learning problem is very challenging because it requires inference to evaluate the partition function (or its gradient). In this section we show how our importance sampling scheme can be used to approximate the value of the partition function, leading to a new learning algorithm. The algorithm we obtain is similar to structured prediction learning algorithms and cutting plane techniques [30, 28, 26], used for example in training structured support vector machines. A key difference is that our approach is used to (approximately) optimize the likelihood (in a generative setting), rather than minimizing a loss function in a discriminative setting.

### 7.1 LEARNING ALGORITHM

Structured support vector machines (SSVM) [30] and other structured prediction learning methods [18, 5] are trained by solving a convex optimization problem in which the number of constraints is exponential. The problems can be solved tractably by iteratively constructing a sufficient subset of constraints and employing an optimization oracle to find the next constraint to include. In this way the subset of the constraints is enlarged iteratively and provides a lower bound on the optimization objective.

The learning approach based on set importance sampling is similar, but using the set importance sampling technique as an optimization oracle. Beginning from the logarithm of equation (3),  $\max_{\theta} \theta \frac{1}{M} \sum_{i=1}^M \phi(\mathbf{x}_i) - \log Z(\theta)$ , we can introduce a variable  $\alpha$  which takes the place of  $\log Z$  and cast the optimization as follows

$$\begin{aligned} & \underset{\theta, \alpha}{\text{maximize}} && \theta \frac{1}{M} \sum_{i=1}^M \phi(\mathbf{x}_i) - \alpha \\ & \text{subject to} && \alpha \geq \log Z(\theta) \end{aligned}$$

We then express  $Z(\theta)$  using the approximation given by equation (2) as

$$\alpha \geq \log Z(\theta) \geq \max_{i=1}^k \max_{\mathbf{x} \in \mathcal{S}_i} \theta \phi(\mathbf{x}) - \log \gamma(\mathbf{x}, q_i) \quad (4)$$

Note this is an exponentially large set of *linear* constraints in  $\theta$  and  $\alpha$ , and therefore corresponds to a linear program (LP). Because the number of constraints is exponential in the number of variables, as in structured learning we consider only a subset  $C$  of constrained configurations  $\mathbf{x}$ . The reduced LP becomes,

$$\begin{aligned} & \underset{\theta}{\text{maximize}} && \theta \frac{1}{M} \sum_{i=1}^M \phi(\mathbf{x}_i) - \alpha \\ & \text{subject to} && \alpha \geq \theta \phi(\mathbf{x}) + \beta(\mathbf{x}) \quad \forall \mathbf{x} \in C \end{aligned} \quad (5)$$

where  $\beta(\mathbf{x}) = \max_{i | \mathbf{x} \in \mathcal{S}_i} (-\log \gamma(\mathbf{x}, q_i))$  and intuitively is the maximum importance weight for a given  $\mathbf{x}$  under all set-proposal distributions  $q_i$  (see Appendix A).  $C$  is initially set to the training data set  $\{\mathbf{x}_1, \dots, \mathbf{x}_M\}$ , and is enlarged during each learning iteration by searching for the most violated constraint, i.e.  $\max_x \theta \phi(\mathbf{x}) + \beta(\mathbf{x})$ .

The full learning procedure is described in Algorithm 3. The input to the algorithm are the  $M$  training examples, the vector of sufficient statistics  $\phi$  and the (optional) choice of set-proposal distributions  $q_1 \dots q_k$  (for example uniform, based on the training examples, or adaptive if no  $q_i$  are provided). Each iteration of learning begins by finding the optimal weights for the LP in equation (5). Following the solution of the LP, we obtain the pair  $(\theta_i, \alpha_i)$ . Then, using these learned weights  $\theta_i$ , importance sampling over sets is used to approximate  $\log Z$  for various set-proposal distributions and importance weights, and each of these samples (modes) is added to constraint set  $C$ . Note that Algorithm 3 takes advantage of an optimization oracle to solve the LP in equation (5). Another optimization oracle is used within our importance sampling over sets procedure to estimate  $\log Z$  (by optimizing equation (4) using the current parameter estimate  $\theta_i$ ). Intuitively, the value of the partition function is not just approximated using the MAP assignment, but thanks to the importance weights, we are able to obtain better estimates. For example, if using the current weight vector  $\theta_i$  the distribution is close to uniform, an approximation based on the MAP assignment would be poor, but we can still get good approximation to the partition function thanks to the importance weights.

Because at each iteration a (convex) linear program is solved to obtain the weights  $\theta$ , at each iteration the weights obtained for the constraints  $C$  are guaranteed to be globally optimal for the approximate likelihood objective. This

**Input** :  $\mathbf{x}_m, m = 1, \dots, M, \phi(\mathbf{x}), T, q_i, i = 1, \dots, k$   
**Output**: Learned weight parameters  $\theta$

```

1 converged ← False
2 i ← 0
3 C ← { $\mathbf{x}_m, m = 1, \dots, M$ }
4 while not converged do
5   i ← i + 1
6    $\theta_i, \alpha_i =$  solve LP (5) subject to C
7   for t = 1, ..., T do
8     |  $\mathbf{x}_{i,t}^*, \log Z_{est,t} =$  Run ISS with  $\theta_i, \{q_1, \dots, q_k\}$ 
9   end
10   $\log Z_{est} \leftarrow$  median  $\log Z_{est,t}$ 
11  if  $\alpha_i \geq \log Z_{est}$  then
12    | converged ← True
13  else
14    | C ← C  $\cup \{\mathbf{x}_{i,t}^*, t = 1, \dots, T\}$ 
15  end
16 end
17 Return  $\theta_i$ 

```

**Algorithm 3:** Iterative learning algorithm

is in contrast to gradient-based learning algorithms. Moreover, as more constraints are added to  $C$  at each iteration,  $C$  approaches  $\mathcal{X}$  and the LP objective is guaranteed to decrease monotonically towards the optimal approximate log likelihood of the training data.

## 8 EXPERIMENTAL RESULTS

### 8.1 PARTITION FUNCTION

One application of importance sampling over sets is for problems in which computing  $\max_{\mathbf{x}} w(\mathbf{x})$  is tractable, but  $\sum_{\mathbf{x}} w(\mathbf{x})$  is intractable. An example are functions which are log-supermodular. For such problems we can leverage fast optimization (for example using graph cuts), as long as  $w(\mathbf{x})/\gamma(\mathbf{x})$  stays tractable. For example, it is sufficient that  $\log(1/\gamma(\mathbf{x}))$  is supermodular.

We evaluated importance sampling over sets (ISS) against standard inference algorithms: junction tree (EXACT), belief propagation (BP), mean-field (MF), the MAP configuration (MAP), and naive importance sampling (IS). For junction tree, belief propagation and mean-field, the libDAI library was used [20].

First, we evaluated importance sampling over sets for functions which are not log-supermodular, to demonstrate the effectiveness of the method on general models. Table 1 shows estimates of the log partition function of the Ising Models from the 2011 Probabilistic Inference Challenge (PIC2011)<sup>1</sup>. These models have “mixed” interactions and therefore are not log-supermodular. For general functions

<sup>1</sup> [www.cs.huji.ac.il/project/PASCAL/showNet.php](http://www.cs.huji.ac.il/project/PASCAL/showNet.php)

which are not log-supermodular, each  $\arg \max$  in ISS was solved as an integer quadratic program (IQP) in CPLEX, with a search granularity of  $\frac{n}{10}$  to find the heaviest sets as discussed in section 5. The log partition function estimates in Table 1 use a uniform proposal distribution to show that even in the absence of a proposal distribution the ISS method performs better than both naive importance sampling and the MAP configuration (which are both special-cases of ISS).

Our second experiment validated ISS for functions which are log-supermodular, and thus for which ISS can be run in polynomial time. Fig. 1 evaluates the importance sampling over sets method on attractive (log-supermodular) Ising models with varying coupling strengths. Models have a field factor of 2.0, although we observed that a range of field factors gave almost identical results. For these log-supermodular potentials, optimization was performed with graph cuts using the OpenGM [2] library. For these experiments, importance sampling algorithms (IS and ISS) use the adaptive importance sampling scheme as a proposal distribution, where first ISS was run and the final empirical marginals in iteration  $n$  were also used for IS.

Figure 1: Log partition function error of various inference algorithms for 10x10 Ising grids with attractive (log-supermodular) interactions, a field factor of 2.0, and various coupling strengths. Importance sampling (IS) and importance sampling over sets (ISS) use adaptive set importance sampling.

Across a range of attractive Ising models, the set importance sampling technique provides very accurate estimates of the log partition function. Moreover, due to the log-supermodularity of the potentials, the ISS technique scales to much larger models, providing accurate estimates in polynomial time while other algorithms fail to converge. Tables 2 and 3 show the log partition function estimates and run-times for various Ising grid sizes, ranging from 10x10

Table 2: Log partition function estimates for various Ising model sizes. "-" indicates that no solution was obtained after 10 minutes. As in Table 1, ISS estimates are between MF (which tends to under-estimate) and BP (which tends to over-estimate)

|      | BP     | MF     | MAP    | IS     | ISS    |
|------|--------|--------|--------|--------|--------|
| 10   | 207.6  | 202.7  | 202.0  | 161.2  | 206.4  |

| 100  | 20930  | 19910  | 20679  | 14670  | 20690  |
| 300  | 1.91E5 | 1.82E5 | 1.88E5 | 1.35E5 | 1.88E5 |
| 1000 | 2.11E6 | -      | 2.09E6 | 1.48E6 | 2.09E6 |

Table 3: Time (in seconds) to estimate logZ for Ising model sizes. "-" indicates that the algorithm did not converge within 10 minutes.

|      | EXACT | BP  | MF  | MAP | IS | ISS |
|------|-------|-----|-----|-----|----|-----|
| 10   | 1     | 1   | 1   | 1   | 1  | 1   |
| 20   | -     | 1   | 1   | 1   | 1  | 1   |
| 50   | -     | 5   | 8   | 1   | 1  | 5   |
| 100  | -     | 15  | 112 | 1   | 1  | 3   |
| 300  | -     | 119 | -   | 8   | 1  | 27  |
| 1000 | -     | -   | -   | 105 | 15 | 300 |

to 1000x1000. Notably, for the 300x300 models mean-field did not converge, but was still run for 10 minutes to give a solution. Similarly for 1000x1000 models, belief propagation did not converge but gave a solution after 10 minutes. For 1000x1000 models mean-field did not complete a single iteration within 10 minutes.

Finally, we extend the evaluation beyond Ising models by analyzing restricted Boltzmann machines (RBMs). Table 4 shows log partition function estimates for the largest RBM in [25] (784 visible units, 500 hidden units, trained on the MNIST dataset). AIS is the Annealed Importance Sampling technique described in that work. BP failed to converge. MF converged quickly but was less accurate than AIS. The quick convergence of mean-field was also noted by [24]. AIS was run in two modes, "no data" which estimated logZ from the model alone, and "data" which additionally used the training data to initialize the algorithm. In a similar spirit, due to the quick convergence of MF, and further demonstrating the flexibility of ISS to use any choice of proposal distribution, we ran mean-field to obtain marginals and used these as the proposal distribution for both IS and ISS. By leveraging MF as a proposal distribution ISS matches the accuracy of AIS with data. The ISS approach is valid even when no data is available.

