## Abstract

Learning graphical model parameters from incomplete data is a non-convex optimization problem. Iterative algorithms, such as Expectation Maximization (EM), can be used to get a local optimum solution. However, little is known about the quality of the learned local optimum, compared to the unknown global optimum. We exploit variables that are always observed in the dataset to get an upper bound on the global optimum which can give insight into the quality of the parameters learned by estimation algorithms.

## 1 Introduction

Probabilistic graphical models (PGMs) have been useful to many fields, including computer vision, bioinformatics, natural language processing, and statistical physics; see [20, 32, 17, 22]. A graphical model represents a joint probability distribution compactly using a structure populated with parameters. In this paper, we consider two types of graphical models: Markov Random Fields (MRFs) and Bayesian networks (BNs).

An MRF consists of an undirected graph defining conditional independence relationships between variables, and a factor for every maximal clique in the graph; see [15, 16, 24]. A Bayesian network consists of a directed acyclic graph associated with conditional probability tables; see [4].

Learning graphical model parameters from data is typically reduced to finding the maximum likelihood parameters: ones that maximize the probability of a dataset, due to their attractive statistical properties [6]. However, due to the complexity of learning maximum likelihood parameters, other simplified methods have also been proposed in literature such as pseudo-likelihood [2], ratio matching [10], composite maximum likelihood [30], contrastive divergence [9], and more recently the LAP algorithm [23].

A key distinction is commonly drawn between complete and incomplete datasets. In a complete dataset, the value of each variable is known in every example in the dataset, whereas in an incomplete dataset, some variables may have missing values. Computationally, learning from incomplete data can be much harder than learning from complete data, as we discuss next.

When the data is complete, learning maximum likelihood parameters can be done efficiently in BNs by one pass through the dataset, and by solving a convex optimization problem in MRFs. However, in MRFs, evaluating the objective or computing the gradient requires doing inference, to compute the partition function, which is #P-hard [27]. Iterative algorithms, such as gradient descent [28], conjugate gradient (CG) [8], L-BFGS [21], iterative proportional fitting (IPF) [13], and more recently EDML [25] can be used to get the global optimum solution.

On the other hand, if the data is incomplete, the optimization problem is generally non-convex, i.e. has multiple local optima. Iterative algorithms, such as expectation maximization (EM) [5, 18] and gradient descent can be used to get a local optimum solution; see Chapter 19 in [24]. The fixed points of these algorithms correspond to the stationary points of the likelihood function. Hence, these algorithms are not guaranteed to converge to global optima. As such, they are typically applied to multiple seeds (initial parameter estimates), while retaining the best estimates obtained across all seeds. However, little is known about the quality of the learned estimates, compared to the unknown global optimum.

In this paper, we propose an upper bound on the unknown global optimum that can give insight into the quality of the learned estimates, as compared to the global optimum. It may also help derive branch-and-bound methods to get the global optimum. Our proposed technique exploits variables that are always observed and requires solving a convex optimization problem. In case of BNs, this convex optimization problem can be solved efficiently.

The paper is organized as follows. In Section 2, we de-

fine our notation and give an introduction to the problem of learning graphical model parameters. We propose the MRF and BN upper bounds in Sections 3, and 4, respectively. The experimental results are given in Section 5. We review some of the related work in Section 6, and conclude in Section 7.

## 2 Learning Parameters

In this section, we define our notation, and review how parameter estimation for graphical models is formulated as an optimization problem.

### 2.1 Notation

Upper case letters ( $X$ ) denote variables and lower case letters ( $x$ ) denote their values. Variable sets are denoted by bold-face upper case letters ( $\mathbf{X}$ ) and their instantiations by bold-face lower case letters ( $\mathbf{x}$ ).

We use  $\theta$  to denote the set of all network parameters. Parameter learning in graphical models is the process of estimating these parameters  $\theta$  from a given dataset.

A *dataset* is a multi-set of *examples*. Each example is an instantiation of some network variables. We will use  $\mathcal{D}$  to denote a dataset and  $\mathbf{d}_1, \dots, \mathbf{d}_N$  to denote its  $N$  examples. The following is a dataset over four binary variables:

| example | $E$ | $B$       | $A$       | $C$ |
|---------|-----|-----------|-----------|-----|
| 1       | $e$ | $\bar{b}$ | $a$       | ?   |
| 2       | ?   | $\bar{b}$ | $\bar{a}$ | ?   |
| 3       | $e$ | $\bar{b}$ | $\bar{a}$ | ?   |

This dataset has three examples,  $\mathbf{d}_1$ ,  $\mathbf{d}_2$  and  $\mathbf{d}_3$ . For a binary variable  $X$ , we will use  $x$  and  $\bar{x}$  to denote its two values. Moreover, a “?” indicates a missing value of a variable in an example. The first example above corresponds to instantiation  $e, \bar{b}, a$ , while the second example corresponds to instantiation  $\bar{b}, \bar{a}$ .

A variable  $X$  is *fully observed* in a dataset iff the value of  $X$  is known in each example of the dataset (i.e., “?” cannot appear in the column corresponding to variable  $X$ ). Variables  $A$  and  $B$  are fully observed in the above dataset. Moreover, a variable  $X$  is *hidden* in a dataset iff its value is unknown in every example of the dataset (i.e., only “?” appears in the column of variable  $X$ ). Variable  $C$  is hidden in the above dataset. When all variables are fully observed in a dataset, the dataset is said to be *complete*. Otherwise, the dataset is *incomplete*. The above dataset is incomplete. Finally, we will use  $\mathcal{D}_{\mathbf{O}}$  to denote the dataset which results from removing variables outside  $\mathbf{O}$  from dataset  $\mathcal{D}$ .

### 2.2 Markov Random Fields

An MRF is an undirected graph over variables  $\mathbf{X}$ , populated with factors. The MRF parameters are given by the

vector  $\theta = (\dots, \theta_{\mathbf{X}_f}, \dots)$ , where  $\mathbf{X}_f$  are the variables of factor  $f$ . Component  $\theta_{\mathbf{X}_f}$  is a parameter set for a factor  $f$ , assigning a number  $\theta_{\mathbf{X}_f} > 0$  for each instantiation  $\mathbf{x}_f$  of variable set  $\mathbf{X}_f$ .

Given a dataset  $\mathcal{D}$  with examples  $\mathbf{d}_1, \dots, \mathbf{d}_N$ , the *log likelihood* of parameter estimates  $\theta$  is defined as:

$$\ell\ell(\theta|\mathcal{D}) = \sum_{i=1}^N \log Z_{\theta}(\mathbf{d}_i) - N \log Z_{\theta}. \quad (1)$$

Here,  $Z_{\theta}$  is the partition function,  $Z_{\theta} = \sum_{\mathbf{x}} \prod_f \theta_{\mathbf{x}_f}$  and  $Z_{\theta}(\mathbf{d}_i) = \sum_{\mathbf{x} \sim \mathbf{d}_i} \prod_f \theta_{\mathbf{x}_f}$  ( $\mathbf{d}_i \sim \mathbf{x}$  means that instantiations  $\mathbf{d}_i$  and  $\mathbf{x}$  are compatible). For simplicity, we will assume a tabular representation of factors as opposed to an exponential representation as given in [24, Chapter 19]. In our experiments, however, we use the exponential representation to avoid the need for explicit non-negativity constraints.

The first term in Equation 1 is called the data term, whereas the second term is called the model term. If the data is complete, Equation 1 can be formulated as a convex optimization problem, and the data term becomes trivial to evaluate. However, when the data is incomplete, Equation 1 is non-convex.

### 2.3 Bayesian Networks

A Bayesian network is a directed acyclic graph populated with conditional probability tables (CPTs). Generally, we will use  $X$  to denote a variable in a Bayesian network and  $\mathbf{U}$  to denote its parents. For every variable instantiation  $x$  and parent instantiation  $\mathbf{u}$ , the Bayesian network includes a parameter  $\theta_{x|\mathbf{u}}$  that represents the probability  $Pr(X=x|\mathbf{U}=\mathbf{u})$ . This implies the requirement that  $\sum_x \theta_{x|\mathbf{u}} = 1$ , for each parent instantiation  $\mathbf{u}$ .

Given a dataset  $\mathcal{D}$  with examples  $\mathbf{d}_1, \dots, \mathbf{d}_N$ , the *log likelihood* of parameter estimates  $\theta$  is defined as:

$$\ell\ell(\theta|\mathcal{D}) = \sum_{i=1}^N \log Pr_{\theta}(\mathbf{d}_i).$$

Here,  $Pr_{\theta}$  is the distribution induced by the network structure and parameters  $\theta$ . One typically seeks maximum likelihood parameters

$$\theta^* = \underset{\theta}{\operatorname{argmax}} \ell\ell(\theta|\mathcal{D}).$$

It is not uncommon to also assume a Dirichlet prior on network parameters. In particular, for each variable  $X$  with values  $x_1, \dots, x_n$ , and parent instantiation  $\mathbf{u}$ , a Dirichlet prior is specified using exponents  $\psi_{x_1|\mathbf{u}}, \dots, \psi_{x_n|\mathbf{u}}$ . This prior induces a density  $\propto \prod_{i=1}^n [\theta_{x_i|\mathbf{u}}]^{\psi_{x_i|\mathbf{u}} - 1}$  over the parameters  $\theta_{x_1|\mathbf{u}}, \dots, \theta_{x_n|\mathbf{u}}$  of variable  $X$  given parent instantiation  $\mathbf{u}$ . It is also common to assume that exponents are  $> 1$ , which guarantees a unimodal density. With

Figure 1: Auxiliary MRF graph under fully observed variables  $\mathbf{O} = \{O_1, O_2\}$ .

Figure 2: Auxiliary MRF graph under fully observed variables  $\mathbf{O} = \{O_1, O_2, O_3\}$ .

Dirichlet priors, the objective function becomes

$$\ell\ell(\theta|\mathcal{D}) + \log \rho(\theta).$$

Here,  $\rho(\theta)$  is proportional to the prior density on parameters  $\theta$ , and is given by

$$\rho(\theta) = \prod_{X \mathbf{u}} \prod_x [\theta_{x|\mathbf{u}}]^{\psi_{x|\mathbf{u}} - 1}.$$

Parameters that optimize the above objective function are called MAP estimates as they maximize the posterior density of the parameters given the dataset.

When every exponent  $\psi_{x|\mathbf{u}}$  is equal to 1 (uninformative prior), we get  $\rho(\theta) = 1$  and MAP estimates reduce to maximum likelihood estimates. Moreover, when every exponent  $\psi_{x|\mathbf{u}}$  is equal to 2, MAP estimates reduce to maximum likelihood estimates with Laplace smoothing. This is a common technique to deal with the problem of insufficient counts (i.e., instantiations that never appear in the dataset, leading to zero probabilities and division by zero). We will use Laplace smoothing in our experiments.

### 3 An Upper Bound for MRFs

In this section, we utilize variables that are always observed in a dataset to obtain an upper bound on the likelihood. The bound is obtained by solving a convex optimization problem over an auxiliary MRF, which is defined next.

#### 3.1 Decomposition

The auxiliary MRF is obtained by first decomposing the MRF graph  $G$  using variables  $\mathbf{O}$  that are fully observed in the dataset.

Figure 3: Auxiliary MRF graph under fully observed variables  $\mathbf{O} = \{O_1, O_2, O_3\}$ .

**Definition 1** Let  $G|\mathbf{O}$  be the result of deleting variables  $\mathbf{O}$  from graph  $G$ . A component of  $G|\mathbf{O}$  is a maximal set of nodes  $\mathbf{S}$  that are connected in  $G|\mathbf{O}$ . A variable  $B$  is a boundary for component  $\mathbf{S}$  iff edge  $B - S$  appears in  $G$ ,  $B \notin \mathbf{S}$  and  $S \in \mathbf{S}$ .

Boundary variables must be included in  $\mathbf{O}$ . Moreover, component variables cannot intersect with  $\mathbf{O}$ . Figures 1–3 depict the components and boundaries of some MRF graphs.

We are now ready to define the auxiliary MRF by defining its graph. The auxiliary MRF will then have one factor over each maximal clique of this graph.

**Definition 2** The auxiliary graph for graph  $G$  and variables  $\mathbf{O}$  is denoted  $A_{G|\mathbf{O}}$  and defined as follows: (1) The nodes of  $A_{G|\mathbf{O}}$  are the variables  $\mathbf{O}$ ; (2)  $A_{G|\mathbf{O}}$  has an edge  $X - Y$  iff the edge exists in  $G$  or  $X$  and  $Y$  are boundary variables of some component of  $G|\mathbf{O}$ .