## 8.2 LEARNING

In this final section we present preliminary analysis and empirical justification for the learning algorithm. We gen-

Table 1: Comparison of methods estimating the log partition function for Ising Models. The Importance Sampling (IS) and Importance Sampling over Sets (ISS) methods uses a uniform proposal distribution run over 5 random seeds, with the median presented. Shown in brackets next to ISS is the median number of constrained variables in the heaviest weighted set. The best estimate for each model is shown in bold.

eratively trained a naive Bayes model represented as an MRF on the MNIST handwritten digit dataset (size 28x28 images) and observed the algorithm’s capability to learn weights which accurately modeled the data. The learned model contained 794 variables and 7840 parameters. Examples were used as described in Algorithm 3. Fig. 2 shows a visualization of the learned weights as training progresses. The top image in Fig. 2 shows weights after 5 iterations of training, while the bottom image shows weights after 1000 iterations. Early in training the model captures with high confidence the most common patterns in the digits, but also noise. As training progresses, the model learns to generalize and differentiate between random noise and statistical variations in the data. Adaptive ISS was used as a proposal distribution, and similar results were obtained using marginals defined by the training data.

A straightforward extension of this work is extending the learning to latent variable models such as restricted Boltzmann machines, which the cutting-plane technique may be well-suited to given the accuracy of ISS in estimating RBM partition functions. We leave learning larger and more complex models to future work as the current contribution focuses on the importance sampling over sets technique.

Figure 2: Visualization of learned weights of an undirected naive Bayes model trained generatively on the MNIST dataset. The top image shows weights after 5 iterations of training while the bottom image shows weights after 1000 iterations. Large positive weights are shown in white and large negative weights are shown in black.

## 9 CONCLUSIONS

We introduced a novel probabilistic inference algorithm called importance sampling over sets, based on randomly selecting (exponentially large) subsets of states rather than individual ones as in traditional importance sampling. By solving MAP inference queries over the sampled sets we obtain estimates of the partition function of undirected graphical models. This idea was incorporated into a novel maximum likelihood learning algorithm where the optimization oracle was used to obtain cutting planes. We demonstrated empirically that our scheme provides accurate answers on a range of benchmark instances and scales to very large problems with up to a million variables.

## Abstract

Monte Carlo tree search (MCTS) algorithms can encounter difficulties when solving Markov decision processes (MDPs) in which the outcomes of actions are highly stochastic. This stochastic branching can be reduced through state abstraction. In online planning with a time budget, there is a complex tradeoff between loss in performance due to overly coarse abstraction versus gain in performance from reducing the problem size. Coarse but unsound abstractions often outperform sound abstractions for practical budgets. Motivated by this, we propose a progressive abstraction refinement algorithm that refines an initially coarse abstraction during search in order to match the abstraction to the sample budget. Our experiments show that the algorithm combines the strong performance of coarse abstractions at small sample budgets with the ability to exploit larger budgets for further performance gains.

## 1 INTRODUCTION

When solving planning problems with a time budget, choosing the right representation is crucial. The native representation is often too detailed. It may treat many situations as distinct that are actually similar, causing the planner to spend its limited budget planning for irrelevant contingencies and fail to discover the long term consequences of actions. We should ignore details when deliberation time is limited, but given more time we should increase the level of detail to make better decisions. We consider how to design online planning algorithms that benefit from this type of progressive attention to detail.

Our approach is based on the Monte Carlo tree search (MCTS) paradigm. MCTS methods [Browne et al., 2012] select an action in a given state by constructing a lookahead search tree using a domain simulator. Because MCTS

methods plan for only one state at a time, their asymptotic sample complexity is generally independent of the size of the state space. Rather, they are limited by the search depth achievable with a given time budget, which must be deep enough to estimate the quality of actions in the current state.

A full expectimax tree of depth  $d$  has of the order  $O(|\mathcal{A}| \cdot B)^d$  nodes, where  $|\mathcal{A}|$  is the size of the action set and  $B$  is the number of possible outcomes per action. To achieve a larger value of  $d$ , it is necessary to limit branching in the tree. One way is to reduce  $|\mathcal{A}|$ , an approach taken in previous works such as [Pinto and Fern, 2014]. The other approach, and the one we consider, is to reduce  $B$ .

MCTS algorithms limit  $B$  by selective sampling. Sparse sampling (SS) algorithms [Kearns et al., 2002] limit  $B$  to a constant. Trajectory sampling (TS) algorithms like UCT [Kocsis and Szepesvári, 2006] focus exploration toward actions with higher estimated values, so that  $B$  and  $d$  are small in non-optimal subtrees. In this paper, we investigate a version of sparse sampling that employs state abstraction to further reduce  $B$ .

We limit ourselves to *state aggregation* abstractions, in which the ground states are partitioned into a set of aggregate states. Classes of aggregation abstractions that guarantee bounded performance loss in tree search algorithms have been constructed based on the value function [Hostetler et al., 2014] and on bisimilarity [Jiang et al., 2014]. But while performance loss bounds guarantee asymptotic accuracy, practical time budgets may preclude running a search to convergence. Thus the accuracy and size of the abstraction interact in a complex way to determine the actual search performance. Small budgets call for coarser abstractions, while large budgets can support finer abstractions [Jiang et al., 2014].

Our observation from experience with state abstraction in MCTS has been that search with the coarsest possible abstraction — the abstraction that maps all states to a single equivalence class — often substantially outperforms search in the ground state space for moderate search budgets. Yet

the optimal policy is seldom representable in this abstract space, and there comes a point at which search with such an abstraction cannot exploit further increases in the budget.

Our main contribution is an algorithm — PARSS — that exploits the strengths of coarse abstractions while retaining the convergence and optimality guarantees of search in the ground state space. We achieve this by beginning with a coarse abstraction and refining it during search to create a more detailed abstraction, thus allowing performance to continue to improve after the point where search with the starting abstraction would have reached a plateau. We prove that with suitable implementation choices, PARSS converges to the same result and with the same worst-case sample complexity as a sparse sampling search over the ground state space. Finally, we conduct experiments demonstrating the strength of very coarse abstractions in anytime online planning and the ability of PARSS to further improve upon their performance.

## 2 BACKGROUND

We consider a Monte Carlo tree search (MCTS) algorithm for online planning in Markov decision processes (MDPs). A discounted MDP is a 5-tuple  $M = \langle \mathcal{S}, \mathcal{A}, P, R, \gamma \rangle$ , where  $\mathcal{S}$  and  $\mathcal{A}$  are finite sets of states and actions,  $P(s'|s, a)$  is the transition function,  $R(s)$  gives the instantaneous reward in  $s$ , and  $\gamma \in [0, 1]$  is the discount factor. Note that undiscounted problems (ie.  $\gamma = 1$ ) pose no problem in our online planning setting.

Tree search algorithms construct sampled approximations of the *expectimax tree* over  $M$  rooted at the current state  $s_0$ . The expectimax tree itself defines an MDP over state-action histories as follows. Let  $\mathcal{H}(M, s_0) = \{s_0\} \times \mathcal{A} \times \mathcal{S} \times \dots$  be the set of state-action histories in  $M$  starting in  $s_0$ . We write  $\mathcal{H}^n$  for the set of histories of length  $n$ . Given a history  $h = s_0 a_1 s_1 \dots a_n s_n \in \mathcal{H}^n$ , we write  $s(h) \equiv s_n$  and  $a(h) \equiv a_n$  for the final state and final action in the history,  $p(h) \equiv s_0 a_1 s_1 \dots a_{n-1} s_{n-1}$  for the prefix of the history, and  $\ell(h) \equiv n$  for the length of the history. Using this notation, we overload the  $P$  and  $R$  functions to apply to histories by defining  $P(h'|h, a) = \mathbf{1}_{p(h')=h} \mathbf{1}_{a(h')=a} P(s'|s(h), a)$  and  $R(h) = R(s(h))$ . The *Tree MDP* induced by a general MDP  $M$  and rooted at  $h_0 = s_0$  is the tuple  $T(M, s_0) = \langle \mathcal{H}, \mathcal{A}, P, R, h_0, \gamma \rangle$ .

A solution of a Tree MDP is a policy  $\pi : \mathcal{H} \rightarrow \mathcal{A}$  mapping histories to actions. The *value* of a policy is given by the value function  $V^\pi(h) = R(h) + \sum_{h' \in \mathcal{H}} P(h'|h, \pi(h)) V^\pi(h')$ . A policy is *optimal* if  $V^\pi(h) = V^*(h)$ , where  $V^*(h)$  is the optimal value function,  $V^*(h) = R(h) + \max_{a \in \mathcal{A}} \sum_{h' \in \mathcal{H}} P(h'|h, a) V^*(h')$ . Equivalently, an optimal policy  $\pi^*$  is such that  $\pi^*(h) = \arg \max_{a \in \mathcal{A}} Q^*(h, a)$ , where  $Q^*(h, a) = R(h) + \sum_{h' \in \mathcal{H}} P(h'|h, a) \max_{a' \in \mathcal{A}} Q^*(h', a')$ .

## 2.1 SPARSE SAMPLING

Our proposed algorithm derives from the sparse sampling (SS) algorithm [Kearns et al., 2002]. SS estimates  $Q^*(h_0, a)$  by constructing a sampled approximation of the Tree MDP rooted at  $h_0$ . An SS tree of depth  $d$  and width  $C$  defines a finite horizon estimate  $Q^d(h, a) = R(h) + \frac{\gamma}{C} \sum_{h' \in k(h, a)} \max_{a' \in \mathcal{A}} Q^{d-1}(h', a')$  of  $Q^*$ , with terminal values  $Q^0(h, a) = R(h)$ . Each  $k(h, a)$  is a collection of  $C$  iid samples  $h' \sim P(\cdot|h, a)$ , possibly containing duplicates. The greedy policy with respect to  $Q^d$ ,  $\pi_{SS}(h) = \arg \max_{a \in \mathcal{A}} Q^d(h, a)$ , achieves bounded suboptimality with sample complexity independent of the size of the state space. Our algorithm (Section 4) is based on Forward Search Sparse Sampling (FSSS) [Walsh et al., 2010], an SS algorithm that incorporates pruning.

## 2.2 STATE ABSTRACTION

We consider the simplest form of state abstraction — state aggregation — in which the abstract states are the members of a partition of the ground state space. Given a Tree MDP  $T = \langle \mathcal{H}, \mathcal{A}, P, R, h_0, \gamma \rangle$ , a state abstraction of  $T$  is an equivalence relation  $\chi$  on the set  $\mathcal{H}$ . The abstraction relation induces an abstract state space  $\mathcal{H}/\chi$  whose members are the equivalence classes of  $\mathcal{H}$  with respect to  $\chi$ . We will write  $T/\chi$  as shorthand for  $\langle \mathcal{H}/\chi, \mathcal{A}, P, R, h_0, \gamma \rangle$ . The equivalence class of  $h$  with respect to  $\chi$  is denoted  $[h]_\chi$ , and we say that two states  $h$  and  $g$  are equivalent with respect to  $\chi$ , denoted  $h \simeq_\chi g$ , if  $[h]_\chi = [g]_\chi$ . The abstraction relation for a Tree MDP must be such that  $h \simeq_\chi g \Rightarrow p(h) \simeq_\chi p(g)$  to ensure that  $T/\chi$  is also a Tree MDP.