Figures 1–3(c) depict some auxiliary MRF graphs.

#### 3.2 Optimization

We will next use the auxiliary MRF graph to formulate a convex optimization problem, called the auxiliary problem. The solution of this auxiliary problem will provide an upper bound on the likelihood.

**Definition 3** Given an MRF graph  $G$ , and a corresponding dataset  $\mathcal{D}$  with fully observed variables  $\mathbf{O}$ , the auxiliary optimization problem is that of learning the parameters of auxiliary MRF  $A_{G|\mathbf{O}}$  from dataset  $\mathcal{D}_{\mathbf{O}}$ .

The auxiliary optimization problem is always convex. This follows since the graph  $A_{G|\mathbf{O}}$  contains only variables  $\mathbf{O}$ , which are fully observed in the dataset  $\mathcal{D}$ . Hence, the auxiliary optimization problem corresponds to learning the parameters of an MRF under complete data ( $\mathcal{D}_{\mathbf{O}}$  is a complete dataset in this case).

The following theorem shows that the solution of the convex optimization problem provides an upper bound on the likelihood.

**Theorem 1** Let  $G$  be an MRF graph and  $\mathcal{D}$  be a corre-

sponding dataset with fully observed variables  $\mathbf{O}$ . Let  $f(\theta)$  be the likelihood function for MRF graph  $G$ , and let  $g(\theta)$  be the likelihood function for its auxiliary MRF graph  $A_{G|\mathbf{O}}$ . We then have  $f(\theta) \leq g(\theta^*)$ , where  $\theta^*$  is the global optimum for  $g(\theta)$ .

**Proof** Let  $F_1(\mathbf{X}_1), \dots, F_n(\mathbf{X}_n)$  be the factors of auxiliary MRF  $A_{G|\mathbf{O}}$ , representing parameters  $\theta$  (i.e., each  $F_j(\mathbf{x}_j)$  is a parameter in  $\theta$ ). Note that  $\mathbf{X}_j$  is a maximal clique of the auxiliary graph and  $\mathbf{X}_j \subseteq \mathbf{O}$ . Let the dataset  $\mathcal{D}$  be  $\{\mathbf{d}_1, \dots, \mathbf{d}_N\}$ . The convex optimization problem  $g(\theta)$  is then

$$\text{maximize } g(\theta) = \sum_{i=1}^N \log Z_{\theta}(\mathbf{d}_i) - N \log Z_{\theta} \quad (2)$$

where

$$Z_{\theta} = \sum_{\mathbf{o}} \prod_{j=1}^n F_j(\mathbf{x}_j), \quad \mathbf{x}_j \sim \mathbf{o} \quad (3)$$

$$Z_{\theta}(\mathbf{d}_i) = \prod_{j=1}^n F_j(\mathbf{x}_j), \quad \mathbf{x}_j \sim \mathbf{d}_i \quad (4)$$

We will now expand the above equations for optimizing the auxiliary likelihood  $g(\theta)$  so we can optimize the original likelihood  $f(\theta)$ . The basic observation is that  $f(\theta)$  can be written in terms of marginals over the fully observed variables. However, these marginals are not free to take any values, as they have to correspond to some original parameters that realize such marginals. Hence, we must constrain these marginals, which correspond to auxiliary parameters  $F_i(\mathbf{x}_i)$ , in terms of the original parameters. We do this next.

First, note that for each factor  $f_k(\mathbf{Y}_k)$  of the original MRF  $G$ , there is some factor  $F_j(\mathbf{X}_j)$  of the auxiliary MRF, such that  $\mathbf{Y}_k \cap \mathbf{O} \subseteq \mathbf{X}_j$ . We will therefore assign each original factor  $f_k$  to a corresponding auxiliary factor  $F_j$ , writing  $f_k^j$  to denote this assignment.

Next, for each auxiliary factor  $F_j(\mathbf{X}_j)$ , let  $\mathbf{Z}_j$  be the variables appearing in original factors  $f_k^j$ , but not in the auxiliary factor  $F_j$ . Consider now the following equation, which defines auxiliary parameters  $F_j(\mathbf{x}_j)$  in terms of original parameters  $f_k^j(\mathbf{y}_k)$ :

$$F_j(\mathbf{x}_j) = \sum_{\mathbf{z}_j} \prod_k f_k^j(\mathbf{y}_k), \quad \mathbf{y}_k \sim \mathbf{x}_j \mathbf{z}_j \quad (5)$$

The original optimization problem  $f(\theta)$  can now be defined using Equations 2, 3 and 4, subject to the equality constraints of Equation 5 (i.e., we are now optimizing the original parameters  $f_k^j(\mathbf{y}_k)$ ). By relaxing these equality constraints, and optimizing over the auxiliary parameters  $F_j(\mathbf{x}_j)$ , we get back the auxiliary optimization problem. Since the latter is obtained by relaxing constraints, we have  $f(\theta) \leq g(\theta^*)$ .  $\square$

Figure 4: A chain MRF with alternating fully observed variables, and its corresponding auxiliary MRF.

Figure 5: A binary tree MRF with alternating fully observed levels, and its corresponding auxiliary MRF.

Note that when all variables are fully observed in the dataset  $\mathcal{D}$  (i.e., the dataset is complete), the auxiliary MRF graph corresponds to the original MRF graph, and the bound becomes exact.

### 3.3 Computing the Bound

The proposed upper bound can be computed using standard methods for estimating parameters under complete data. These methods require inference on the auxiliary MRF, whose complexity depends on the treewidth of its underlying graph. This treewidth can be larger or smaller than the treewidth of the original MRF, depending on the patterns of data incompleteness. We will illustrate this next using a set of examples, in which fully observed nodes are shaded, while hidden nodes are left unshaded.

Figures 4 and 5 show MRFs of bounded treewidth and certain patterns of data incompleteness that lead to auxiliary MRFs with bounded treewidth. In particular, Figure 4 shows a chain with alternating fully observed and hidden variables, which results in an auxiliary MRF with treewidth 1, regardless of the chain length. Figure 5 shows a complete binary tree with alternating fully observed levels, leading to an auxiliary MRF with treewidth 2, regardless of the tree depth.

Figure 6 shows an example where the auxiliary MRF has a lower treewidth. However, Figure 7 shows an  $n \times n$  grid, leading to an auxiliary MRF with treewidth  $2n - 1$ . Similarly, Figure 8 shows an MRF with treewidth 1, yet an auxiliary MRF of treewidth  $n$ .

Figure 6: An MRF structure that leads to an auxiliary MRF of lower treewidth.

Figure 7: A grid with alternating fully observed rows, and its corresponding auxiliary MRF.

#### 4 An Upper Bound for Bayesian Networks

We now present a similar upper bound on the likelihood function for a Bayesian network structure  $G$ . Again, the bound is defined based on the set of fully observed variables  $\mathbf{O}$  in a dataset.

**Definition 4 ([26])** Let  $G|\mathbf{O}$  be the result of deleting edges in DAG  $G$  that are outgoing from variables  $\mathbf{O}$ . A component of  $G|\mathbf{O}$  is a maximal set of variables  $\mathbf{S}$  that are connected in  $G|\mathbf{O}$ . A variable  $B$  is a boundary for component  $\mathbf{S}$  iff edge  $B \rightarrow S$  appears in  $G$ ,  $B \notin \mathbf{S}$  and  $S \in \mathbf{S}$ .

Figure 9 depicts an example DAG with its components and boundaries. Note that the boundary variables  $\mathbf{B}$  of a component must all be fully observed,  $\mathbf{B} \subseteq \mathbf{O}$ . Moreover, for any component  $\mathbf{S}$ , the variables  $\mathbf{S} \cap \mathbf{O}$  must be leaf nodes in  $G|\mathbf{O}$ .

We will next interpret the boundary variables  $\mathbf{B}$  of each component  $\mathbf{S}$  as the parents of observed variables in component  $\mathbf{S}$ . This interpretation will be used to define an auxiliary distribution over the fully observed variables.

**Definition 5** The auxiliary distribution for DAG  $G$  and variables  $\mathbf{O}$  is denoted  $P_{G|\mathbf{O}}$  and defined as follows: (1)  $P_{G|\mathbf{O}}$  is over the variables  $\mathbf{O}$ , (2)  $P_{G|\mathbf{O}}$  is the product of factors  $Pr(\mathbf{L}|\mathbf{B})$ , where  $\mathbf{B}$  is the boundary variables of some component  $\mathbf{S}$  and  $\mathbf{L} = \mathbf{S} \cap \mathbf{O}$ .

Figure 8: An MRF structure with treewidth 1, and its corresponding auxiliary MRF of treewidth  $n$ .

Figure 9: A DAG and its components under fully observed variables  $\mathbf{O} = \{V, X, Z\}$ .

Each probability  $Pr(\mathbf{l}|\mathbf{b})$  will be interpreted as an auxiliary parameter  $\theta_{\mathbf{l}|\mathbf{b}}$ . We can now state our upper bound.

**Theorem 2** Let  $G$  be a DAG and  $\mathcal{D}$  be a corresponding dataset with fully observed variables  $\mathbf{O}$ . Let  $f(\theta)$  be the likelihood function for  $G$  and  $\mathcal{D}$ , and let  $g(\theta)$  be the likelihood function for the auxiliary distribution  $P_{G|\mathbf{O}}$ . We then have  $f(\theta) \leq g(\theta^*)$ , where  $\theta^*$  is the global optimum for  $g(\theta)$ .

**Proof** We now sketch the proof of this theorem, which is similar to the one for MRFs. That is, we express auxiliary parameters in terms of original parameters, allowing us to formulate the original optimization problem as an optimization problem with non-convex equality constraints (which relate auxiliary and original parameters). By relaxing these equality constraints, we obtain a convex optimization problem that provides an upper bound on the original optimization problem. Hence, it suffices to show the non-convex equality constraints in this case.

Consider a factor  $Pr(\mathbf{X}|\mathbf{U})$  of the auxiliary distribution, and the corresponding parameters  $\theta_{\mathbf{x}|\mathbf{u}}$ . Variables  $\mathbf{X}$  must then be leaves of some component  $\mathbf{S}$  in  $G|\mathbf{O}$ , and  $\mathbf{U}$  must correspond to the boundary variables of component  $\mathbf{S}$ . One can then express each auxiliary parameter  $\theta_{\mathbf{x}|\mathbf{u}}$  in terms of original parameters that pertain only to the variables in component  $\mathbf{S}$ . In particular, let  $Pr(\cdot)$  be the distribution induced by the original DAG  $G$  and let  $\mathbf{y}$  be an instantiation of variables  $\mathbf{S} \setminus \mathbf{X}$ . We then have  $Pr(\mathbf{x}|\mathbf{u}) = \sum_{\mathbf{y}} Pr(\mathbf{x}, \mathbf{y}|\mathbf{u})$ . Moreover,  $Pr(\mathbf{x}, \mathbf{y}|\mathbf{u})$  can be expressed in terms of original parameters pertaining only to variables  $\mathbf{S}$ . This follows since, given  $\mathbf{U}$ ,  $\mathbf{S}$  is independent of all other variables in DAG  $G$ .  $\square$

One difference from the upper bound for MRFs is that this bound can be computed more efficiently. In particular, the optimal estimate  $\theta^*$  can be identified using a single pass through the dataset  $\mathcal{D}_{\mathbf{O}}$ . Similarly,  $g(\theta^*)$  can be computed using a single pass through the dataset, once the estimate  $\theta^*$  is identified.

## 5 Experimental Results

Our experiments are structured as follows. Given a network  $G$ , we generate a dataset  $\mathcal{D}$  while ensuring that a certain percentage of variables are fully observed, with all others hidden. Using dataset  $\mathcal{D}$ , we estimate the parameters of network  $G$  using EM.

We compare the local optimum learned by EM, to the proposed bound gotten using decomposition, and to the bound that assumes all distributions are valid (which we call the naive bound).

The naive bound is computed by discarding the graph structure and assigning a probability to every data example based on its number of occurrences in the dataset. This effectively assumes a fully connected graph. Consider, for example, a simple dataset with a data example  $\mathbf{d}_1$  that is repeated twice and another  $\mathbf{d}_2$  that is repeated 3 times. The naive bound assigns a probability  $\frac{2}{5}$  to  $\mathbf{d}_1$ , and  $\frac{3}{5}$  to  $\mathbf{d}_2$ , and computes the likelihood:  $(\frac{2}{5})^2 \times (\frac{3}{5})^3$ .