An abstraction  $\chi$  is *sound* if there is an optimal policy  $\pi^*$  over  $T$  such that  $h \simeq_\chi g \Rightarrow \pi^*(h) = \pi^*(g)$  for all  $h, g \in \mathcal{H}$ . Classes of aggregation abstractions that are sound or that guarantee bounded performance loss in MCTS algorithms have been studied by Hostetler et al. [2014] and Jiang et al. [2014].

## 2.3 ABSTRACTION REFINEMENT

State equivalence abstractions form a complete lattice ordered by abstraction granularity.

**Definition 1.** Abstraction  $\psi$  is *finer* than  $\chi$ , denoted  $\psi \preceq \chi$ , if  $h \simeq_\psi g \Rightarrow h \simeq_\chi g$ . If in addition  $\psi \neq \chi$ , then  $\psi$  is *strictly finer* than  $\chi$ , denoted  $\psi \prec \chi$ .

The finest abstraction is the *bottom* or *ground* abstraction  $\perp$ , which maps all states to singleton sets,  $[h]_\perp = \{h\} \forall h$ . The coarsest abstraction is the *top* abstraction  $\top$ , which maps all ground states of the same length to the same abstract state,  $[h]_\top = \mathcal{H}^{\ell(h)} \forall h$ . Searching in the abstract problem  $T/\top$  amounts to searching for the best open-loop policy in  $T$ , while searching in  $T/\perp$  is equivalent to searching in the ground space.

The lattice structure of equivalence abstractions ensures that by iteratively constructing strict refinements of any initial abstraction we will eventually reach the bottom abstraction  $\perp$ , which is trivially sound. Furthermore, this property does not depend on how the refinements are chosen.

### 3 MOTIVATING EXAMPLE: THE SAVING PROBLEM

To illustrate the type of problem structure that motivates our approach to state abstraction, we created a toy problem called the Saving problem (Figure 1). The Saving problem is an episodic task in which the agent must accumulate wealth by choosing to either *save*, *invest*, or *borrow* at each time step. The *save* action always yields an immediate reward of 1. The *borrow* action takes out a “loan”, which gives an immediate reward of 2 and starts a countdown timer  $t_b$  from  $T_b$  to 0. The agent cannot *borrow* again while  $t_b > 0$ . When  $t_b$  reaches 0, the agent receives a reward of  $-3$ , representing repaying the loan with interest. Thus the true value of *borrow* is  $-1$ , unless the episode will end before the loan is repaid. The *invest* action gives 0 immediate reward, but gives the agent the right to take the *sell* action sometime during the next  $T_i$  time steps. The *sell* action gives a reward  $price(t)$  if executed at time  $t$ , where each  $price(t) \sim \text{DiscreteUniform}\{p_{\min}, p_{\max}\}$  for  $p_{\min}, p_{\max} \in \mathbb{Z}$ . The agent can have only one investment at a time.

We instantiate the Saving problem with  $p_{\min} = -4$ ,  $p_{\max} = 4$ ,  $T_i = 4$ , and  $T_b = 4$ . With these parameters, *invest* is nearly always optimal, but only if the agent takes advantage of the investment period  $T_i$  in order to sell the investment for more than  $\mathbb{E}[price] = 0$ . *Borrow* is almost always the worst action, but the agent must search to a depth of at least  $T_b$  to discover its negative consequences.

Let us consider how the two extremes of state abstraction interact with the Saving problem, beginning with the ground abstraction  $\perp$ . To avoid falling into the *borrow* trap, the search must reach a depth of at least  $T_b$ . A full expectimax tree of depth  $T_b$  has size of the order  $O((|\mathcal{A}|B)^{T_b})$ , where  $B = p_{\max} - p_{\min} + 1$  is the stochastic branching due to the random fluctuation of *price*. If we are restricted to a sample budget  $k \ll (|\mathcal{A}|B)^{T_b}$ , then the constructed tree will be very incomplete, and the agent may accidentally choose to *borrow* or not to *invest* due to sampling variance.

At the other extreme, when searching with the top abstraction  $\top$ , the size of the abstract tree is of the order  $O(|\mathcal{A}|^{T_b})$ . This tree is much smaller in practical terms, so searches will tend to give lower-variance estimates and *borrow* should be chosen less often. On the other hand, since search with  $\top$  cannot discriminate between states, the value of *invest* will be estimated as  $\mathbb{E}[price] = 0$ . This estimate is less than 2, which is the opportunity cost of doing *invest* and *sell* instead of doing *save* twice. Thus search with  $\top$

Figure 1: Schematic diagram of the *invest* and *borrow* actions in the Saving problem. Edges labeled with an action show its immediate reward.

will incorrectly choose to *save* rather than *invest*. This failure mode of open loop replanning was noted by Weinstein and Littman [2012].

These two extremes illustrate an important point: the appropriate abstraction depends on the sample budget. The top abstraction  $\top$  is superior for small budgets. Although  $\top$  is unsound in this domain, the search is operating in a much smaller state space, resulting in lower variance and less chance of incorrectly choosing *borrow*. Conversely,  $\perp$  is best with a large sample budget, since  $\perp$  is sound whereas coarser abstractions might not be sound. With intermediate sample budgets, it is not clear how to determine the appropriate abstraction granularity.

### 4 PROGRESSIVE ABSTRACTION REFINEMENT

The difficulties illustrated in the Saving problem motivate our proposed algorithm. We construct an abstract sparse sampling algorithm that begins with the coarsest abstraction  $\top$  and progressively refines the abstraction during search. If the algorithm is interrupted early in the search, it gives an answer based on a coarse but inaccurate abstraction. As more samples accumulate, the abstraction is refined and the abstract search transforms smoothly into a search over the ground state space.

The algorithm is built on top of the Forward Search Sparse Sampling (FSSS) algorithm of Walsh et al. [2010]. We first describe how to modify FSSS to construct a search tree over the abstract state space induced by a fixed abstraction. We then “wrap” the abstract search in a progressive abstraction refinement procedure.

In our algorithm descriptions, we treat each history  $h$  as an object, in the sense that two histories  $h$  and  $g$  are dis-

tinct even if they describe the same sequence of states and actions. Abstract states  $H$  are collections of ground histories  $h$ , and may contain duplicates. The immediate reward for an abstract state is denoted  $\mathcal{R}(H)$  and is equal to the average reward over its constituent ground states,  $\mathcal{R}(H) = \frac{1}{|H|} \sum_{h \in H} R(h)$ . We also assume the availability of admissible value bounds  $V_{\min}$  and  $V_{\max}$  such that  $V_{\min} \leq V^\pi(h) \leq V_{\max}$  for all ground states  $h \in \mathcal{H}$  and for all policies  $\pi$  over  $\mathcal{H}$ .

#### 4.1 ABSTRACTION IN SPARSE SAMPLING

Forward Search Sparse Sampling (FSSS) [Walsh et al., 2010] is an enhancement of ordinary sparse sampling (SS) that incorporates pruning based on upper and lower bounds on the values of subtrees. It provides the same performance guarantees as SS and often does less computation.

Abstract FSSS (AFSSS; Algorithm 1) is a straightforward extension of FSSS. AFSSS constructs an FSSS tree over abstract states. The abstract tree encapsulates a tree of ground states, whose structure is defined by collections of ground successors  $k(h, a)$ . Each abstract *state node* is a collection  $H = \{h_i\}$  of ground states. Associated with each abstract state node are an upper and a lower value bound  $U(H)$  and  $L(H)$ <sup>1</sup> and a visit count  $n(H)$ . Each state node  $H$  such that  $n(H) > 0$  has an *action node* successor  $Ha$  for each  $a \in \mathcal{A}$ . Action nodes have associated value bounds  $U(H, a)$  and  $L(H, a)$ , abstraction relations  $\chi(H, a)$ , and abstract successor sets  $K(H, a)$ . The visit count  $n(H, a)$  for an action node  $Ha$  is equal to the number of ground successors of  $Ha$ ,  $n(H, a) = \sum_{h \in H} |k(h, a)|$ .

The inputs to AFSSS are an abstract FSSS tree  $\mathcal{T}$ , sampling width  $C$ , and maximum depth  $d$ . Like FSSS, AFSSS proceeds in a series of top-down trials that each traverse a path from the root node to a leaf state node. When extending a path, the algorithm chooses action nodes optimistically (Line 11), and chooses state nodes with the largest gap between  $U$  and  $L$  (Line 12). If the path reaches an unvisited state node (Line 9), that node is *expanded* by initializing and sampling its action node successors. The backup operation (Line 28) combines the average immediate reward over ground states with the discounted future return bounds over abstract states weighted by their empirical frequency.

When sampling an action node  $Ha$  (Line 22), the algorithm must ensure that  $n(H, a) \geq C$  to satisfy the sparse sampling property. We accomplish this by sampling ground successors  $h' \sim P(\cdot|h, a)$  for each ground state  $h \in H$  and adding them to the ground successor collections  $k(h, a)$  until  $|k(h, a)| = \lceil C/|H| \rceil$  for all  $h \in H$ . Note that this sampling method will sometimes draw more than  $C$  samples

<sup>1</sup>As in FSSS, these quantities bound the value estimate of the full SS tree conditioned on the samples so far. The value of an abstract state is a particular weighted average of ground values. See [Hostetler et al., 2014] for details.

for an abstract action node  $Ha$ . It is crucial that sampling is done in this way to allow the abstraction refinement algorithm we will build on top of AFSSS (Section 4.2) to have the same performance guarantees as FSSS.

AFSSS terminates when the time budget is exceeded or the tree has converged (Line 3). The tree has converged if

$$L(H_0, a^*) \geq \max_{a \neq a^*} U(H_0, a) \quad (1)$$

where  $a^* = \arg \max_{a \in \mathcal{A}} L(H_0, a)$ .