Before we present our results, we have the following observations on our data generation model. First, we made all unobserved variables hidden (as opposed to missing at random) as this leads to a more difficult learning problem, especially for EM. Second, it is not uncommon to have a significant number of variables that are always observed in real-world datasets. For example, in the UCI repository: the internet advertisements dataset has 1558 variables, only 3 of which have missing values; the automobile dataset has 26 variables, where 7 have missing values; the dermatology dataset has 34 variables, where only age can be missing; and the mushroom dataset has 22 variables, where only one variable has missing values [1].

In our experiments, we use the following networks: alarm, andes, asia, win95pts, diagnose, pigs, spect, water, together with chains, trees, and grids. Network win95pts (76 variables) is an expert system for printer troubleshooting in Windows 95, whereas Network pigs is used for diagnosing the PSE disease. Network andes is an intelligent tutoring system. Network diagnose is from the UAI 2008 evaluation. Network spect is a naive Bayes network induced from a dataset in the UCI ML repository, with 1 class variable and 22 attributes. Chains, trees, and grids are randomly generated networks. The other networks are commonly used benchmarks.

Figures from 10 to 25 show the objective function values gotten by EM for different benchmarks and for different percentages of fully observed variables, together with the proposed bound (decomposition bound), and the naive bound. We have the following observations on the results.

In most cases, our proposed bound was much tighter than the naive bound. One can also see that the proposed bound coincides (or almost coincides) with the EM’s curve in Fig-

Figure 10: Upper bound for network Alarm.

ures 11, 15, 18, 19, 20, 21, 22, 23, 24, and 25. This shows that the bound can be tight in many cases. When the bound coincides with the EM curve, it provides a certificate that EM is getting the global optimum in these cases.

Moreover, in Figures 10, 14, and 17, as the number of fully observed variables increases, the gap between the proposed bound and EM’s curve tends to shrink, which suggests that the bound becomes tight and that EM gets close to the global optimum in these cases. On the other hand, for cases where the proposed bound was not close to the EM’s curve, it could be that EM is getting a local optimum, or the bound is not tight, in these cases.

Furthermore, we note that the excellent performance of the upper bound on Network Spect in Figure 15, and on tree networks in Figures 20, 21, and 22 is partially because hidden variables associated with leaf nodes in these networks can be ignored from the computation of the likelihood, as their values are summed out.

We finally conduct an experiment to see how often EM approaches the bound if started from different seeds; using a  $3 \times 3$  grid while fully observing 50% of the variables. Figure 26 shows the difference in likelihood between the upper bound and EM for this benchmark, when started from different seeds (x-axis). One can see that EM gets close to the bound in many cases for this benchmark. We note, however, that a more comprehensive study is needed for assessing the quality of EM estimates under different seeds—a study that can be significantly aided by the proposed upper bound.

## 6 Related Work

Decomposing Bayesian networks based on fully observed variables was proposed in [26] to speed-up parameter estimation. Our bound relies on this decomposition as a first step in formulating the auxiliary optimization problem.

Variational methods (see [14]) can provide lower bounds on the likelihood in graphical models. Moreover, an upper bound for the likelihood in the context of Gaussian mixtures was proposed in [3]. However, this bound only works

asymptotically. An upper bound on maximum likelihood that only works for phylogenetic trees was proposed in [7]. Techniques for computing upper and lower bounds on likelihoods in sigmoid and noisy-OR networks were proposed in [12].

Some work also exists for obtaining upper and lower bounds on the partition function. In particular, mean field theory, e.g. [33, 14], provides such a lower bound (tighter bounds have also been derived [19]). In contrast, upper bounds are not widely available [31]. For the special case of the Ising Model, a recursive procedure was proposed for upper bounding the log partition function [11]. An upper bound on the partition function of an arbitrary MRF was proposed in [31] based on solving a convex variational problem. While bounds on the partition function can be used to get an upper bound on the likelihood, the non-convex term related to the data remains non-convex, which does not make the bound easy to compute. The bound we proposed, however, is based on solving a convex optimization problem.

## 7 Conclusion

We proposed a technique for obtaining an upper bound on the global optimum in parameter estimation. The technique applies to incomplete datasets and exploits variables that are always observed in the dataset. The bound is computed by solving a convex optimization problem, which can be solved by a single pass through the dataset in Bayesian networks. The proposed bound can be useful in providing a certificate of global optimality for parameters learned by estimation algorithms. Empirically, we showed that the bound can be tight, and can be used to show that an estimation algorithm is obtaining the global optimum or an estimate that is very close to the optimum.

## Abstract

A variety of advanced statistics are used to evaluate player actions in the National Hockey League, but they fail to account for the context in which an action occurs or to look ahead to the long-term effects of an action. We apply the Markov Game formalism to develop a novel approach to valuing player actions in ice hockey that incorporates context and lookahead. Dynamic programming is used to learn Q-functions that quantify the impact of actions on goal scoring resp. penalties. Learning is based on a massive dataset that contains over 2.8M events in the National Hockey League. The impact of player actions is found to vary widely depending on the context, with possible positive and negative effects for the same action. We show that lookahead makes a substantial difference to the action impact scores. Players are ranked according to the aggregate impact of their actions. We compare this impact ranking with previous player metrics, such as plus-minus, total points, and salary.

## 1 INTRODUCTION

A fundamental goal of sports statistics is to understand which actions contribute to winning in what situation. As sports have entered the world of big data, there is increasing opportunity for large-scale machine learning to model complex sports dynamics. The research described in this paper applies AI techniques to model the dynamics of ice hockey; specifically the Markov Game model formalism [Littman, 1994], and related computational techniques such as the dynamic programming value iteration algorithm. We make use of a massive dataset about matches in the National Hockey League (NHL). This dataset comprises all play-by-play events from 2007 to 2014, for a total of over 2.8M events/actions and almost 600K play sequences. The

Markov Game model comprises over 1.3M states. Whereas most previous works on Markov Game models aim to compute optimal strategies or policies [Littman, 1994] (i.e., minimax or equilibrium strategies), we learn a model of how hockey is actually played, and do not aim to compute optimal strategies. In reinforcement learning (RL) terminology, we use dynamic programming to compute an *action-value* Q-function in the *on policy* setting [Sutton and Barto, 1998]. In RL notation, the expression  $Q(s, a)$  denotes the expected reward of taking action  $a$  in state  $s$ .

**Motivation** Motivation for learning a Q-function for NHL hockey dynamics includes the following.

*Knowledge Discovery.* The Markov Game model provides information about the likely consequences of actions. The basic model and algorithms can easily be adapted to study different outcomes of interest, such as goals and penalties.

*Player Evaluation.* One of the main tasks for sports statistics is evaluating the performance of players [Schumaker et al., 2010]. A common approach is to assign action values, and sum the corresponding values each time a player takes the respective action. An advantage of this additive approach is that it provides highly interpretable player rankings. A simple and widely used example in ice hockey is the +/- score: for each goal scored by (against) a player's team when he is on the ice, add +1 (-1) point. Researchers have developed several extensions of +/- for hockey [Macdonald, 2011; Spagnola, 2013; Schuckers and Curro, 2013].

There are two major problems with the previous action count approaches used in ice hockey. (1) They are unaware of the *context* of actions within a game. For example, a goal is more valuable in a tied-game situation than when the scorer's team is already four goals ahead [Pettigrew, 2015]. Another example is that if a team manages two successive shots on goal, the second attempt typically has a higher chance of success. In the Markov Game model,  $context = state$ . Formally, the Q function depends *both* on the state  $s$  and the action  $a$ . Richer state spaces therefore capture more of the context of an action. (2) Previous ac-

tion scores are based on immediate positive consequences of an action (e.g. goals following a shot). However, an action may have medium-term and/or ripple effects rather than immediate consequences in terms of visible rewards like goals. Therefore evaluating the impact of an action requires *lookahead*. Long-term lookahead is especially important in ice hockey because evident rewards like goals occur infrequently [Lock and Schuckers, 2009]. For example, if a player receives a penalty, this leads to a manpower disadvantage for his team, known as a powerplay for the other team. It is easier to score a goal during a powerplay, but this does not mean that a goal will be scored immediately after the penalty. For another example, if a team loses the puck in their offensive zone, the resulting counterattack by the other team may lead to a goal eventually but not immediately. The dynamic programming value iteration algorithm of Markov Decision Processes provides a computationally efficient way to perform unbounded lookahead.

**Evaluation** Our evaluation learns Q-functions for two reward events, scoring the next goal and receiving the next penalty. We observe a wide variance of the impact of actions with respect to states, showing context makes a substantial difference. We provide examples of the context dependence to give a qualitative sense of how the Markov Game model accounts for context. To evaluate player performance, we use the Q-function to quantify the value of a player’s action in a context. The action values are then aggregated over games and seasons to get player impact scores. Player impact scores correlate with plausible alternative scores, such as a player’s total points, but improve on these measures, as our impact score is based on many more events.

**Contributions** We make our extensive dataset available on-line, in addition to our code and the learned Markov game model [Routley et al., 2015]. The main contributions of this paper may be summarized as follows:

1. The first Markov Game model for a large ice hockey state space (over 1.3M), based on play sequence data.
2. Learning a Q-function that models play dynamics in the National Hockey League from a massive data set (2.8M events). We introduce a variant of AD-Trees as a data structure to (1) compute and store the large number of sufficient statistics required [Moore and Lee, 1998], and (2) support value iteration updates.
3. Applying the Q-function to define a context-aware look-ahead measure of the value of an action, over configurable objective functions (rewards).
4. Applying the context-aware action values to score hockey player actions, including how players affect penalties as well as goals.

**Paper Organization.** We review related work in measuring player contributions and machine learning in sports in Section 2. We then give some background information on the ice hockey domain and NHL play-by-play sequences data. Our Markov Game model translates the hockey domain features into the Markov formalism. We describe how we implement a scalable value iteration for the ice hockey domain. The evaluation section addresses the impact of context and lookahead. We apply the model to rank the aggregate performance of players and describe the resulting player ranking. We view our work as taking the first step, not the last, in applying AI modelling techniques to ice hockey. Therefore, we conclude with a number of potential extensions and open problems for future work.

## 2 RELATED WORK

**Evaluating Actions and Players in Ice Hockey** Several papers aim to improve the basic +/- score with statistical techniques [Macdonald, 2011; Gramacy et al., 2013; Spagnola, 2013]. A common approach is to use regression techniques where an indicator variable for each player is used as a regressor for a goal-related quantity (e.g., log-odds of a goal for the player’s team vs. the opposing team). The regression weight measures the extent to which the presence of a player contributes to goals for his team or prevents goals for the other team. These approaches look at only goals, no other actions. The only context they take into account is which players are on the ice when a goal is scored. Regression could be combined with our Markov game model to capture how team impact scores depend on the presence or absence of individual players.

The closest predecessor to our work in ice hockey is the Total Hockey Rating (THoR) [Schuckers and Curro, 2013]. This assigns a value to all actions, not only goals. Actions were evaluated based on whether or not a goal occurred in the following 20 seconds after an action. This work used data from the 2006/2007 NHL season only. THoR assumes a fixed value for every action and does not account for the context in which an action takes place. Furthermore, the window of 20 seconds restricts the lookahead value of each action. Our Q-learning method is not restricted to any particular time window for lookahead.

**Expected Possession Value** [Cervone et al., 2014] uses spatial-temporal tracking data for basketball to build the POINTWISE model for valuing player decisions and player actions. Conceptually, their approach to defining action values is the closest predecessor to ours: The counterpart to the value of a state in a Markov game is called expected possession value (EPV). The counterpart to the impact of an action on this value is called EPV-added (EPVA). Cervone *et al.* emphasize the broad potential of the context-based impact definitions: “we assert that most questions that coaches, players, and fans have about basketball, par-

ticularly those that involve the offense, can be phrased and answered in terms of EPV.”

While the definition of action impact is conceptually very similar, Cervone et al. use neither AI terminology nor AI techniques, which we cover in this paper. Moreover, all the underlying details are different between our model and theirs: The NHL does not yet have and therefore we do not use spatial tracking data, which is the main focus of Cervone et al.. Cervone et al. discuss the advantages of using a discrete state space for stochastic consistency, but consider it computationally infeasible for their data. We show that leveraging AI data structures and algorithms makes handling a large discrete state space feasible for ice hockey. Including the local action history in the state space allows us to capture the medium-term effects of actions. This is more important for ice hockey than for basketball, because scoring in basketball occurs at much shorter intervals.

**Markov Decision Process Models for Other Sports** MDP-type models have been applied in a number of sports settings, such as baseball, soccer and football. For review, please see Cervone et al. [2014]. Our work is similar in that our method uses value iteration on a Markovian state space, however, previous Markov models in sports use a much smaller state space. The goal of these models is to find an optimal policy for a critical situation in a sport or game. In contrast, we learn in the on-policy setting whose aim is to model hockey dynamics as it is actually played.