#### 4.2 PROGRESSIVE ABSTRACTION REFINEMENT FOR SPARSE SAMPLING

Our proposed algorithm (Algorithm 3) begins by building an abstract FSSS tree with respect to  $\mathcal{T}$ . After building the abstract tree, it begins to refine the abstraction, and contin-

4:      $\chi(H, a) \leftarrow \text{REFINE}(\chi(H, a))$ 
5:     SPLIT( $H, a, \chi$ )
6:     UPDATETREE( $H, a$ )
```

---

ues until there are no more useful refinements to perform. We call the algorithm Progressive Abstraction Refinement for Sparse Sampling (PARSS).

PARSS combines AFSSS with an instantiation of the generic refinement procedure PAR described in Algorithm 2. The PAR procedure consists of four steps. The SELECT function either returns an action node  $Ha$  whose associated abstraction relation  $\chi(H, a)$  should be refined, or indicates that no refinement is to be done. The REFINE procedure is then called on the selected abstraction relation. After refinement, the tree is SPLIT recursively to respect the new abstraction. Finally, UPDATETREE re-computes the tree statistics as necessary. The implementations of SPLIT (Line 10) and UPDATETREE (Line 20) for AFSSS are straightforward. The remaining operations, SELECT and REFINE, are described in the next two sections.

After each PAR operation, PARSS calls AFSSS on the refined tree. This is necessary because refinement may have changed the value bounds of the root node such that the tree no longer satisfies the convergence criterion.

#### 4.2.1 Implementing SELECT

To ensure soundness, the SELECT operation must eventually select all action nodes  $Ha$  such that refining  $Ha$  could change the root action choice. A selection mechanism that guarantees this is said to be *complete*.

**Definition 2.** A SELECT mechanism is *complete* if it returns an action node  $Ha$ , whenever such an  $Ha$  exists, such that:

1.  $\chi(H, a) \succ \perp$ .
2.  $U(H, a) < V_{\max}$

These conditions ensure that refining  $\chi(H, a)$  could potentially alter the choice of root action. Condition (2.2) excludes action nodes in which  $U(H, a) = V_{\max}$ , since in this case refining below  $Ha$  cannot increase  $U(H, a)$  and thus cannot affect the root action choice. This situation arises when nodes have been generated by the EXPAND operation in AFSSS, but have not been visited yet.

The requirements of Definition 2 place few constraints on the order in which nodes are selected. There are several heuristic reasons to prefer refining near the root first. The

34:    BACKUP( $H, a$ )
35:    BACKUP( $H$ )
```

---

most important is that actions near the root are part of more different policies than actions near the leaves. Since the value of an action node only affects the root value if that action is part of the optimal policy, refining nodes that are members of more policies makes it more likely that the refinement will affect the root value. In discounted problems, nodes at shallow depths are also less affected by discounting. These observations suggest that a breadth-first ordering is a reasonable choice.

In our experiments, we used a randomized breadth-first strategy to choose the next node to refine. Our SELECT implementation is divided into subtree selection and node selection phases. First, a subtree  $H_0a$  that is not fully refined is chosen uniformly at random. Then we find the shallowest depth  $d$  at which some descendent of  $H_0a$  satisfies the

conditions of Definition 2, and return one such descendent at depth  $d$  uniformly at random.

#### 4.2.2 Implementing REFINE

Due to the lattice structure of partition abstractions, repeated refinements will eventually yield the ground abstraction  $\perp$ , provided the refinements are strict. Thus, we require that REFINE produces *strict* refinements, to guarantee that the refinement process continues to make progress.

**Definition 3.** REFINE is a *strict refinement function* if  $\text{REFINE}(\chi) \prec \chi$ .

The best choice of REFINE implementation will depend on the problem being solved. In our experiments, we tried the following two variations.

**Random Refinement.** The simpler approach, `REFINERANDOM`, first chooses the largest set  $H'$  in the partition induced by  $\chi(H, a)$ . It then randomly permutes the equivalence classes in  $H'/\perp$  and greedily divides them into two sets of approximately equal size. This option is fast to compute but does not exploit structure in the ground state space.

**Tree-based Refinement.** If we have access to a set of features  $\{\phi_i(h)\}$  for each state, we can take a more sophisticated approach. `REFINEDT` is based on an incrementally-constructed decision tree. Each abstraction relation  $\chi(H, a)$  is defined by a decision tree  $D$ . The leaves of  $D$  define the members of a partition of the successors of  $Ha$ . Interior nodes are labeled with a feature  $i$  and a threshold  $\theta$ . The refinement operation chooses the largest leaf node  $N$  of  $D$  and adds a new split to  $D$  dividing  $N$  into two new sets  $X$  and  $Y$ , choosing splits greedily to maximize an evaluation function  $f(X, Y)$ .

The evaluation function  $f$  can be designed to encourage desired properties in the partitions. For example, if  $\chi$  is such that for all  $H \in \mathcal{H}/\chi$ , all members of  $H$  have the same optimal action and the same optimal value, then  $\chi$  is sound in sparse sampling [Hostetler et al., 2014]. This condition is called  $a^*$ -irrelevance [Li et al., 2006]. We define an evaluation function that encourages  $a^*$ -irrelevance using upper bounds  $u(h)$  and  $u(h, a)$  for ground state values. These can be computed along with the bounds for the abstract states during the `BACKUP` step (Algorithm 1, Line 28).

Using these bounds on the ground states, we define the evaluation function

$$f(X, Y) = |\bar{u}(X) - \bar{u}(Y, a^*)| + |\bar{u}(Y) - \bar{u}(X, b^*)|,$$

where  $\bar{u}(H) = \frac{1}{|H|} \sum_{h \in H} u(h)$ ,  $\bar{u}(H, a) = \frac{1}{|H|} \sum_{h \in H} u(h, a)$ ,  $a^* = \arg \max_{a \in \mathcal{A}} \bar{u}(X, a)$  and  $b^* = \arg \max_{b \in \mathcal{A}} \bar{u}(Y, b)$ . Splits that maximize  $f$  will tend to put ground states that have different optimal actions or different optimal values into different abstract states.

### 4.3 ANALYSIS OF PARSS

The PARSS algorithm can be viewed as a different way of orchestrating the sampling of a sparse tree. If run to termination, it provides the same performance guarantees with the same sample complexity as ordinary sparse sampling.

**Definition 4.** An abstract search tree  $\mathcal{T} = \langle K, L, U, H_0 \rangle$  is an *abstract FSSS tree with respect to  $\chi$* , or an *AFSSS( $\chi$ ) tree* in shorthand, if

1. For each abstract state node  $H, \forall h, g \in H, h \simeq_\chi g$ ;
2. For every abstract state node  $H$  such that  $n(H) > 0$ ,  $n(H, a) \geq C$  for all  $a \in \mathcal{A}$ ,
3. All value bounds  $L$  and  $U$  are admissible (Section 4.1),
4.  $\mathcal{T}$  satisfies the AFSSS convergence criterion (1).

One can easily verify that the output of AFSSS is an abstract FSSS tree.

**Proposition 1.** Consider a PARSS implementation where the `SELECT` and `REFINE` operations satisfy the conditions of Definitions 2 and 3. If the current search tree  $\mathcal{T}$  is an abstract FSSS tree with respect to abstraction  $\chi$ , then after one iteration of the loop in Algorithm 3, Line 7, the resulting tree  $\mathcal{T}'$  is an abstract FSSS tree with respect to an abstraction  $\psi$  such that  $\psi \prec \chi$ .

*Proof.* By assumption,  $\text{REFINE}(\chi(H, a))$  returns a new abstraction  $\psi$  such that  $\psi(H, a) \prec \chi(H, a)$ , and therefore  $\psi \prec \chi$ . The `SPLIT` operation partitions the subtree  $Ha$  according to  $\psi$ , establishing condition (4.1). The `UPSAMPLE` loop in `UPDATETREE` (Line 21) adds samples and performs backups in the subtree  $Ha$  to establish (4.2) and (4.3) for the subtree. Then values are backed up from  $Ha$  to the root node (Line 23), which establishes (4.3) for the rest of the tree. Finally, the call to `AFSSS` (Line 9) establishes convergence (4.4).  $\square$

**Proposition 2.** If PARSS does not exhaust its time budget, it terminates after drawing at most  $(|\mathcal{A}| \cdot C)^d$  samples from the transition function  $P$ , and the resulting search tree is an abstract FSSS tree with respect to  $\perp$ .

*Proof.* By Proposition 1, each iteration of the loop in Algorithm 3, Line 7 produces a strictly refined AFSSS tree. Due to the lattice structure of aggregation abstractions (Section 2.3), the abstraction relations  $\chi(H, a)$  will be equal to  $\perp$  for all  $H, a$  after a finite number of iterations. The tree at this point is an abstract FSSS tree with respect to  $\perp$ . The worst-case sample complexity occurs if all abstract nodes  $H$  in the fully-refined tree are singletons.  $\square$

**Proposition 3.** PARSS achieves the same error bounds and sample complexity as ordinary sparse sampling.

*Proof.* Proposition 2 establishes that PARSS yields an AFSSS( $\perp$ ) tree  $\mathcal{T}$  with the same worst-case sample complexity as SS (ie.  $O((|\mathcal{A}| \cdot C)^d)$ ).  $\mathcal{T}$  is different from a ground FSSS tree in that states that are equal in the ground representation are aggregated in  $\mathcal{T}$ . Because the FSSS pruning mechanism is sound [Walsh et al., 2010],  $\mathcal{T}$  achieves the same error bounds as an SS tree in which identical states are aggregated. The error bounds for sparse sampling remain valid in this case [Kearns et al., 2002], thus the conclusion follows.  $\square$

## 5 RELATED WORK

The PARSS algorithm begins with an abstract tree search under abstraction  $\top$ , which as we have noted is equivalent to searching for an open loop policy. Several works have explored the use of open loop policies for value estimation. Weinstein and Littman [2012] applied this idea in continuous action MDPs, drawing on theory developed by Bubeck and Munos [2010]. Weinstein and Littman [2013] later developed a related algorithm with a different optimization mechanism and applied it to legged locomotion tasks. Hauser [2011] used forward search with open loop policies to plan in partially observable continuous spaces.

Incremental construction of state space partitions starting from the top abstraction  $\top$  has been a common approach to abstraction discovery in MDPs, in algorithms such as the G algorithm [Chapman and Kaelbling, 1991], the PARTI-GAME algorithm [Moore and Atkeson, 1995], and the UTREE algorithm [McCallum, 1996]. The REFINEDT operation (Section 4.2.2) is similar to UTREE.

One closely related work is the Tree Learning Search (TLS) algorithm of Van den Broeck and Driessens [2011]. TLS contains all of the main ideas we use in PARSS, but applied in the UCT algorithm and targeted at continuous action spaces. Each state node of a TLS tree has an associated decision tree that represents a discretization of the action space. The decision trees are grown incrementally when data indicate that an existing action equivalence class leads to states with large variation in their values.

Another closely related work is that of Jiang et al. [2014], which describes a different abstraction refinement procedure for UCT. Their search proceeds in “batches” of samples. In between each batch, all of the abstraction relations are recomputed to satisfy a local approximate homomorphism criterion with respect to the sampled tree, and then the next batch of samples is drawn via search in the new abstract state space. A key difference from our approach is that their algorithm computes a particular abstraction with specified approximation bounds. With more samples, the computed abstraction becomes a better estimate of the target abstraction. In contrast, our method computes progressively finer abstractions as the sample budget increases.

Table 1: Best parameters for each algorithm. Parameter quality is measured by AUAC( $w_{\text{mag}}$ ).

## 6 EXPERIMENTS

We evaluated PARSS with both REFINEDT and REFINERANDOM refinement procedures (“PARSS+DT” and “PARSS+RAND”; Section 4.2.2) in comparison to flat FSSS (“GROUND”), AFSSS with the top abstraction (“TOP”), and AFSSS with random abstractions of different fixed branching factors (“RANDOM”). We compared the anytime performance of the algorithms with both sample budgets and time budgets.

### 6.1 DOMAINS

Our test domains included the Saving problem described earlier (Section 3) as well as several other benchmark domains. We chose domains that exhibit varying amounts of stochastic branching and on which we suspected that the top abstraction would not be optimal.

**Racetrack.** Racetrack is the classic RL domain of Barto et al. [1995]. The agent controls a car in a grid world. The state specifies the car’s position and velocity, and the actions apply an acceleration  $a \in \{-1, 0, 1\} \times \{-1, 0, 1\}$  to the car. The objective is to reach a goal state in as few steps as possible without crashing into a wall. We incorporate stochasticity by making both components of the acceleration action subject independently to a random “slip” with probability 0.2, which causes 0 acceleration to be applied in that direction rather than the intended amount. We used both the “small” and “large” circuits of Barto et al. [1995].

**Spanish Blackjack.** Spanish Blackjack is a more complicated variation of the casino game Blackjack (or “21”). In Spanish Blackjack, the player may split to a total of up to 4 hands, may double down after splitting, may re-double the same hand up to a total of three times, and may hit after doubling. There are also bonuses for making 21 in 5 cards, 6 cards, or 7 or more cards, or with either 7,7,7 or 6,7,8.

**Academic Advising.** The Academic Advising domain [Guerin et al., 2012] was featured at the International Planning Competition at ICAPS in 2014. The agent must take

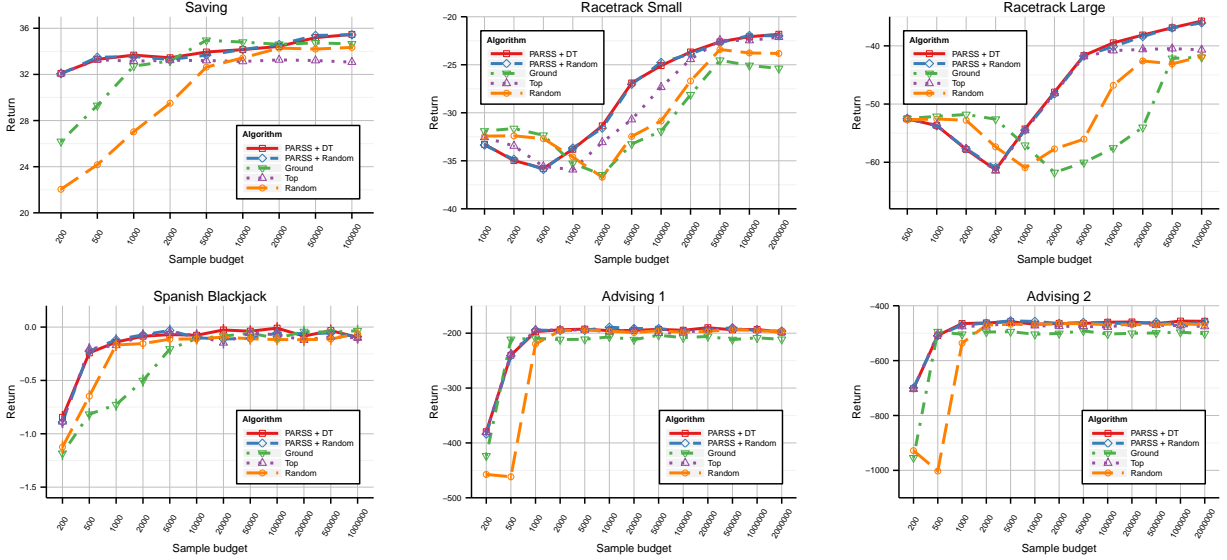

Figure 2: Performance vs. sample budget. Results are for the parameters that maximized  $AUAC(w_{\text{mag}})$ . Confidence intervals are shown, but are mostly smaller than the marker shapes except for Spanish Blackjack.

and pass all of the required courses in an academic program. The courses are linked by prerequisite relationships, and the chance of passing a course depends on how many of its prerequisites have been passed. We used MDP instances 1 and 2 from the IPC 2014.

In the IPC version of Advising, the agent can either *pass* or *fail* a course. We implemented a generalized problem that has integer grades in the range  $\{0, \dots, g\}$  to increase stochastic branching. We set  $g = 4$  and set 2 as the minimum passing grade for required courses.

## 6.2 METHODOLOGY

We evaluated each algorithm for several combinations of the  $C$  and  $d$  parameters. The range of  $d$  spanned 3 - 4 consecutive integers for each problem and  $C$  spanned 3 - 4 consecutive values in the sequence  $\{5, 10, 20, 50, 100, 200\}$ . Specific ranges were chosen based on pilot experiments.

For the sample budget experiments, we restricted the algorithms to a maximum number of samples from the transition function. We evaluated sample budgets in the sequence  $\{200, 500, 1000, 2000, \dots\}$  for each parameter combination. For each budget, we measured average return over 2000 to 10000 episodes, depending on the domain.

We report results for the combinations of parameters that maximized the weighted area under the anytime curve. Given a budget sequence  $\mathcal{B} = \{b_1, \dots, b_n\}$ , we calculate AUAC as

$$AUAC(w)(\mathcal{B}) = \sum_{i=2}^n w(b_i, b_{i-1}) \frac{\rho(b_i) + \rho(b_{i-1})}{2}, \quad (2)$$

where  $\rho(b)$  is the sample average of the return of the algorithm with budget  $b$  and  $w : \mathcal{B} \times \mathcal{B} \mapsto \mathbb{R}^{\geq 0}$  is a weight function. In our main experiment, we use the weight function  $w_{\text{mag}}(b_i, b_{i-1}) = \log b_i - \log b_{i-1}$ , which reflects a preference for good performance across orders of magnitude of budget.

Performance comparisons based on sample budgets can be misleading, since more-sophisticated algorithms do more work per sample. For those domains in which PARSS showed superior performance, we ran experiments with a time budget using the same parameters that achieved the best sample budget performance. The time budgets were measured in milliseconds and were drawn from the sequence  $\{10, 16, 25, 40, 63, 100, \dots\}$ .

## 6.3 RESULTS

The two variations of PARSS had superior anytime performance with a sample budget in Saving and in both Racetracks (Figure 2), and were equal to TOP on the other domains. TOP outperformed GROUND in all domains except Saving but it plateaued at a suboptimal value in Saving and Racetrack Large. The pattern of performance on Saving was as expected, with TOP plateauing while both variants of PARSS continued to improve and equaled the best performance of GROUND.

In Blackjack and both Advising domains, the  $AUAC(w_{\text{mag}})$  performance measure emphasized quick convergence, and the best  $C$  and  $d$  parameters were at the small end of their ranges (Table 6.1). TOP (and thus PARSS) converged more quickly than GROUND, and in both Advising domains also converged to a better value. PARSS did not diverge

Figure 3: Performance vs. time budget. Parameter settings are the same as for the sample budget experiments.

Figure 4: Selected results with best parameters according to  $AUAC(w_{flat})$ .

from TOP in these domains, indicating that abstraction refinement was not beneficial.

The RANDOM abstraction, which is a compromise between TOP and GROUND, tended to fall in between those two abstractions, although RANDOM performed poorly on Saving for small budgets.

The results with time budgets were qualitatively similar to the sample budget results (Figure 3).

To examine the sensitivity of our results to the choice of anytime performance measure, we also evaluated the algorithms with the parameters that maximized  $AUAC$  with respect to the alternative weight function  $w_{flat}(b_i, b_{i-1}) = b_i - b_{i-1}$ . Weighting with  $w_{flat}$  gives equal weight to all budgets in the range, and thus gives greater emphasis to large budgets compared to  $w_{mag}$ . In the domains shown (Figure 4), the different budget weighting resulted in some qualitative changes to the results, but the relative ranking of the algorithms remained the same. Note that the divergence between PARSS and TOP in Advising 2 is due to noise in parameter selection. There were no noteworthy differences in the domains not shown.

There was no difference in performance between PARSS+DT and PARSS+RAND. It appears that either REFINEDT does not find better refinements than REFINERANDOM, or else the quality of refinements does not matter much to overall performance. We expected the simpler REFINERANDOM mechanism to have an advantage under a time budget, but this was not the case.

To summarize, our main experimental findings were:

- TOP was clearly superior to GROUND overall;
- PARSS equaled the performance of TOP, or surpassed TOP through abstraction refinement;
- The two refinement mechanisms — REFINERANDOM and REFINEDT — had identical performance;
- Relative performance results with time budgets were qualitatively similar to those with sample budgets.

## 7 SUMMARY

We have described an extension of sparse sampling called Progressive Abstraction Refinement for Sparse Sampling (PARSS) that adapts the granularity of its state representation to the available planning budget. PARSS exploits the benefits of coarse, unsound abstractions for small budgets while transitioning smoothly to more accurate abstractions when given a larger budget. We proved that PARSS has the same sample complexity and accuracy guarantees as SS. Our experiments demonstrated that planning with the coarsest abstraction, equivalent to open loop planning, yields strong anytime performance on several benchmark domains, and confirmed that PARSS can improve upon that strong performance as budgets increase.

## Abstract

We present a scalable Bayesian model for low-rank factorization of massive tensors with binary observations. The proposed model has the following key properties: (1) in contrast to the models based on the logistic or probit likelihood, using a zero-truncated Poisson likelihood for binary data allows our model to scale up in the number of *ones* in the tensor, which is especially appealing for massive but sparse binary tensors; (2) side-information in form of binary pairwise relationships (e.g., an adjacency network) between objects in any tensor mode can also be leveraged, which can be especially useful in “cold-start” settings; and (3) the model admits simple Bayesian inference via batch, as well as *online* MCMC; the latter allows scaling up even for *dense* binary data (i.e., when the number of ones in the tensor/network is also massive). In addition, non-negative factor matrices in our model provide easy interpretability, and the tensor rank can be inferred from the data. We evaluate our model on several large-scale real-world binary tensors, achieving excellent computational scalability, and also demonstrate its usefulness in leveraging side-information provided in form of mode-network(s).

## 1 INTRODUCTION

With the recent surge in multiway, multirelational, or “tensor” data sets (Nickel et al., 2011; Kang et al., 2012), learning algorithms that can extract useful knowledge from such data are becoming increasingly important. Tensor decomposition methods (Kolda and Bader, 2009) offer an attractive way to accomplish this task. Among tensor data, of particular interest are real-world *binary* tensors, which are now ubiquitous in problems involving social networks, rec-

ommender systems, and knowledge bases, etc. For instance, in a knowledge base, predicate relations defined over the tuples (subjects, objects, verbs) can be represented in form of a binary three-way tensor (Kang et al., 2012).

Usually, real-world binary tensors are massive (each dimension can be very large) but extremely sparse (very few ones in the tensor). For example, in a recommender system, each positive example (e.g., an item selected a set) implicitly creates several negative examples (items *not* chosen). Likewise, in a knowledge base, the validity of one relation automatically implies invalidity of several other relations. In all these settings, the number of negative examples greatly overwhelms the number of positive examples.