### 3 DOMAIN DESCRIPTION: HOCKEY RULES AND HOCKEY DATA

We outline the rules of hockey and describe the dataset available from the NHL.

#### 3.1 HOCKEY RULES

We give a brief overview of rules of play in the NHL [National Hockey League, 2014]. NHL games consist of three periods, each 20 minutes in duration. A team has to score more goals than their opponent within three periods in order to win the game. If the game is still tied after three periods, the teams will enter a fourth overtime period, where the first team to score a goal wins the game. If the game is still tied after overtime during the regular season, a shootout will commence. During the playoffs, overtime periods are repeated until a team scores a goal to win the game. Teams have five skaters and one goalie on the ice during even strength situations. Penalties result in a player sitting in the penalty box for two, four, or five minutes and the penalized team will be shorthanded, creating a manpower differential between the two teams. The period where one team is penalized is called a powerplay for the opposing team with a manpower advantage. A shorthanded

goal is a goal scored by the penalized team, and a powerplay goal is a goal scored by the team on the powerplay.

#### 3.2 DATA FORMAT

The NHL provides information about sequences of play-by-play events, which are scraped from <http://www.nhl.com> and stored in a relational database. The real-world dataset is formed from 2,827,467 play-by-play events recorded by the NHL for the complete 2007-2014 seasons, regular season and playoff games, and the first 512 games of the 2014-2015 regular season. A breakdown of this dataset is shown in Table 1. The type of events recorded by the NHL from the 2007-2008 regular season and onwards are listed in Table 2. There are two types of events: actions performed by players and start and end markers for each play sequence. Every event is marked with a continuous timestamp, and every action is also marked with a zone  $Z$  and which team, Home or Away, carries out the action.

Table 1: Size of Dataset

|                            |           |
|----------------------------|-----------|
| <b>Number of Teams</b>     | 32        |
| <b>Number of Players</b>   | 1,951     |
| <b>Number of Games</b>     | 9,220     |
| <b>Number of Sequences</b> | 590,924   |
| <b>Number of Events</b>    | 2,827,467 |

Table 2: NHL Play-By-Play Events Recorded

| <b>Action Event</b> | <b>Start/End Event</b>   |
|---------------------|--------------------------|
| Faceoff             | Period Start             |
| Shot                | Period End               |
| Missed Shot         | Early Intermission Start |
| Blocked Shot        | Penalty                  |
| Takeaway            | Stoppage                 |
| Giveaway            | Shootout Completed       |
| Hit                 | Game End                 |
| Goal                | Game Off                 |
|                     | Early Intermission End   |

### 4 MARKOV GAMES

A Markov Game [Littman, 1994], sometimes called a stochastic game, is defined by a set of states,  $S$ , and a collection of action sets, one for each agent in the environment. State transitions are controlled by the current state and one action from each agent. For each agent, there is an associated reward function mapping a state transition to a reward. An overview of how our Markov Game model fills in this schema is as follows. There are two players, the Home Team  $H$  and the Away Team  $A$ . In each state,

only one team performs an action, although not in a turn-based sequence. This reflects the way the NHL records actions. Thus at each state of the Markov Game, exactly one player chooses No-operation. State transitions follow a semi-episodic model [Sutton and Barto, 1998] where play moves from episode to episode, and information from past episodes is recorded as a list of *context features*. The past information includes the goal score and manpower. A sequence in the NHL play-by-play data corresponds to an episode in Markov decision process terminology. *Within* each episode/sequence, our game model corresponds to a game tree with perfect information as used in AI game research [Russell and Norvig, 2010]. We introduce the following generic notation for all states, following [Russell and Norvig, 2010; Littman, 1994].

- $Occ(s)$  is the number of occurrences of state  $s$  as observed in the play-by-play data.
- $Occ(s, s')$  is the number of occurrences of state  $s$  being immediately followed by state  $s'$  as observed in the play-by-play data.  $(s, s')$  forms an edge in the transition graph of the Markov Game model.
- The transition probability function  $TP$  is a mapping of  $S \times S \rightarrow (0, 1]$ . We estimate it using the observed transition frequency  $\frac{Occ(s, s')}{Occ(s)}$ .

We begin by defining context features, then play sequences.

#### 4.1 STATE SPACE: CONTEXT FEATURES

Previous work on Markov process models for ice hockey [Thomas et al., 2013] defined states in terms of hand-selected features that are intuitively relevant for the game dynamics, such as the goal differential and penalties. We refer to such features as **context features**. Context features remain the same throughout each play sequence.

Table 3: Context Features

| Notation | Name                  | Range     |
|----------|-----------------------|-----------|
| $GD$     | Goal Differential     | $[-8, 8]$ |
| $MD$     | Manpower Differential | $[-3, 3]$ |
| $P$      | Period                | $[1, 7]$  |

A **context state** lists the values of relevant features at a point in the game. These features are shown in Table 3, together with the range of integer values observed. Goal Differential  $GD$  is calculated as Number of Home Goals - Number of Away Goals. A positive (negative) goal differential means the home team is leading (trailing). Manpower Differential  $MD$  is calculated as Number of Home Skaters on Ice - Number of Away Skaters on Ice. A positive manpower differential typically means the home team

is on the powerplay (away team is penalized), and a negative manpower differential typically means the home team is shorthanded (away team is on the powerplay).<sup>1</sup> Period  $P$  represents the current period number the play sequence occurs in, typically ranging in value from 1 to 5. Periods 1 to 3 are the regular play of an ice hockey game, and periods 4 and onwards are for overtime and shootout periods as needed.

Potentially, there are  $(17 \times 7 \times 7) = 833$  context states. In our NHL dataset, 450 context states occur at least once. Table 4 includes statistics for the top-20 context states over all 590,924 play sequences, and lists 52,793 total goals and 89,612 total penalties. Positive differences are for the home team and negative differences are for the away team. For example, a Goal Difference of 7.1% means the home team is 7.1% more likely to score a goal in that context state than the away team. Similarly, a Penalty Difference of -33.2% means the away team is 33.2% more likely to receive a penalty in that context state than the home team. Our Markov model is very well calibrated, due to the frequency estimation method, meaning that its predictions match the observed frequencies of goals and penalties. We explain below how the model predictions are computed.

A number of previous papers on hockey dynamics have considered the context features of play sequences. The important trends that it is possible to glean from statistics such as those shown in Table 4 have been discussed in several papers. Our data analysis confirms these observations on a larger dataset than previously used. Notable findings include the following.

1. Home team advantage: the same advantages in terms of context features translate into higher scoring rates.
2. Penalties are more frequent than goals, except for the overtime period 4 (cf. [Schuckers and Brozowski, 2012]).
3. Gaining a powerplay substantially increases the conditional probability of scoring a goal [Thomas et al., 2013].
4. Gaining a powerplay also significantly increases the conditional probability of receiving a penalty [Schuckers and Brozowski, 2012].
5. Shorthanded goals are surprisingly likely: a manpower advantage translates only into a goal scoring difference of at most 64.8%, meaning the shorthanded team scores the next goal with a conditional probability of 17.6%. (Home team powerplay when  $P = 1$ .)

While such patterns provide interesting and useful insights into hockey dynamics, they do not consider action events.

<sup>1</sup>Pulling the goalie can also result in a skater manpower advantage.

Table 4: Statistics for Top-20 Most Frequent Context States. GD = Goal Differential, MD = Manpower Differential, P = Period.

| GD | MD | P | #Sequences | #Goals | #Penalties | Observed        |                    | Model Predicts  |                    |
|----|----|---|------------|--------|------------|-----------------|--------------------|-----------------|--------------------|
|    |    |   |            |        |            | Goal Difference | Penalty Difference | Goal Difference | Penalty Difference |
| 0  | 0  | 1 | 78,118     | 5,524  | 11,398     | 7.06%           | -2.26%             | 7.06%           | -2.26%             |
| 0  | 0  | 2 | 38,315     | 2,935  | 5,968      | 7.60%           | -2.92%             | 7.60%           | -2.92%             |
| 0  | 0  | 3 | 30,142     | 2,050  | 3,149      | 5.85%           | -2.19%             | 5.85%           | -2.19%             |

| 3  | 0  | 3 | 10,819     | 678    | 1,859      | 0.29%           | 1.24%              | 0.29%           | 1.24%              |
| -3 | 0  | 3 | 7,569      | 469    | 1,184      | 7.04%           | -6.25%             | 7.04%           | -6.25%             |
| 0  | 1  | 2 | 7,480      | 851    | 1,157      | 56.99%          | 25.67%             | 56.99%          | 25.67%             |
| 0  | 0  | 4 | 7,024      | 721    | 535        | 5.69%           | -10.65%            | 5.69%           | -10.65%            |
| 0  | -1 | 2 | 6,853      | 791    | 1,150      | -52.47%         | -37.39%            | -52.47%         | -37.39%            |

This means that analysis at the sequence level does not consider the internal dynamics within each sequence, and that it is not suitable for evaluating the impact of hockey actions. We next extend our state space to include actions.

#### 4.2 STATE SPACE: PLAY SEQUENCES

We expand our state space with actions and action histories. The basic set of 8 possible actions is listed in Table 2. Each of these actions has two parameters: which team  $T$  performs the action and the zone  $Z$  where the action takes place. Zone  $Z$  represents the area of the ice rink in which an action takes place.  $Z$  can have values Offensive, Neutral, or Defensive, relative to the team performing an action. For example,  $Z = \text{Offensive zone}$  relative to the home team is equivalent to  $Z = \text{Defensive zone}$  relative to the away team. A specification of an action plus parameters is an **action event**. Using action description language notation [Levesque et al., 1998], we write action events in the form  $a(T, Z)$ . For example,  $\text{faceoff}(\text{Home}, \text{Neutral})$  denotes the home team wins a faceoff in the neutral zone. We usually omit the action parameters from generic notation and write  $a$  for a generic action event.

A **play sequence**  $h$  is a sequence of events starting with exactly one start marker, followed by a list of action events, and ended by at most one end marker. Start and end markers are shown in Table 2, adding shots and faceoffs as start markers, and goals as end markers. We also allow empty history  $\emptyset$  as a valid play sequence. A **complete** play sequence ends with an end marker. A **state** is a pair

$s = \langle \mathbf{x}, h \rangle$  where  $\mathbf{x}$  denotes a list of context features and  $h$  an action history. State  $s$  represents a play sequence consisting of action events  $a_1, a_2, \dots, a_n$  and with a particular  $GD, MD,$  and  $P$  as the context. If the sequence  $h$  is empty, then state  $s$  is purely a context node. Table 5 shows an example of a NHL play-by-play action sequence in tabular form. Potentially, there are  $(7 \times 2 \times 3)^{40} = 42^{40}$  action histories. In our dataset, 1,325,809 states, that is, combinations of context features and action histories, occur at least once. We store sequence data in SQL tables (see Table 5). SQL provides fast retrieval, and native support for the necessary COUNT operations.

Table 5: Sample Play-By-Play Data in Tabular Format

| GameId | Period | Sequence Number | Event Number | Event                       |
|--------|--------|-----------------|--------------|-----------------------------|
| 1      | 1      | 1               | 1            | PERIOD START                |
| 1      | 1      | 1               | 2            | faceoff(Home,Neutral)       |
| 1      | 1      | 1               | 3            | hit(Away,Neutral)           |
| 1      | 1      | 1               | 4            | takeaway(Home,Defensive)    |
| 1      | 1      | 1               | 5            | missed_shot(Away,Offensive) |
| 1      | 1      | 1               | 6            | shot(Away,Offensive)        |
| 1      | 1      | 1               | 7            | giveaway(Away,Defensive)    |
| 1      | 1      | 1               | 8            | takeaway(Home,Offensive)    |
| 1      | 1      | 1               | 9            | missed_shot(Away,Offensive) |
| 1      | 1      | 1               | 10           | goal(Home,Offensive)        |
| 1      | 1      | 2               | 11           | faceoff(Away,Neutral)       |
| ...    |        |                 |              |                             |

#### 4.3 STATE TRANSITIONS

If  $h$  is an incomplete play sequence, we write  $h \star a$  for the play sequence that results from appending  $a$  to  $h$ , where  $a$  is an action event or an end marker. Similarly if  $s = \langle \mathbf{x}, h \rangle$ ,

then  $s \star a \equiv \langle \mathbf{x}, h \star a \rangle$  denotes the unique successor state that results from executing action  $a$  in  $s$ . This notation utilizes the fact that context features do not change until an end marker is reached. For example, the goal differential does not change unless a goal event occurs. If  $h$  is a complete play sequence, then the state  $\langle \mathbf{x}, h \rangle$  has a unique successor  $\langle \mathbf{x}', \emptyset \rangle$ , where the mapping from  $\mathbf{x}$  to  $\mathbf{x}'$  is determined by the end marker. For instance, if the end marker is  $goal(Home, *)$ , then the goal differential increases by 1. A sample of our state transition graph is shown in Figure 1. Note that  $R(s)$  is the reward value for the state, and will be discussed in Section 4.4. In Figure 1, the reward encodes the objective of scoring a goal.