Unfortunately, binary tensor factorization methods (Nickel et al., 2011; Xu et al., 2013; Rai et al., 2014), based on probit or logistic likelihood, scale poorly for massive binary tensors because these require evaluating the likelihood/loss-function on *both* ones as well as zeros in the tensor. One possibility is to use heuristics such as *undersampling* the zeros, but such heuristics usually result in less accurate solutions. Another alternative is to use the *squared loss* (Hidasi and Tikk, 2012; Nickel et al., 2012) as the model-fit criterion, which facilitates linear scalability in the number of ones in the tensor. However, such an approach can often lead to suboptimal results (Ermis and Bouchard, 2014) in practice.

It is therefore desirable to have methods that can perform efficient tensor decomposition for such data, ideally with a computational-complexity that depends only on the number of nonzeros (i.e., the ones) in the tensor, rather than the “volume” of the tensor. Motivated by this problem, we present a scalable Bayesian model for the Canonical PARAFAC (CP) tensor decomposition (Kolda and Bader, 2009), with an inference-complexity that scales linearly in the number of ones in the tensor. Our model uses a zero-truncated Poisson likelihood for each binary observation in the tensor; this obviates the evaluation of the likelihoods for the zero entries. At the same time, the significant speed-up is not at the cost of sacrificing on the quality of the solution. As our experimental results show, the proposed like-

---

\*Equal contribution

likelihood model yields comparable or better results to logistic likelihood based models, while being an order of magnitude faster in its running-time on real-world binary tensors. Note that replacing the zero-truncated Poisson by the standard Poisson makes our model also readily applicable for count-valued tensors (Chi and Kolda, 2012); although, in this exposition, we will focus exclusively on binary tensors.

Often, side-information (Acar et al., 2011; Beutel et al., 2014), e.g., pairwise relationships (partially/fully observed), may also be available for objects in some of the tensor dimensions. For example, in addition to a binary tensor representing AUTHORS  $\times$  WORDS  $\times$  VENUES associations, the AUTHOR  $\times$  AUTHOR co-authorship network may be available (at least for some pairs of authors). Such a network may be especially useful in “cold-start” settings where there is no data for some of the entities of a mode in the tensor (e.g., for some authors, there is no data in the tensor), but a network between entities in that mode may be available (See Fig 1 for an illustration). Our model allows leveraging such network(s), without a significant computational overhead, using the zero-truncated Poisson likelihood *also* to model these binary pairwise relationships.

To facilitate efficient fully Bayesian inference, we develop easy-to-implement batch as well as *online* MCMC inference; the latter is especially appealing for handling *dense* binary data, i.e., when the number of ones in the tensor and/or the network is also massive. Another appealing aspect about the model is its interpretability; a Dirichlet prior on the columns of each factor matrix naturally imposes non-negativity. In addition, the rank of decomposition can be inferred from the data.

## 2 CANONICAL PARAFAC (CP) TENSOR DECOMPOSITION

The Canonical PARAFAC (CP) decomposition (Kolda and Bader, 2009) offers a way to express a tensor as a sum of rank-1 tensors. Each rank-1 tensor corresponds to a specific “factor” in the data. More specifically, the goal in CP decomposition is to decompose a tensor  $\mathcal{Y}$  of size  $n_1 \times n_2 \times \dots \times n_K$ , with  $n_k$  denoting the size of  $\mathcal{Y}$  along the  $k^{\text{th}}$  mode (or “way”) of the tensor, into a set of  $K$  factor matrices  $\mathbf{U}^{(1)}, \dots, \mathbf{U}^{(K)}$  where  $\mathbf{U}^{(k)} = [\mathbf{u}_1^{(k)}, \dots, \mathbf{u}_R^{(k)}]$ ,  $k = \{1, \dots, K\}$ , denotes the  $n_k \times R$  factor matrix associated with mode  $k$ .

In its most general form, CP decomposition expresses the tensor  $\mathcal{Y}$  via a weighted sum of  $R$  rank-1 tensors as

$$\mathcal{Y} \sim f\left(\sum_{r=1}^R \lambda_r \mathbf{u}_r^{(1)} \odot \dots \odot \mathbf{u}_r^{(K)}\right) \quad (1)$$

In the above, the form of the link-function  $f$  depends on the type of data being modeled (e.g.,  $f$  can be Gaussian for real-valued, Bernoulli-logistic for binary-valued, Poisson for count-valued tensors). Here  $\lambda_r$  is the weight associated

with the  $r^{\text{th}}$  rank-1 component, the  $n_k \times 1$  column vector  $\mathbf{u}_r^{(k)}$  represents the  $r^{\text{th}}$  latent factor of mode  $k$ , and  $\odot$  denotes vector outer product.

We use subscript  $\mathbf{i} = \{i_1, \dots, i_K\}$  to denote the  $K$ -dimensional index of the  $\mathbf{i}$ -th entry in the tensor  $\mathcal{Y}$ . Using this notation, the  $\mathbf{i}$ -th entry of the tensor  $\mathcal{Y}$  can be written as  $y_{\mathbf{i}} \sim f\left(\sum_{r=1}^R \lambda_r \prod_{k=1}^K u_{i_k r}^{(k)}\right)$ .

## 3 TRUNCATED POISSON TENSOR DECOMPOSITION FOR BINARY DATA

Our focus in this paper is on developing a probabilistic, fully Bayesian method for scalable low-rank decomposition of massive *binary* tensors. As opposed to tensor decomposition models based on the logistic likelihood for binary data (Xu et al., 2013; Rai et al., 2014), which require evaluation of the likelihood for both ones as well as zeros in the tensor, and thus can be computationally infeasible to run on massive binary tensors, our proposed model only requires the likelihood evaluations on the *nonzero* (i.e., the ones) entries in the tensor, and can therefore easily scale to massive binary tensors. Our model is applicable to tensors of any order  $K \geq 2$  (the case  $K = 2$  being a binary matrix).

Our model is based on a decomposition of the form given in Eq. 1; however, instead of using a Bernoulli-logistic link  $f$  to generate each binary observation  $y_{\mathbf{i}}$  in  $\mathcal{Y}$ , we assume an additional layer (Eq. 2) which takes a *latent* count-valued  $y_{\mathbf{i}}$  in  $\mathcal{Y}$  and thresholds this latent count at one to generate the actual *binary*-valued entry  $b_{\mathbf{i}}$  in the observed binary tensor, which we will denote by  $\mathcal{B}$ :

$$b_{\mathbf{i}} = \mathbf{1}(y_{\mathbf{i}} \geq 1) \quad (2)$$

$$\mathcal{Y} \sim \text{Pois}\left(\sum_{r=1}^R \lambda_r \mathbf{u}_r^{(1)} \odot \dots \odot \mathbf{u}_r^{(K)}\right) \quad (3)$$

$$\mathbf{u}_r^{(k)} \sim \text{Dir}(a^{(k)}, \dots, a^{(k)}) \quad (4)$$

$$\lambda_r \sim \text{Gamma}(g_r, \frac{p_r}{1 - p_r}) \quad (5)$$

$$p_r \sim \text{Beta}(c\epsilon, c(1 - \epsilon)) \quad (6)$$

Marginalizing out  $y_{\mathbf{i}}$  from Eq. 2 leads to the following (equivalent) likelihood model

$$b_{\mathbf{i}} \sim \text{Bernoulli}\left(1 - \exp\left(-\sum_{r=1}^R \lambda_r \prod_{k=1}^K u_{i_k r}^{(k)}\right)\right) \quad (7)$$

Note that the thresholding in (2) looks similar to a probit model for binary data (which however thresholds a *normal* at zero); however, the probit model (just like the logistic model) also needs to evaluate the likelihood at the zeros, and can therefore be slow on massive binary data with lots of zeros. Likelihood models of the form (Eq. 7) have previously also been considered in work on statistical models of undirected networks (Morup et al., 2011; Zhou, 2015).

Interestingly, the form of the likelihood in 7 also resembles the complementary log-log function Collett (2002); Piegorsch (1992), which is known to be a better model for imbalanced binary data than the logistic or probit likelihood, making it ideal for handling sparse binary tensors.

The conditional posterior of the latent count  $y_i$  is given by

$$y_i | b_i, \lambda, \{u_{i_k r}^{(k)}\}_{k=1}^K \sim b_i \cdot \text{Pois}_+(\sum_{r=1}^R \lambda_r \prod_{k=1}^K u_{i_k r}^{(k)}) \quad (8)$$

where  $\text{Pois}_+(\cdot)$  is zero truncated Poisson distribution. Eq. (8) suggests that if  $b_i = 0$ , then  $y_i = 0$  almost surely with probability one, which can lead to significant computational savings, if the tensor has a large number of zeros. In addition, our model also enables leveraging a reparameterization (Section 3.2) of the Poisson distribution in terms of a multinomial, which allows us to obtain very simple Gibbs-sampling updates for the model parameters.

Note that the Dirichlet prior on the latent factors  $\mathbf{u}_r^{(k)}$  naturally imposes non-negativity constraints (Chi and Kolda, 2012) on the factor matrices  $\mathbf{U}^{(1)}, \dots, \mathbf{U}^{(K)}$ . Moreover, since the columns  $\mathbf{u}_r^{(k)}$  of these factor matrices sums to 1, each  $\mathbf{u}_r^{(k)}$  can also be interpreted as a *distribution* (e.g., a “topic”) over the  $n_k$  entities in mode  $k$ . Furthermore, the gamma-beta hierarchical construction (Zhou et al., 2012) of  $\lambda_r$  (Eq 5 and 6) allows inferring the rank of the tensor by setting an upper bound  $R$  on the number of factors and inferring the appropriate number of factors by shrinking the coefficients  $\lambda_r$ ’s to close to zero for the irrelevant factors. These aspects make our model interpretable as well as provide it the ability to do model selection (i.e., inferring the rank), in addition to being computationally efficient by focusing the computations only on the nonzero entries in the tensor  $\mathcal{B}$ .

### 3.1 LEVERAGING MODE NETWORKS

Often, in addition to the binary tensor  $\mathcal{B}$ , *pairwise* relationships between entities in one or more tensor modes may be available in form of a symmetric binary network or an undirected graph. Leveraging such forms of side-information can be beneficial for tensor decomposition, especially if the amount of missing data in the main tensor  $\mathcal{B}$  is very high (Acar et al., 2011; Beutel et al., 2014; Rai et al., 2015), and, even more importantly, in “cold-start” settings, where there is no data in the tensor for entities along some of the tensor mode(s), as shown in Fig 1. In the absence of any side-information, the posterior distribution of the latent factors  $\mathbf{u}_r^{(k)}$  of such entities in that tensor mode would be the same as the prior (i.e., just a random draw). Leveraging the side-information (e.g., a network) helps avoid this.