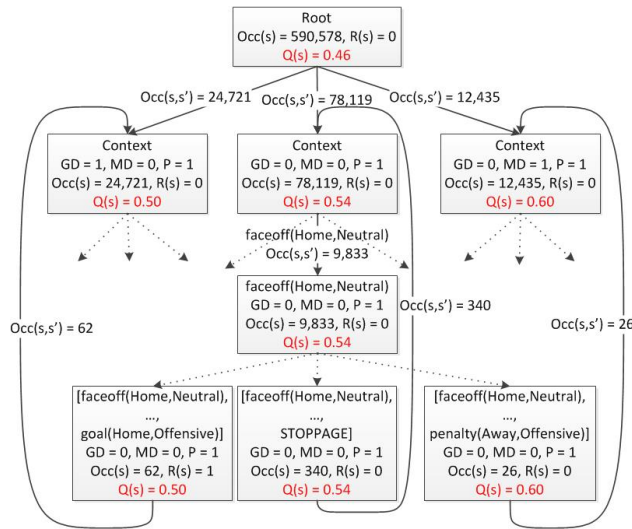

Figure 1: State Transition Graph

Since the complete action history is encoded in the state, action-state pairs are equivalent to state pairs. For example, we can write  $Q(s \star a)$  to denote the expected reward from taking action  $a$  in state  $s$ , where  $Q$  maps states to real numbers, rather than mapping action-state pairs to real numbers, as is more usual.

#### 4.4 REWARD FUNCTIONS: NEXT GOAL AND NEXT PENALTY

A strength of Markov Game modelling is value iteration can be applied to many reward functions depending on what results are of interest. We focus on two: scoring the next goal, and receiving the next penalty (a cost rather than a reward). These are two important events that change the course of an ice hockey game. For example, penalties affect goal scoring differentials, as shown in Table 4. Penalties are also one path to goals that a coach may want to understand in more detail. For instance, if a team receives an unusual number of penalties, a coach may want to know which players are responsible and by which actions. The next goal objective can be represented in the Markov Game

model as follows.

1. For any state  $s$  with a complete play sequence that ends in a Home resp. Away goal, we set  $R_H(s) := 1$  resp.  $R_A(s) := 1$ . For other states the reward is 0.
2. Any state  $s$  with a complete play sequence that ends in a Home resp. Away goal is an absorbing state (no transitions from this state).

With these definitions, the expected reward represents the probability that if play starts in state  $s$ , a random walk through the state space of unbounded length ends with a goal for the Home team resp. the Away team. The cost function for Receiving the Next Penalty can be represented in exactly the same way.

## 5 CONSTRUCTING THE STATE TRANSITION GRAPH

The main computational challenge is to build a data structure for managing the state space. The state space is large because each (sub)sequence of actions defines a new state. Since we are modelling the actual hockey dynamics in the on policy setting, we need consider only action sequences observed in some NHL match, rather than the much larger space of all possible action sequences. We use the classic AD-tree structure [Moore and Lee, 1998] to compute and store sufficient statistics over observed action sequences. The AD-tree is a tree of play sequences where a node is expanded only with those successors observed in at least one match. The play sequence tree is augmented with additional edges that model further state transitions; for example, a new action sequence is started after a goal. The augmented AD-tree structure compactly manages sufficient statistics, in this case state transition probabilities. It also supports value iteration updates very efficiently.

We outline an algorithm for Context-Aware State Transition Graph construction. The root node initializes the graph, and is an empty node with no context or event information. For each node, the context information  $GD$ ,  $MD$ , and  $P$  are set when the new node is created, and the new action  $a$  is added to the sequence along with the zone  $Z$  that  $a$  occurs in. The reward  $R(s)$  is also applied to each node. The node counts  $Occ(s)$  and edge counts  $Occ(s, s')$  are applied to each node and edge respectively, and are used to generate transition probabilities  $TP$  for the value iteration using observed frequencies. The NHL play-by-play event data records goals, but no separate event for the shot leading to the goal exists. Following [Schuckers and Curro, 2013], we record the shot leading to the goal in addition to the goal itself by injecting a shot event into the event sequence prior to the goal.

## 6 VALUE ITERATION

Recall that since states encode action histories, in our model learning the expected value of states is equivalent to learning a Q-function (Section 4.3). In reinforcement learning terms, there is no difference between the value function  $V$  and the Q-function in our model. We can therefore apply standard value iteration over states [Sutton and Barto, 1998] to learn a Q-function for our ice hockey Markov Game. Algorithm 1 shows pseudo-code. We compute separate Q-functions for the Home team and for the Away team. Since we are in the on policy setting, we have a fixed policy for the other team. This means we can treat the other team as part of the environment, and reduce the Markov Game to two single-agent Markov decision processes. In our experiments, we use a relative convergence of 0.0001 as our convergence criterion, and 100,000 as the maximum number of iterations.

---

### Algorithm 1 Dynamic Programming for Value Iteration

---

**Require:** Markov Game model, convergence criterion  $c$ , maximum number of iterations  $M$

```

1:  $lastValue = 0$ 
2:  $currentValue = 0$ 
3:  $converged = false$ 
4: for  $i = 1; i \leq M; i \leftarrow i + 1$  do
5:   for all states  $s$  in the Markov Game model do
6:     if  $converged == false$  then
7:        $Q_{i+1}(s) =$ 
            $R(s) + \frac{1}{Occ(s)} \sum_{(s,s') \in E} (Occ(s,s') \times Q_i(s'))$ 
8:        $currentValue = currentValue + |Q_{i+1}(s)|$ 
9:     end if
10:  end for
11:  if  $converged == false$  then
12:    if  $\frac{currentValue - lastValue}{currentValue} < c$  then
13:       $converged = true$ 
14:    end if
15:  end if
16:   $lastValue = currentValue$ 
17:   $currentValue = 0$ 
18: end for

```

---

## 7 EVALUATION AND RESULTS

We discuss the results of action values in Section 7.1 and player values in Section 7.2.

### 7.1 ACTION IMPACT VALUES

The main quantity we consider is the **impact** of an action as a function of context (= Markov state). This is defined as follows:

$$impact(s, a) \equiv Q_T(s \star a) - Q_T(s)$$

where  $T$  is the team executing the action  $a$ . In a zero-sum game, the state value is usually defined as the final result following optimal play [Russell and Norvig, 2010]. Intuitively, the value specifies which player has a better position in a state. Since we are not modelling optimal play, but actual play in an on policy setting, the expected difference in rewards is the natural counterpart. The impact quantity measures how performing an action in a state affects the expected reward difference. Figure 2 shows a boxplot for the action impact values as they range over different contexts, i.e., states in the Markov Game model. (Boxplots produced with MATLAB R2014a.) The red dots are outliers beyond 2.7 s.d. A cutoff of -0.2 and 0.2, shown by the horizontal dashed line, was used for the impact values on both boxplots. While the Q-values are based on the frequency of states, we weight all states equally in discussing the properties of the Q-function. The boxplot does not include Q-values for states whose frequency is below 5%. It is clear from Figure 2 that *depending on the context and event history, the value of an action can vary greatly*. The context-dependence is observed for both scoring goals and receiving penalties.

**Impact on Scoring the Next Goal.** All actions, with the exception of faceoffs won in the offensive zone, have at least one state where the action has a positive impact, and another state with a negative impact. Two examples of how the value of the same action can depend on the context include the following, which we found by examining states with extreme impact values.

*Blocked Shot.* Blocking the first shot on net when killing a penalty decreases a team’s scoring rate ( $impact = -0.0864$ ). But blocking the second shot on net increases the scoring rate ( $impact = 0.1399$ ).

*Penalty.* Receiving a penalty when on the powerplay is very bad ( $impact = -0.1789$ ). But if a player, while on the penalty kill, receives a penalty while goading their opponent into an offsetting penalty, the penalty actually increases their team’s scoring rate ( $impact = 0.0474$ ).

The THoR player ratings compute the impact of actions based on goals that immediately follow the action ([Lock and Schuckers, 2009; Schuckers et al., 2011]; see Section 2). The values given for each action in [Lock and Schuckers, 2009] are displayed as an asterisk in Figure 2(a). The THoR values agree with our median impact values in terms of whether an action generally has positive or negative impact. For example, penalties are known to generally be good for the opposing team, and shots are good for the shooter’s team. THoR values are close to the median Markov model values in 6 out of 10 cases. This comparison suggests THoR aggregates action values over many contexts the Markov game models explicitly. In a le-

sion study described in the supplementary material, we examine directly defining the value of an action as the average impact of the action over all states. Using the average impact as a fixed action value leads to a loss of information, as measured by the entropy of the prediction for which team scores the next goal. Another lesion study described in the supplementary material assesses the importance of propagating information between states, especially from one play sequence to subsequent ones. Our results show that goal impact values of the actions change substantially depending on how much information the model propagates.

**Impact on Receiving Penalties.** The range of action values with the probability of the next penalty as the objective function is shown in Figure 2(b). Faceoffs in the Offensive Zone and takeaways cause penalties for the opponent. Giveaways and goals tend to be followed by a penalty for the player’s team. The latter finding is consistent with the observation that there are more penalties called against teams with higher leads [Schuckers and Brozowski, 2012]. A possible explanation is referees are reluctant to penalize a trailing team.

Figure 3: 2013-2014 Player Goal Impact Vs. Season Points

## 7.2 PLAYER VALUATIONS

As players perform actions on behalf of their team, it is intuitive to apply the impact scores of team actions to the players performing the action, yielding player valuations. To calculate player valuations, we apply the impact of an action to the player as they perform the action. Next, we sum the impact scores of a player’s actions over a single game, and then over a single season, to compute a net season impact score for the player. This procedure is equivalent to comparing the actions taken by a specific player to those of the league-average player, similar to previous work [Pettigrew, 2015; Cervone et al., 2014]. We compare

Table 6: 2013-2014 Top-8 Player Impact Scores For Goals

| Name           | Goal Impact | Points | +/- | Salary       |
|----------------|-------------|--------|-----|--------------|
| Jason Spezza   | 29.64       | 66     | -26 | \$5,000,000  |
| Jonathan Toews | 28.75       | 67     | 25  | \$6,500,000  |
| Joe Pavelski   | 27.20       | 79     | 23  | \$4,000,000  |
| Marian Hossa   | 26.12       | 57     | 26  | \$7,900,000  |
| Patrick Sharp  | 24.43       | 77     | 12  | \$6,500,000  |
| Sidney Crosby  | 24.23       | 104    | 18  | \$12,000,000 |
| Claude Giroux  | 23.89       | 86     | 7   | \$5,000,000  |
| Tyler Seguin   | 23.89       | 84     | 16  | \$4,500,000  |

impact on Next Goal Scored with three other player ranking metrics: points earned, salary, and +/- . To avoid confounding effects between different seasons, we use only the most recent full season, 2013-2014. Player impact scores are shown in Table 6. Tables for all seasons are available as well [Routley, 2015]. Figure 3 shows that next goal impact correlates well with points earned. A point is earned for each goal or assist by a player. Since these players have a high impact on goals, they also tend to have a positive +/- rating. Jason Spezza is an anomaly, as he has the highest impact score but a very negative +/- score. This is because his Ottawa team performed poorly overall in the 2013-2014 season: The team overall had a goal differential of -29, one of the highest goal differentials that season. This example shows that impact scores distinguish a player who generally performs useful actions but happens to be on a poor team.

In Table 7, we see player impact with respect to Next Penalty Received. High impact numbers indicate a tendency to cause penalties for a player’s own team, or prevent penalties for the opponent. We compare the Q-function impact numbers to Penalties in Minutes (PIM), +/- , and salary. Players with high Q-function numbers have high penalty minutes as we would expect. They also have low +/- , which shows the importance of penalties for scoring chances. Their salaries tend to be lower. There are however notable exceptions, such as Dion Phaneuf, who draws a high salary although his actions have a strong tendency to incur penalties.

Table 7: 2013-2014 Top-8 Player Impacts For Penalties

| Name            | Penalty Impact | PIM | +/- | Salary      |
|-----------------|----------------|-----|-----|-------------|
| Chris Neil      | 62.58          | 211 | -10 | \$2,100,000 |
| Antoine Roussel | 54.26          | 209 | -1  | \$625,000   |
| Dion Phaneuf    | 52.52          | 144 | 2   | \$5,500,000 |
| Zac Rinaldo     | 48.65          | 153 | -13 | \$750,000   |
| Rich Clune      | 47.08          | 166 | -7  | \$525,000   |
| Tom Sestito     | 46.34          | 213 | -14 | \$650,000   |
| Zack Smith      | 44.55          | 111 | -9  | \$1,500,000 |
| David Perron    | 42.49          | 90  | -16 | \$3,500,000 |

(a) Impact on the probability of Scoring the Next Goal. Higher numbers are *better* for the team that performs the action. (b) Impact on the probability of Receiving the Next Penalty. Higher numbers are *worse* for the team that performs the action.

Figure 2: Action Impact Values vary with context. The central mark is the median, the edges of the box are the 25th and 75th percentiles. The whiskers are at the default value, approximately 2.7 s.d.

## 8 CONCLUSION

We have constructed a Markov Game Model for a massive set of NHL play-by-play events with a rich state space. Tree-based data structures support efficient parameter estimation and storage. Value iteration computes the values of each action given its context and sequence history—the Q-function of the model. Compared to previous work that assigns a single value to actions, the Q-function incorporates two powerful sources of information for valuing hockey actions: (1) It takes into account the context of the action, represented by the Markov Game state. (2) It models the medium-term impact of an action by propagating its effect to future states. Propagating action effects across sequences utilizes the ordering of play sequences in a game, rather than treating sequences as an unordered independent set. Analysis of the computed Q-function shows the impact of an action varies greatly with context, and medium-term ripple effects make a difference. We apply our model to evaluate the performance of players in terms of their actions’ total impact. Impact scores for the next goal correlate with points. The impact of players on the next penalty has to our knowledge not been previously considered, and shows some surprises, as some highly-paid players hurt their team by causing penalties. In sum, the Q-function is a powerful AI concept that captures much information about hockey dynamics as the game is played in the NHL.

**Future Work** The NHL data provides a rich dataset for real-world event modelling. A number of further AI techniques can be applied to utilize even more of the available information than our Markov Game model does. A promis-

ing direction is to extend our discrete Markov Game model with data about continuous quantities. These include (i) the time between events, (ii) the absolute game time of the events, (iii) location of shots [Krzywicki, 2005]. Our use of reinforcement learning techniques has been mainly for finding patterns in a rich data set, in the spirit of descriptive statistics and data mining. Another goal is to *predict* a player or team’s future performance based on past performance using machine learning techniques. For example, sequence modelling would be able to generalize from play sequence information. A promising model class are Piecewise Constant Conditional Intensity Models for continuous time event sequences [Gunawardana et al., 2011; Parikh et al., 2012]. These models are especially well suited for sequences with a large set of possible events, such as our action events. Another extension is to evaluate players with respect to similar players [Cervone et al., 2014], for instance, players who play the same position. A potential future application for improving play and advising coaches is in finding strengths and weaknesses of teams: We can use the Q-function to find situations in which a team’s mix of actions provides a substantially different expected result from that of a generic team.

## Abstract

Probabilistic latent-variable models are a fundamental tool in statistics and machine learning. Despite their widespread use, identifying the parameters of basic latent variable models continues to be an extremely challenging problem. Traditional maximum likelihood-based learning algorithms find valid parameters, but suffer from high computational cost, slow convergence, and local optima. In contrast, recently developed spectral algorithms are computationally efficient and provide strong statistical guarantees, but are not guaranteed to find valid parameters. In this work, we introduce a two-stage learning algorithm for latent variable models. We first use a spectral method of moments algorithm to find a solution that is *close* to the optimal solution but not necessarily in the valid set of model parameters. We then incrementally refine the solution via an exterior point method until a local optima that is arbitrarily near the valid set of parameters is found. We perform several experiments on synthetic and real-world data and show that our approach is more accurate than previous work, especially when training data is limited.

## 1 INTRODUCTION & RELATED WORK

Probabilistic latent variable models are a fundamental tool in statistics and machine learning that have successfully been deployed in a wide range of applied domains including robotics, bioinformatics, speech recognition, document analysis, social network modeling, and economics. Despite their widespread use, identifying the parameters of basic latent variable models like multi-view models and hidden Markov models (HMMs) continues to be an extremely challenging problem. Researchers often resort to local search heuristics such as expectation maximization (EM) (Dempster et al., 1977) that attempt to find param-

eters that maximize the likelihood of the observed data. Unfortunately, EM has a number of well-documented drawbacks, including high computational cost, slow convergence, and local optima.

In the past 5 years, several techniques based on *method of moments* (Pearson, 1894) have been proposed as an alternative to maximum likelihood for learning latent variable models (Hsu et al., 2009; Siddiqi et al., 2010; Song et al., 2010; Parikh et al., 2011, 2012; Hsu and Kakade, 2012; Anandkumar et al., 2012a,c,b; Balle et al., 2012; Cohen et al., 2013; Song et al., 2014). These algorithms first estimate low-order moments of observations, such as means and covariances, and then apply a sequence of linear algebra to recover the model parameters. Moment estimation is linear in the number of training data samples, and parameter estimation, which relies on techniques like the singular value decomposition (SVD) is typically fast and numerically robust.

For example, moment-based algorithms have been proposed for learning *observable* representations of HMMs, which explicitly avoid recovering HMM transition and observation matrices (Hsu et al., 2009; Siddiqi et al., 2010; Song et al., 2010). These *spectral* algorithms first perform a SVD of second-order moments of adjacent observations, and then use this result, along with additional low-order moments, to recover parameters for filtering, predicting, and simulating from the system. Unlike previous maximum likelihood-based approaches, spectral algorithms are fast, statistically consistent, and do not resort to local search.

Spectral algorithms were recently extended to the more difficult problem of estimating the parameters of latent variable models including the stochastic transition and observation matrices of HMMs (Anandkumar et al., 2012c).<sup>1</sup> Again, the estimators are based on SVD and a sequence of linear operations, applied to low-order moments of observations and come with learning guarantees under mild rank

---

<sup>1</sup>In contrast to the *observable* representation identified by the previous spectral learning algorithms (Hsu et al., 2009; Siddiqi et al., 2010; Song et al., 2010).

conditions. This work has been further extended to learning parameters of parametric and nonparametric multi-view latent variable models (Anandkumar et al., 2012b; Song et al., 2014) by introducing a symmetric tensor decomposition algorithm that unifies several previous method of moments-based approaches.

One of the benefits of method of moments over EM and other local search heuristics is that moment-based algorithms come with theoretical guarantees such as statistical consistency and finite sample bounds. In other words, under mild assumptions, method of moments can guarantee that as the amount of training data increases, the learned parameters are converging to the true parameters of the model that generated the data (Hsu et al., 2009; Anandkumar et al., 2012b). This is especially promising because the resulting parameters can be used to *initialize* EM in a two-stage learning algorithm (Zhang et al., 2014; Balle et al., 2014), resulting in the best of both worlds: parameters found by method of moments provide a good initialization for a maximum likelihood approach.

Unfortunately, spectral method of moments algorithms and two-stage learning algorithms have worked less well in practice. With finite samples, method of moments estimators are *not* guaranteed to find a valid set of parameters. Although error in the estimated parameters are bounded, the parameters themselves may lie outside the class of valid models. For example, the learned transition matrix of a HMM may have small negative entries. A consequence is that the learned model cannot be used or even serve as an initialization for EM.

To fix these problems, the method of moments solution is typically projected onto the space of valid model parameters: e.g. by flipping the sign of negative parameters and renormalizing the model (Cohen et al., 2013), or projecting the parameters onto the  $\ell_1$ -ball (Duchi et al., 2008). While these heuristics produce a useable model, it invalidates any theoretical guarantees: the resulting model may no longer be close to the true parameters. As demonstrated in Balle et al., models that are learned by method of moments and then “corrected” in this way, do not necessarily serve as a good initialization to EM (Balle et al., 2014).

### 1.1 EXTERIOR POINT METHODS

Consider the problem of minimizing objective function  $r(\mathbf{v}) : \mathbb{R}^n \rightarrow \mathbb{R}^+$ , subject to the constraint  $\mathbf{v} \in \mathcal{A}$ . Generally, a series of unconstrained optimization problem are solved to achieve a local optima in the limit. The optimization problem in the  $k^{th}$  step can be written as:

$$\text{minimize } r(\mathbf{v}) + l_k(\mathbf{v})$$

with the local optima  $\mathbf{v}^{(k)}$ . By defining the function  $l_k(\mathbf{v})$  appropriately, one can then show that  $\mathbf{v}^* = \lim_{k \rightarrow \infty} \mathbf{v}^{(k)}$  is a local optima of the original constrained optimization

Figure 1: Exterior point methods versus projection followed by interior point methods. The dashed line shows the feasible set and the optimal solution is labeled  $\mathbf{X}^*$ . Starting from the method of moments solution  $\mathbf{X}$ , the exterior point method (green arrows) converges to a point arbitrarily close to the feasible set. Current optimization methods for learning latent variable models first project the method of moments solution into the feasible set (blue arrow) and then use an interior point method (red arrows show interior point method trajectory). Assuming that the initial solution is near to the optimal solution, as in this example, the projection step may change the convergence point to a point far from the optimal solution  $\mathbf{X}^*$ .

problem (Bloom, 2014). In *Interior point* methods every intermediate solution  $\mathbf{v}^{(k)}$  is in the feasible set, however, in *exterior point* methods, only the convergence point of the sequence needs to be feasible (Byrne, 2008). Examples of interior and exterior point methods are Barrier function methods (Boyd and Vandenberghe, 2004), and exact penalty function methods (Fletcher, 2013) respectively. In exterior point methods, the function  $l_k(\mathbf{v})$  usually has a positive value for solutions outside the feasible set to discourage these solutions and a value of zero for feasible inputs. In interior point methods, the function  $l_k(\mathbf{v}) \rightarrow \infty$  when  $\mathbf{v}$  approaches to the boundary of the constraint set. Polyak (2008), and Yamashita and Tanabe (2010) propose primal-dual exterior point methods for convex and non-convex optimization problems respectively. In Section 3, we show that by defining  $l_k(\mathbf{v})$  appropriately, the algorithm converges to a local optima arbitrarily close to the feasible set by doing simple *forward-backward splitting* steps (Combettes and Pesquet, 2011).

An important advantage of exterior point methods is that they are likely to achieve a better local minimum than interior point methods when the feasible set is narrow by allowing solutions to exist outside the feasible set during the intermediate steps of the optimization (Yamashita and Tanabe, 2010).

### 1.2 THE PROPOSED METHOD

One of the primary drawbacks of using method of moments for learning latent variable models, is that the estimated pa-

parameters can lie outside the class of valid models (Balle et al., 2014). To combat this problem, we propose a two-stage algorithm for learning the parameters of latent variable models.

In the first stage, the parameters are estimated via a spectral method of moments algorithm (similar to Anandkumar et al. (2012c)). Like previous method of moments-based learning algorithms, if the estimated moments are inaccurate, then the estimated parameters of this model may lie outside of the model class.

In the second stage, the estimate is refined by an iterative optimization scheme. Unlike previous work that projects method of moments onto the feasible space of model parameters and then uses the projected parameters to initialize EM (Zhang et al., 2014; Balle et al., 2014), we use exterior point methods for non-convex optimization directly initialized with the result of method of moments *without modification*. The exterior point method iteratively refines the solution until a local optima that is arbitrarily close to the valid set of model parameters is found. A comparison between the two approaches is illustrated in Figure 1.

### 1.3 BASICS AND NOTATION

We use following notation to distinguish scalars, vectors, matrices, and third-order tensors: scalars are denoted by either lowercase or uppercase letters, vectors are written as boldface lowercase letters, matrices correspond to boldface uppercase letters, and third-order tensors are represented by calligraphic letters. In this paper,  $(\mathbf{A})_{ij}$  means the entry in the  $i^{\text{th}}$  row and  $j^{\text{th}}$  column of the matrix  $\mathbf{A}$ , we use similar notation to index entries of vectors and third-order tensors. Furthermore, the  $i^{\text{th}}$  column of the matrix  $\mathbf{A}$  is denoted as  $(\mathbf{A})_i$ , i.e.,  $\mathbf{A} = [(\mathbf{A})_1, (\mathbf{A})_2, \dots, (\mathbf{A})_n]$ . We show a  $n \times m$  matrix with entries one by  $\mathbf{1}^{n \times m}$ ,  $n \times n$  identity matrices by  $\mathbf{I}^n$ , and  $n \times n \times n$  identity tensors by  $\mathcal{I}^n$ . We use  $\mathbb{R}_+^{n \times m}$  to show the set of  $n$  by  $m$  matrices with non-negative entries, and  $\Delta^n$  is the set of all  $n + 1$ -dimensional vector on the  $n$ -dimensional simplex.