For entities of the  $k$ -th mode of tensor  $\mathcal{B}$ , we assume a symmetric binary network  $\mathbf{A}^{(k)} \in \{0, 1\}^{n_k \times n_k}$ , where  $A_{i_k j_k}^{(k)}$

Figure 1: Binary tensor with an associated binary network between objects in mode-1 of the tensor (in general, network for other modes may also be available). In the “cold-start” setting as shown above, data along some of the tensor dimensions will be completely missing

denotes the relationship between mode- $k$  entities  $i_k$  and  $j_k$ .

Just like our tensor decomposition model, we model the mode- $k$  network  $\mathbf{A}^{(k)}$  as a weighted sum of rank-1 symmetric matrices, with a similar likelihood model as we use for the tensor observations. In particular, we assume a latent count  $X_{i_k j_k}^{(k)}$  for each binary entry  $A_{i_k j_k}^{(k)}$ , and threshold it at one to generate  $A_{i_k j_k}^{(k)}$

$$A_{i_k j_k}^{(k)} = \mathbf{1}(X_{i_k j_k}^{(k)} \geq 1) \quad (9)$$

$$\mathbf{X}^{(k)} \sim \text{Pois}(\sum_{r=1}^R \beta_r \cdot \mathbf{u}_r^{(k)} \odot \mathbf{u}_r^{(k)}) \quad (10)$$

$$\beta_r \sim \text{Gamma}(f_r, \frac{h_r}{1 - h_r}) \quad (11)$$

$$h_r \sim \text{Beta}(d\alpha, d(1 - \alpha)) \quad (12)$$

Note that since  $\mathbf{A}^{(k)}$  is symmetric, only the upper (or lower) triangular portion needs to be considered, and moreover, just like in the case of the tensor  $\mathcal{B}$ , due to the truncated Poisson construction, the likelihood at only the nonzero entries needs to be evaluated for this part as well.

### 3.2 REPARAMETERIZED POISSON DRAWS

To simplify posterior inference (Section 4), we make use of two re-parameterizations of a Poisson draw (Zhou et al., 2012). The first parameterization is to express each latent count variable  $y_i$  and  $X_{i_k j_k}^{(k)}$  as a sum of another set of  $R$  latent counts  $\{\tilde{y}_{i r}\}_{r=1}^R$  and  $\{\tilde{X}_{i_k j_k r}^{(k)}\}_{r=1}^R$ , respectively

$$y_i = \sum_{r=1}^R \tilde{y}_{i r}, \quad \tilde{y}_{i r} \sim \text{Pois}(\lambda_r \prod_{k=1}^K u_{i_k r}^{(k)}) \quad (13)$$

$$X_{i_k j_k}^{(k)} = \sum_{r=1}^R \tilde{X}_{i_k j_k r}^{(k)}, \quad \tilde{X}_{i_k j_k r}^{(k)} \sim \text{Pois}(\beta_r u_{i_k r}^{(k)} u_{j_k r}^{(k)}) \quad (14)$$

The second parameterization assumes that the latent counts  $\{\tilde{y}_{i r}\}$  and  $\{\tilde{X}_{i_k j_k r}^{(k)}\}$  are drawn from a multinomial

$$\begin{aligned} \tilde{y}_{i 1}, \dots, \tilde{y}_{i R} &\sim \text{Mult}(y_i; \zeta_{i 1}, \dots, \zeta_{i R}) \\ \zeta_{i r} &= \frac{\lambda_r \prod_{k=1}^K u_{i_k r}^{(k)}}{\sum_{r=1}^R \lambda_r \prod_{k=1}^K u_{i_k r}^{(k)}} \end{aligned} \quad (15)$$

$$\begin{aligned} \tilde{X}_{i_k j_k 1}^{(k)}, \dots, \tilde{X}_{i_k j_k R}^{(k)} &\sim \text{Mult}(X_{i_k j_k}^{(k)}; \kappa_{i_k j_k 1}^{(k)}, \dots, \kappa_{i_k j_k R}^{(k)}) \\ \kappa_{i_k j_k r}^{(k)} &= \frac{\beta_r u_{i_k r}^{(k)} u_{j_k r}^{(k)}}{\sum_{r=1}^R \beta_r u_{i_k r}^{(k)} u_{j_k r}^{(k)}} \end{aligned} \quad (16)$$

As we show in Section 4, these parameterizations enable us to exploit the gamma-Poisson as well as the Dirichlet-multinomial conjugacy to derive simple, closed-form Gibbs sampling updates for the model parameters.

## 4 INFERENCE

Exact inference in the model is intractable and we resort to Markov Chain Monte Carlo (MCMC) (Andrieu et al., 2003) inference. In particular, the reparameterization discussed in Section 3.2 allows us to derive simple Gibbs sampling updates for all the latent variables, except for the latent counts  $y_i$ , which are drawn from a truncated Poisson distribution via rejection sampling. As discussed earlier, the computational-cost for our inference method scales linearly w.r.t. the number of ones in the tensor (plus the number of nonzeros in the network, if side-information is used). This makes our method an order of magnitude faster than models based on logistic or probit likelihood for binary data (Rai et al., 2014; Xu et al., 2013), without sacrificing on the quality of the results. The relative speed-up depends on the ratio of total volume of the tensor to the number of ones, which is given by  $(\prod_{k=1}^K n_k) / \text{nnz}(\mathcal{B})$ ; here  $\text{nnz}(\mathcal{B})$  denotes the number of nonzeros in the tensor.

In this section, we present both batch MCMC (Section 4.1) as well as an online MCMC (Section 4.2) method for inference in our model. The online MCMC algorithm is based on the idea of Bayesian Conditional Density Filtering (CDF) (Guhaniyogi et al., 2014), and can lead to further speed-ups over the batch MCMC if the number of nonzeros in the tensor is also massive. The CDF algorithm provides an efficient way to perform online MCMC sampling using surrogate conditional sufficient statistics (Guhaniyogi et al., 2014).

For both batch MCMC and CDF based online MCMC, we provide the update equations, with and without the side-information, i.e., the mode network(s). For what follows, we define four quantities:  $s_{j,r}^{(k)} = \sum_{i:i_k=j} \tilde{y}_{i_r}$ ,  $s_r = \sum_i \tilde{y}_{i_r}$ ,  $v_{i_k,r} = \sum_{j_k} \tilde{X}_{i_k j_k r}^{(k)}$  and  $v_r = \sum_{i_k} \sum_{j_k} \tilde{X}_{i_k j_k r}^{(k)}$ , which denote aggregates computed using the latent counts  $\tilde{y}_{i_r}$  and  $\tilde{X}_{i_k j_k r}^{(k)}$ . These quantities will be used at various places in the description of the inference algorithms that we present here.

### 4.1 BATCH MCMC INFERENCE

#### 4.1.1 Tensor without Mode Network(s)

**Sampling  $y_i$ :** For each observation  $b_i$  in the tensor, the latent count  $y_i$  is sampled as

$$y_i \sim b_i \cdot \text{Pois}_+(\sum_{r=1}^R \lambda_r \prod_{k=1}^K u_{i_k r}^{(k)}) \quad (17)$$

where  $\text{Pois}_+(\cdot)$  is zero truncated Poisson distribution. Eq. (17) suggests that if  $b_i = 0$ , then  $y_i = 0$  almost surely; and if  $b_i = 1$ , then  $y_i \sim \text{Pois}_+(\sum_{r=1}^R \lambda_r \prod_{k=1}^K u_{i_k r}^{(k)})$ . Therefore the  $y_i$ 's only need to be sampled for the nonzero  $b_i$ 's. **Sampling  $\tilde{y}_{i_r}$ :** The latent counts  $\{\tilde{y}_{i_r}\}$  are sampled from a multinomial as Eq. (15). Note that this also needs to be done only for the nonzero  $b_i$ 's.

**Sampling  $\mathbf{u}_r^{(k)}$ :** The columns of each factor matrix have a Dirichlet posterior, and are sampled as

$$\mathbf{u}_r^{(k)} \sim \text{Dir}(a^{(k)} + s_{1,r}^{(k)}, a^{(k)} + s_{2,r}^{(k)}, \dots, a^{(k)} + s_{n_k,r}^{(k)}) \quad (18)$$

**Sampling  $p_r$ :** Using the fact that  $s_r = \sum_i \tilde{y}_{i_r}$  and marginalizing over the  $u_{i_k r}^{(k)}$ 's in (13), we have  $s_r \sim \text{Pois}(\lambda_r)$ . Using this, along with (5), we can express  $s_r$  using a negative binomial distribution, i.e.,  $s_r \sim \text{NB}(g_r, p_r)$ . Due to the conjugacy between negative binomial and beta, we can then sample  $p_r$  as

$$p_r \sim \text{Beta}(c\epsilon + s_r, c(1 - \epsilon) + g_r) \quad (19)$$

**Sampling  $\lambda_r$ :** Again using the fact that  $s_r \sim \text{Pois}(\lambda_r)$  and (5), we have

$$\lambda_r \sim \text{Gamma}(g_r + s_r, p_r) \quad (20)$$

As can be observed, when updating  $\mathbf{u}_r^{(k)}$ ,  $p_r$  and  $\lambda_r$ , the latent counts  $y_i$ 's and  $\tilde{y}_{i_r}$  corresponding to zero entries in  $\mathcal{B}$  are all equal to zero, and have no contribution to sufficient statistics  $s_{j,r}^{(k)}$  and  $s_r$ . Therefore, only the nonzero entries in tensor need to be considered in the computations.

#### 4.1.2 Tensor with Mode Network(s)

In the presence of mode network(s), the update equations for the latent variables  $p_r$ ,  $\lambda_r$ ,  $\tilde{y}_{i_r}$  and  $y_i$ , that are associated solely with the binary tensor  $\mathcal{B}$ , remain unchanged, and can be sampled as described in Section 4.1.1. We however need to sample the additional latent variables associated with mode- $k$  network  $\mathbf{A}^{(k)}$ , and the latent factors  $\mathbf{u}_r^{(k)}$  of mode- $k$  that are shared by the binary tensor  $\mathcal{B}$  as well as the mode- $k$  network.

**Sampling  $X_{i_k j_k}^{(k)}$ :** The latent counts  $X_{i_k j_k}^{(k)}$  are sampled as

$$X_{i_k j_k}^{(k)} \sim A_{i_k j_k}^{(k)} \cdot \text{Pois}_+(\sum_{r=1}^R \beta_r u_{i_k r}^{(k)} u_{j_k r}^{(k)}) \quad (21)$$

This only needs to be done for the nonzero entries in  $\mathbf{A}^{(k)}$ .

**Sampling  $\tilde{X}_{i_k j_k r}^{(k)}$ :** The latent counts  $\tilde{X}_{i_k j_k r}^{(k)}$  are sampled from a multinomial as equation (16). This also only needs to be done for the nonzero entries in  $\mathbf{A}^{(k)}$ .

**Sampling  $\mathbf{u}_r^{(k)}$ :** The columns of each factor matrix have a Dirichlet posterior, and are sampled as

$$\mathbf{u}_r^{(k)} \sim \text{Dir}(a^{(k)} + s_{1,r}^{(k)} + v_{1,r}, \dots, a^{(k)} + s_{n_k,r}^{(k)} + v_{n_k,r}) \quad (22)$$

Note that in the absence of the mode- $k$  network, the terms  $v_{\cdot,r}$  go away and Eq. 22 simply reduces to Eq. 18.