We also define the following functions for ease of notation:  $\text{sum}(\mathbf{X}) = \mathbf{X}^\top \mathbf{1}$  computes column sum of the matrix  $\mathbf{X}$ , and the function  $\text{diag}(\mathbf{v})$ , which returns a diagonal matrix where its diagonal elements are a vector  $\mathbf{v}$ . For matrices or 3-way tensors,  $\text{diag}(\cdot)$  returns diagonal elements of the given input in vector form.

#### 1.3.1 $n$ -mode product (Lathauwer et al., 2000)

The  $n$ -mode product of a tensor  $\mathcal{A} \in \mathbb{R}^{I_1 \times I_2 \times I_3}$  by a matrix  $\mathbf{B} \in \mathbb{R}^{J_n \times I_n}$  for  $1 \leq n \leq 3$ , shown as  $\mathcal{A} \times_n \mathbf{B}$ , is an  $K_1 \times K_2 \times K_3$  tensor, for which  $K_i = I_i$  for all dimensions except the  $n$ -th one which is  $K_n = J_n$ . The entries

are given by:

$$(\mathcal{A} \times_n \mathbf{B})_{i_1 \dots j_n \dots i_3} = \sum_{i_n} (\mathcal{A})_{i_1 \dots i_n \dots i_3} (\mathbf{B})_{j_n i_n}. \quad (1)$$

We benefit from following properties of  $n$ -mode product in future sections:

- Given a tensor  $\mathcal{A} \in \mathbb{R}^{I_1 \times I_2 \times I_3}$  and a matrix  $\mathbf{C} \in \mathbb{R}^{J_n \times I_n}$  of the same size as  $\mathbf{B}$ , one can show that:

$$(\mathcal{A} \times_n \mathbf{B}) \times_n \mathbf{C} = \mathcal{A} \times_n (\mathbf{C}\mathbf{B}). \quad (2)$$

- For a matrix  $\mathbf{D} \in \mathbb{R}^{J_m \times I_m}$  ( $n \neq m$ ):

$$(\mathcal{A} \times_n \mathbf{B}) \times_m \mathbf{D} = (\mathcal{A} \times_m \mathbf{D}) \times_n \mathbf{B}.$$

- For matrices  $\mathbf{A}$ ,  $\mathbf{B}$ , and  $\mathbf{C}$  with appropriate sizes:

$$\mathbf{A} \times_1 \mathbf{B} \times_2 \mathbf{C} = \mathbf{B}\mathbf{A}\mathbf{C}^\top.$$

## 2 PARAMETER ESTIMATION VIA METHOD OF MOMENTS

In this section we derive two method of moments algorithms for estimating the parameters of latent variable models, one for multi-view models and one for HMMs. If the estimated parameters lie outside the feasible set of solutions, they are used to initiate an exterior point method (Section 3).

### 2.1 MULTI-VIEW MODELS

In a multi-view model, observation variables  $o_1, o_2, \dots, o_l$  are conditionally independent given a latent variable  $h$  (Figure 2a). Assume each observation variable can take one of  $n_o$  different values. The observation vector  $\mathbf{x}_t \in \mathbb{R}^{n_o}$  is defined as follows:

$$\mathbf{x}_t = \mathbf{e}_j \text{ iff } o_t = j \text{ for } 0 < j \leq n_o, \quad (3)$$

where  $\mathbf{e}_j$  is the  $j^{\text{th}}$  canonical basis. In this paper, we consider the case where  $l = 3$ , however, the techniques can be easily extended to cases where  $l > 3$ . Let  $h \in \{1, \dots, n_s\}$  be a discrete random variable and  $\Pr\{h = j\} = (\mathbf{w})_j$ , where  $\mathbf{w} \in \Delta^{n_s-1}$ , then the conditional expectation of observation vector  $\mathbf{x}_t$  for  $t \in \{1, 2, 3\}$  is:

$$\mathbb{E}[\mathbf{x}_t | h = i] = \mathbf{u}_i^t, \quad (4)$$

where  $\mathbf{u}_i^t \in \Delta^{n_o-1}$ . We define the observation matrix as  $\mathbf{U}^t = [\mathbf{u}_1^t, \dots, \mathbf{u}_{n_s}^t]$  for  $t \in \{1, 2, 3\}$ , and the diagonal  $n_s \times n_s \times n_s$  tensor  $\mathcal{H}$ , where  $\text{diag}(\mathcal{H}) = \mathbf{w}$  for ease of notation. The following proposition relates  $\mathbf{U}^t$ s and  $\mathbf{w}$  to the moments of  $\mathbf{x}_t$ s.

**Proposition 1. (Anandkumar et al., 2012b)** Assume that columns of  $\mathbf{U}^t$  are linearly independent for each  $t \in \{1, 2, 3\}$ . Define

$$\mathcal{M} = \mathbb{E}(\mathbf{x}_1 \otimes \mathbf{x}_2 \otimes \mathbf{x}_3)$$

Then

$$\mathcal{M} = \mathcal{H} \times_1 \mathbf{U}^1 \times_2 \mathbf{U}^2 \times_3 \mathbf{U}^3 \quad (5)$$

Figure 2: The two latent variable models discussed in the text.

In the next proposition, the moments of  $\mathbf{x}_t$ s are related to a specific  $\mathbf{U}^t$ :

**Proposition 2. (Anandkumar et al., 2012b)** *Assume that columns of  $\mathbf{U}_t$  are linearly independent for each  $t = \{1, 2, 3\}$ . Let  $(a, b, c)$  be a permutation of  $\{1, 2, 3\}$ . Define*

$$\begin{aligned} \mathbf{x}'_a &= \mathbb{E}(\mathbf{x}_c \otimes \mathbf{x}_b) \mathbb{E}(\mathbf{x}_a \otimes \mathbf{x}_b)^{-1} \mathbf{x}_a \\ \mathbf{x}'_b &= \mathbb{E}(\mathbf{x}_c \otimes \mathbf{x}_a) \mathbb{E}(\mathbf{x}_b \otimes \mathbf{x}_a)^{-1} \mathbf{x}_b \\ \mathbf{M}_c &= \mathbb{E}(\mathbf{x}'_a \otimes \mathbf{x}'_b) \\ \mathcal{M}_c &= \mathbb{E}(\mathbf{x}'_a \otimes \mathbf{x}'_b \otimes \mathbf{x}_c) \end{aligned}$$

Then

$$\begin{aligned} \mathbf{M}_c &= \mathbf{U}^c \text{diag}(\mathbf{w}) \mathbf{U}^{c\top} \\ \mathcal{M}_c &= \mathcal{H} \times_1 \mathbf{U}^c \times_2 \mathbf{U}^c \times_3 \mathbf{U}^c \end{aligned} \quad (6)$$

Also, define  $\mathbf{m}^c = \mathbb{E}(\mathbf{x}_c) = \mathbf{U}^c \mathbf{w}$ . Anandkumar et al. (2012b) transform  $\mathcal{M}_c$  to a orthogonally decomposable tensor and recover the matrices  $\mathbf{U}^t$ s and  $\mathbf{w}$  from it. Our approach here is slightly different and is more similar to Anandkumar et al. (2012c): we reduce the problem into the orthogonal decomposition of a matrix derived from  $\mathcal{M}_c$ .

First, let  $\mathbf{S} = \mathbf{V} \boldsymbol{\Sigma}^{-1/2}$ , where columns of  $\mathbf{V}$  are orthonormal eigenvectors of  $\mathbf{M}_c$  and  $\boldsymbol{\Sigma}$  is a diagonal matrix whose elements are corresponding eigenvalues of  $\mathbf{V}$ . The columns of  $\tilde{\mathbf{U}}^c = \mathbf{S}^\top \mathbf{U}^c \text{diag}(\mathbf{w})^{1/2}$  are orthonormal vectors (Anandkumar et al., 2012b). Using this and Equation (6) we have:

$$\begin{aligned} \mathbf{M}_\eta &= \mathcal{M}_c \times_1 \mathbf{S}^\top \times_2 \mathbf{S}^\top \times_3 \boldsymbol{\eta}^\top \\ &= \mathcal{H} \times_1 (\mathbf{S}^\top \mathbf{U}^c) \times_2 (\mathbf{S}^\top \mathbf{U}^c) \times_3 (\boldsymbol{\eta}^\top \mathbf{U}^c) \\ &= \mathcal{I}_{n_s} \times_1 \tilde{\mathbf{U}}^c \times_2 \tilde{\mathbf{U}}^c \times_3 (\boldsymbol{\eta}^\top \mathbf{U}^c) \\ &= \tilde{\mathbf{U}}^c \text{diag}(\boldsymbol{\eta}^\top \mathbf{U}^c) (\tilde{\mathbf{U}}^c)^\top \end{aligned} \quad (7)$$

where  $\boldsymbol{\eta}$  is a random vector sampled from the  $n_o$  dimensional normal distribution. For the first equality we used property in Equation (2), in the second equality we used the fact that  $\mathcal{H} = \mathcal{I}_{n_s} \times_1 \text{diag}(\mathbf{w})^{1/2} \times_2 \text{diag}(\mathbf{w})^{1/2}$ , and finally in the last equality we used equality  $\mathcal{I}_{n_s} \times_3 (\boldsymbol{\eta}^\top \mathbf{U}^c) = \text{diag}(\boldsymbol{\eta}^\top \mathbf{U}^c)$ . In Anandkumar et al. (2012c) it is shown that  $\boldsymbol{\eta}^\top \mathbf{U}^c$  has distinct values with a high probability. Thus,  $\tilde{\mathbf{U}}^c$  can be recovered by a SVD decomposition of  $\mathbf{M}_\eta$ . Then  $\mathbf{w} = ((\tilde{\mathbf{U}}^c)^\top \mathbf{S}^\top \mathbf{m}^c)^\wedge 2$ ,

---

**Algorithm 1** *Moment-based parameter estimation*

---

**Input:** Estimated third order moment  $\hat{\mathcal{M}}_c$  for  $c = \{1, 2, 3\}$

**Output:** Estimated parameters  $\hat{\mathbf{U}}^1, \hat{\mathbf{U}}^2, \hat{\mathbf{U}}^3, \hat{\mathbf{w}}$

---

**for each**  $t \in \{1, 2, 3\}$  **do**

$\hat{\mathbf{M}}_t \leftarrow \hat{\mathcal{M}}_t \times_3 \mathbf{1}$  (compute second-order moment)

$\hat{\mathbf{m}}_t \leftarrow \hat{\mathcal{M}}_t \times_2 \mathbf{1} \times_3 \mathbf{1}$  (compute first-order moment)

$\mathbf{S} \leftarrow \mathbf{V} \boldsymbol{\Sigma}^{-1/2}$  ( $\mathbf{V} \boldsymbol{\Sigma} \mathbf{V}^\top$  is  $\hat{\mathbf{M}}_t$ 's eigenvalue decomposition)

$\boldsymbol{\eta} \leftarrow$  drawn randomly from Normal distribution

$\mathbf{M}_\eta \leftarrow \hat{\mathcal{M}}_t \times_1 \mathbf{S}^\top \times_2 \mathbf{S}^\top \times_3 \boldsymbol{\eta}^\top$  (Eq. 7)

$\tilde{\mathbf{U}}^t \leftarrow \mathbf{K}$  (columns of  $\mathbf{K}$  are  $\mathbf{M}_\eta$ 's eigenvectors)

$\hat{\mathbf{w}}^t \leftarrow ((\tilde{\mathbf{U}}^t)^\top \mathbf{S}^\top \hat{\mathbf{m}}^t)^\wedge 2$

$\hat{\mathbf{U}}^t \leftarrow \mathbf{S}^{+\top} \tilde{\mathbf{U}}^t \text{diag}(\hat{\mathbf{w}}^t)^{-1/2}$

**end for**

$\hat{\mathbf{w}} \leftarrow \frac{\hat{\mathbf{w}}^1 + \hat{\mathbf{w}}^2 + \hat{\mathbf{w}}^3}{3}$

---

where  $^\wedge$  is element-wise power operator. Having computed  $\mathbf{w}$ , one can recover  $\mathbf{U}^c$  via the equation  $\mathbf{U}^c = \mathbf{S}^{+\top} \tilde{\mathbf{U}}^c \text{diag}(\mathbf{w})^{-1/2}$ . Finally, we take the average of 3 copies of  $\mathbf{w}$  which are computed for different values of  $c$ . The overall moment-based approach is shown in Algorithm 1.