**Sampling  $h_r$ :**  $h_r \sim \text{Beta}(d\alpha + v_r, d(1 - \alpha) + f_r)$ .

**Sampling  $\beta_r$ :**  $\beta_r \sim \text{Gamma}(f_r + v_r, h_r)$ .

### 4.1.3 Per-iteration time-complexity

For the binary tensor  $\mathcal{B}$ , computing each  $\zeta_{i_r}$  (Eq. 15) takes  $\mathcal{O}(K)$  time and therefore computing all the  $\{\zeta_{i_r}\}$  takes  $\mathcal{O}(\text{nnz}(\mathcal{B})RK)$  time. Likewise, for the binary mode- $k$  network  $\mathbf{A}^{(k)}$ , computing all the  $\{\kappa_{i_k j_k r}^{(k)}\}$  (Eq. 16) takes  $\mathcal{O}(\text{nnz}(\mathbf{A}^{(k)})R)$  time. These are the most dominant computations in each iteration of our MCMC procedure; updating each  $\mathbf{u}_r^{(k)}$  takes  $\mathcal{O}(n_k)$  time and updating  $\{p_r, h_r\}_{r=1}^R$  and  $\{\lambda_r, \beta_r\}_{r=1}^R$  takes  $\mathcal{O}(R)$  time each. Therefore, the per-iteration time-complexity of our batch MCMC method is  $\mathcal{O}(\text{nnz}(\mathcal{B})RK + \text{nnz}(\mathbf{A}^{(k)})R)$ . The linear dependence on  $\text{nnz}(\mathcal{B})$ ,  $\text{nnz}(\mathbf{A}^{(k)})$ ,  $R$  and  $K$  suggests that even massive, sparse binary tensors and mode network(s) can be handled easily even by our simple batch MCMC implementation. Also note that our model scales linearly even w.r.t.  $R$ , unlike most other methods (Ermis and Bouchard, 2014; Rai et al., 2014) that have *quadratic* dependence on  $R$ .

The above computations can be further accelerated using a distributed/multi-core setting; we leave this for future work. In Section 4.2, however, we present an *online* MCMC method based on the idea of Bayesian Conditional Density Filtering (Guhaniyogi et al., 2014), which leads to further speed-ups, even in single-machine settings.

## 4.2 ONLINE MCMC INFERENCE

We develop an efficient online MCMC sampler for the model, leveraging ideas from the Conditional Density Filtering (CDF) Guhaniyogi et al. (2014). The CDF algorithm for our model selects a minibatch of the tensor (and mode network, if the side-information is available) entries at each iteration, samples the model parameters from the posterior, and updates the sufficient statistics  $s_{j,r}^{(k)}$ ,  $s_r$ ,  $v_{i_k,r}$  and  $v_r$  using the data from the current minibatch.

### 4.2.1 Tensor without Mode Network(s)

We first provide the update equations for the case when there is no side-information (mode network). Denote  $I_t$  as indices of entries of tensor  $\mathcal{B}$  from the minibatch selected at iteration  $t$ . The CDF algorithm at iteration  $t$  proceeds as:

**Sampling  $y_i$ :** For all  $i \in I_t$ , sample  $y_i$  according to equation (17); like in the batch MCMC case, the sampling only

needs to be done for the nonzero  $b_i$ 's.

**Sampling  $\tilde{y}_{i_r}$ :** For all  $i \in I_t$ , sample the latent counts  $\tilde{y}_{i_r}(i \in I_t)$  using (15), again only for the nonzero  $b_i$ 's.

**Updating the conditional sufficient statistics:** Update the conditional sufficient statistics  $s_{j,r}^{(k)}$  as  $s_{j,r}^{(k,t)} = s_{j,r}^{(k,t-1)} + \sum_{i \in I_t: i_k=j} \tilde{y}_{i_r}$  and update  $s_r$  as  $s_r^{(t)} = s_r^{(t-1)} + \sum_{i \in I_t} \tilde{y}_{i,r}$ . These updates basically add to the old sufficient statistics, the contributions from the data in the current minibatch. In practice, we also *reweight* these sufficient statistics by the ratio of the total number of ones in  $\mathcal{B}$  and the minibatch size, so that they represent the average statistics over the entire tensor. This reweighting is akin to the way average gradients are computed in stochastic variational inference methods (Hoffman et al., 2013).

**Updating  $\mathbf{u}_r^{(k)}$ ,  $p_r$ ,  $\lambda_r$ :** Using the following conditionals, draw  $M$  samples  $\{\mathbf{u}_r^{(k,m)}, p_r^{(m)}, \lambda_r^{(m)}\}_{m=1}^M$

$$\mathbf{u}_r^{(k)} \sim \text{Dir}(a^{(k)} + s_{1,r}^{(k,t)}, \dots, a^{(k)} + s_{n_k,r}^{(k,t)}) \quad (23)$$

$$p_r \sim \text{Beta}(c\epsilon + s_r^{(t)}, c(1 - \epsilon) + g_r) \quad (24)$$

$$\lambda_r \sim \text{Gamma}(g_r + s_r^{(t)}, p_r) \quad (25)$$

and either store the sample averages of  $\mathbf{u}_r^{(k)}$ ,  $p_r$ , and  $\lambda_r$ , or their analytic means to use for the next CDF iteration (Guhaniyogi et al., 2014).

### 4.2.2 Tensor with Mode Network(s)

For all the latent variables associated solely with the tensor  $\mathcal{B}$ , the sampling equations for the CDF algorithm in the presence of mode network(s) remain unchanged as the previous case with no network. In the presence of the mode network, the additional latent variables include the sufficient statistics  $v_{i_k,r}$  and  $v_r$ , and these need to be updated in each CDF iteration.

Denote  $J_t$  as indices of entries selected from the mode- $k$  network  $\mathbf{A}^{(k)}$  in iteration  $t$ . The update equations for the latent variables that depend on  $\mathbf{A}^{(k)}$  are as follows:

**Sampling  $X_{i_k j_k}$ :** For  $(i_k, j_k) \in J_t$ , latent count  $X_{i_k j_k}$  is sampled using Eq. (21).

**Sampling  $\tilde{X}_{i_k j_k r}$ :** For  $(i_k, j_k) \in J_t$ , latent counts  $\tilde{X}_{i_k j_k r}$  are sampled from a multinomial using Eq. (16).

**Updating the conditional sufficient statistics:** Update the sufficient statistics associated with the mode- $k$  network as  $v_{i_k,r}^{(t)} = v_{i_k,r}^{(t-1)} + \sum_{j_k, (i_k, j_k) \in J_t} \tilde{X}_{i_k j_k r}^{(t)}$  and  $v_r^{(t)} = v_r^{(t-1)} + \sum_{i_k} \sum_{j_k, (i_k, j_k) \in J_t} \tilde{X}_{i_k j_k r}^{(t)}$ . Just like the way we update the tensor sufficient statistics  $s_{j,r}^{(k)}$  and  $s_r$ , we reweight these mode- $k$  sufficient statistics by the ratio of the total number of ones in  $\mathbf{A}^{(k)}$  and the minibatch size, so that they represent the average statistics over the entire mode- $k$  network.

**Updating  $\mathbf{u}_r^{(k)}$ ,  $h_r$ ,  $\beta_r$ :** Using the following condition-

als, draw  $M$  samples  $\{\mathbf{u}_r^{(k,m)}, h_r^{(m)}, \beta_r^{(m)}\}_{m=1}^M$ . We draw  $\mathbf{u}_r^{(k)} \sim \text{Dir}(a^{(k)} + s_{1,r}^{(k,t)} + v_{1,r}^{(t)}, \dots, a^{(k)} + s_{n_k,r}^{(k,t)} + v_{n_k,r}^{(t)})$ , and  $h_r$  and  $\beta_r$  as

$$\begin{aligned} h_r &\sim \text{Beta}(d\alpha + v_r^{(t)}, d(1 - \alpha) + f_r) \\ \beta_r &\sim \text{Gamma}(f_r + v_r^{(t)}, h_r) \end{aligned} \quad (26)$$

and either store the sample averages of  $\mathbf{u}_r^{(k)}$ ,  $h_r$ ,  $\beta_r$ , or their analytic means to use for the next CDF iteration.

### 4.2.3 Per-iteration time-complexity

The per-iteration time-complexity of the CDF based online MCMC is linear in the number of nonzeros in each minibatch (as opposed to the batch MCMC where it depends on the number of nonzeros in the *entire* tensor and network). Therefore the online MCMC is attractive for *dense* binary data, where the number of nonzeros in the tensor/network is also massive; using a big-enough minibatch size (that fits in the main memory and/or can be processed in each iteration in a reasonable amount of time), the online MCMC inference allows applying our model on such dense binary data as well, which may potentially have several billions of nonzero entries.

## 5 RELATED WORK

With the increasing prevalence of structured databases, social networks, and (multi)relational data, tensor decomposition methods are becoming increasingly popular for extracting knowledge and doing predictive analytics on such data (Bordes et al., 2011; Nickel et al., 2012; Kang et al., 2012). As the size of these data sets continues to grow, there has been a pressing need to design tensor factorization methods that can scale to massive tensor data.

For low-rank factorization of *binary* tensors, methods based on logistic and probit likelihood for the binary data have been proposed (Jenatton et al., 2012; London et al., 2013; Rai et al., 2014; Xu et al., 2013). However, these methods are not suited for massive binary tensors where the number of observations (which mostly consist of zeros, if the tensor is also sparse) could easily be millions or even billions (Inah et al., 2015). As a heuristic, these methods rely on subsampling (Rai et al., 2014) or partitioning the tensor (Zhe et al., 2015), to select a manageable number entries before performing the tensor decomposition, or alternatively going for a distributed setting (Zhe et al., 2013).

In the context of tensor factorization, to the best of our knowledge, the only method (and one that is closest in spirit to our work) that scales linearly w.r.t. the number of ones in the tensor is (Ermis and Bouchard, 2014). Their work explored quadratic loss (and its variations) as a surrogate to the logistic loss and proposed a method (Quad-Approx) with a per-iteration complexity  $\mathcal{O}(\text{nnz}(\mathcal{B})R + R^2 \sum_{k=1}^K n_k)$ . Note that its dependence on

$R$  is quadratic as opposed to our method which is also linear in  $R$ . They also proposed variations based on piecewise quadratic approximations; however, as reported in their experiments (Ermis and Bouchard, 2014), these variations were found to be about twice as slow than their basic Quad-Approx method (Ermis and Bouchard, 2014). Moreover, their methods (and the various other methods discussed in this section) have several other key differences from our proposed model: (1) our model naturally imposes non-negativity on the factor matrices; (2)  $R$  can be inferred from data; (3) our method provides a fully Bayesian treatment; (4) in contrast to their method, which operates in a batch setting, the online MCMC inference allows our model to scale to even bigger problems, where the number of nonzeros could also be massive; and (5) our model also allows incorporating (fully or partially observed) mode-networks as a rich source of side-information.