## 2.2 HIDDEN MARKOV MODELS

Hidden Markov models generate sequences of observations  $\mathbf{x}_1, \mathbf{x}_2, \dots \in \mathbb{R}^{n_o}$ . Each  $\mathbf{x}_t$  is independent of all other observations given the corresponding hidden state  $q_t \in \{1, 2, \dots, n_s\}$  (Figure 2b). Similar to multi-view models,  $n_s$  and  $n_o$  are the number of hidden states and number of observations respectively. Note that observations are represented as *indicator vectors*  $\mathbf{x}_t$ , which are all zero except for exactly one element which is set to 1. The conditional probability distribution of  $\mathbf{x}_t$  given  $q_t$  is defined via an observation matrix  $\mathbf{O} \in \mathbb{R}^{n_o \times n_s}$  according to  $\Pr\{\mathbf{x}_t = \mathbf{e}_i | q_t = j\} = (\mathbf{O})_{ij}$ . The stochastic transition matrix  $\mathbf{T} \in \mathbb{R}^{n_s \times n_s}$  is defined as  $\Pr\{q_{t+1} = i | q_t = j\} = (\mathbf{T})_{ij}$  for all  $t > 1$  and the initial state probability distribu-

tion is  $\boldsymbol{\pi} \in \Delta^{n_s-1}$ . If  $\mathfrak{X} = (\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_T)$  is a sequence of observations, then we define forward and backward variables as

$$\begin{aligned} \Pr\{\mathbf{x}_1, \dots, \mathbf{x}_t, q_t = j\} &= \alpha_t(j) \\ \Pr\{\mathbf{x}_{t+1}, \dots, \mathbf{x}_T, q_t = j\} &= \beta_t(j) \end{aligned} \quad (8)$$

These will help computing the probability of observations. For example,

$$f(\mathfrak{X}; [\mathbf{O}, \mathbf{T}, \boldsymbol{\pi}]) = \sum_{i=1}^{n_s} \sum_{j=1}^{n_s} \alpha_t(i) (\mathbf{T})_{ij} (\mathbf{O})_j^\top \mathbf{x}_t \beta_{t+1}(j) \quad (9)$$

for all  $1 \leq t \leq T$  (Levinson et al., 1983). Note that the values of function  $\alpha_t(\cdot)$  and  $\beta_t(\cdot)$  can be computed efficiently using dynamic programming.

Under mild conditions, HMM parameter estimation reduces to estimating multi-view model parameters, using considering triple of observation  $(\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3)$ .

**Proposition 3. (Anandkumar et al., 2012b)** *let  $h = q_2$  then:*

- $\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3$  are conditionally independent given  $h$ .
- The distribution of  $h$  is  $\mathbf{w} = \mathbf{T}\boldsymbol{\pi}$ .
- For all  $j \in \{1, 2, \dots, n_s\}$

$$\begin{aligned} \mathbb{E}[\mathbf{x}_1 | h = j] &= \mathbf{O} \text{diag}(\boldsymbol{\pi}) \mathbf{T}^\top \text{diag}(\mathbf{w})^{-1/2} \mathbf{e}_j \\ \mathbb{E}[\mathbf{x}_2 | h = j] &= \mathbf{O} \mathbf{e}_j \\ \mathbb{E}[\mathbf{x}_3 | h = j] &= \mathbf{O} \mathbf{T} \mathbf{e}_j \end{aligned}$$

under mild conditions.

Thus, provided that  $\mathbf{O}$  and  $\mathbf{T}$  both have full column rank, the parameters of HMM can be recovered as  $\mathbf{O} = \mathbf{U}^2$ ,  $\mathbf{T} = \mathbf{O}^+ \mathbf{U}^3$ , and  $\boldsymbol{\pi} = \mathbf{T}^{-1} \mathbf{w}$ .

It is also important to note that, using the above proposition and Equation (9) we can alternatively write each entries of tensor  $\mathcal{M} = \mathbb{E}(\mathbf{x}_1 \otimes \mathbf{x}_2 \otimes \mathbf{x}_3)$  as:

$$(\mathcal{M})_{ijk} = f((\mathbf{e}_i, \mathbf{e}_j, \mathbf{e}_k); [\mathbf{O}, \mathbf{T}, \boldsymbol{\pi}]). \quad (10)$$

### 3 EXTERIOR POINT METHODS

While exact parameters can be recovered from the population moments, in practice we work with empirical moments  $\hat{\mathcal{M}}$ , and  $\hat{\mathcal{M}}$  which are computed using a finite set of training data. Thus, the estimated parameters are not necessarily exact and do not necessarily minimize the estimation error  $\|\hat{\mathcal{M}} - \mathcal{H} \times_1 \mathbf{U}^1 \times_2 \mathbf{U}^2 \times_3 \mathbf{U}^3\|_F$ .

In this section, we show that estimated parameters from Section 2 can directly initialize an iterative exterior point method that minimizes the above error while obeying constraints on model parameters. Although this initial seed may violate these constraints, we show that under mild conditions the parameters satisfy the model constraints once

the algorithm converges. First, we prove the convergence of the algorithm for multi-view models and then show how the algorithm can be applied to HMMs.

### 3.1 MULTI-VIEW MODELS

Let  $\mathbf{v} \in \mathbb{R}^{n_s(3n_o+1)}$  be a vector comprised of the parameters of the multi-view model  $\{\mathbf{U}^1, \mathbf{U}^2, \mathbf{U}^3, \text{diag}(\mathcal{H})\}$ , and  $\mathcal{R}(\mathbf{v}) = (\hat{\mathcal{M}} - \mathcal{H} \times_1 \mathbf{U}^1 \times_2 \mathbf{U}^2 \times_3 \mathbf{U}^3)$  be the residual estimation tensor. For ease of notation, we also define function  $s(\cdot) : \mathbb{R}^{n_s(3n_o+1)} \rightarrow \mathbb{R}^{3n_s+1}$  that computes column sum of  $\mathbf{U}^1, \mathbf{U}^2, \mathbf{U}^3$ , and  $\text{diag}(\mathcal{H})$ . As discussed above, the estimated parameters in the previous section do not necessarily minimize the estimation error  $\|\mathcal{R}(\mathbf{v})\|_F$  and also may violate the constraints for the model parameters. With these limitations in mind, we rewrite the factorization in Equation (6) in the form of an optimization problem:

$$\begin{aligned} &\text{minimize } \frac{1}{2} \|\mathcal{R}(\mathbf{v})\|_F^2. \\ &\text{s.t. } \mathbf{v} \in \mathbb{R}_+^{n_s(3n_o+1)}, s(\mathbf{v}) = \mathbf{1} \end{aligned} \quad (11)$$

Defining optimization problem in this form has two advantages over maximum likelihood optimization schemes. First, since  $\hat{\mathcal{M}}$  is computed in the previous stage, the optimization cost is asymptotically independent of the number of training samples which makes the proposed optimization algorithm faster than EM for large training sets. Second, the value of this objective function  $\|\mathcal{R}(\mathbf{v})\|_F$  is also defined *outside* of the feasible set. We use this property to extend the optimization problem for a simple exterior point method in Section 3.1.1, below.

#### 3.1.1 The Optimization Algorithm

Instead of solving constrained optimization problem in Equation (11), we solve the following unconstrained optimization problem:

$$\begin{aligned} &\text{minimize } \frac{1}{2} \|\mathcal{R}(\mathbf{v})\|_F^2 + \frac{\lambda_1}{2} \|s(\mathbf{v}) - \mathbf{1}\|_p^2 \\ &\quad + \lambda_2 |\mathbf{v}|_-, \end{aligned} \quad (12)$$

where  $|\mathbf{v}|_-$  is the absolute sum of all negative elements in the vector  $\mathbf{v}$ , i.e.,  $|\mathbf{v}|_- = \sum_i |(\mathbf{v})_i|_-$ . We set  $p = 2$  in our method. For  $p = 1$ , there exists a  $\lambda_1$  and a  $\lambda_2$  such that the solution to this unconstrained optimization is *also* the solution to the objective in Equation (11). A thorough survey on solving non-differentiable exact penalty functions can be found in (Fletcher, 2013). Our approach, however, is different in the sense that for  $p = 2$  the solution of our optimization algorithm is not guaranteed to satisfy the constraints in Equation (11), however, we show in Theorem 7 that the solution will be arbitrarily close to the simplex. In return for this relaxation, the above optimization problem can be easily solved by a standard *forward-backward splitting* algorithm (Combettes and Pesquet, 2011). In this

---

**Algorithm 2** *The exterior point algorithm*

---

**Input:** Estimated third order moment  $\hat{\mathcal{M}}$ , initial point (obtained from Algorithm 1)  $\mathbf{v}^{(0)}$  is comprised of  $\{\hat{U}^1, \hat{U}^2, \hat{U}^3, \text{diag}(\hat{\mathcal{H}})\}$ , parameters  $\lambda_1$ , and  $\lambda_2$ , sequence  $\{\beta_k\}$ , and constant  $c > 0$   
**Output:** Convergence point  $\mathbf{v}^*$

---

```

k ← 0
while not converged do
  k ← k + 1
  if  $|\mathbf{v}^{(k-1)}|_- > 0$  then
     $\alpha_k \leftarrow \max\{c, \beta_k\}$ 
  else
     $\alpha_k \leftarrow \beta_k$ 
  end if
   $\tilde{\mathbf{v}}^{(k)} \leftarrow \mathbf{v}^{(k-1)} - \alpha_k \nabla g(\mathbf{v}^{(k-1)})$ 
   $\mathbf{v}^{(k)} \leftarrow \text{prox}(\tilde{\mathbf{v}}^{(k)})$  (see Equation (15))
end while

```

---

method, the function is split into a smooth part:

$$g(\mathbf{v}) = \frac{1}{2} \|\mathcal{R}(\mathbf{v})\|_F^2 + \frac{\lambda_1}{2} \|\mathbf{s}(\mathbf{v}) - \mathbf{1}\|_2^2 \quad (13)$$

and a non-smooth part  $\lambda_2 |\mathbf{v}|_-$ . We then minimize the objective function by alternating between a gradient step on the smooth part  $\nabla g(\mathbf{v})$  (forward) and proximal step of the non-smooth part (backward). The overall algorithm is shown in Algorithm 2 where  $\text{prox}(\tilde{\mathbf{v}}^{(k)})$  function is defined as

$$\mathbf{v}^{(k)} = \underset{\mathbf{y}}{\text{argmin}} (\alpha_k \lambda_2 |\mathbf{y}|_- + \frac{1}{2} \|\tilde{\mathbf{v}}^{(k)} - \mathbf{y}\|_F^2). \quad (14)$$

and optimized by following transformation (Shalev-Shwartz and Zhang, 2013):

$$(\mathbf{v}^{(k)})_i = \begin{cases} (\tilde{\mathbf{v}}^{(k)})_i + \alpha_k \lambda_2 & (\tilde{\mathbf{v}}^{(k)})_i < -\alpha_k \lambda_2 \\ 0 & -\alpha_k \lambda_2 \leq (\tilde{\mathbf{v}}^{(k)})_i < 0 \\ (\tilde{\mathbf{v}}^{(k)})_i & 0 \leq (\tilde{\mathbf{v}}^{(k)})_i \end{cases} \quad (15)$$

We only need to find the gradient of function  $g(\mathbf{v})$  for the given model parameter  $\mathbf{v}$ . Following lemma shows the gradient of  $g(\mathbf{v})$  can be computed efficiently.

**Lemma 4.** *Let  $r(\mathbf{v}) = \frac{1}{2} \|\mathcal{R}(\mathbf{v})\|_F^2$ . The following are true for all  $0 < i \leq n_s$ :*

- $\frac{\partial r(\mathbf{v})}{\partial \mathcal{H}_{iii}} = -\mathcal{R}(\mathbf{v}) \times_1 \mathbf{u}_i^1 \times_2 \mathbf{u}_i^2 \times_3 \mathbf{u}_i^3$
- $\nabla_{\mathbf{u}_i^1} r(\mathbf{v}) = -\mathcal{H}_{iii} \times \mathcal{R}(\mathbf{v}) \times_2 \mathbf{u}_i^2 \times_3 \mathbf{u}_i^3$
- $\nabla_{\mathbf{u}_i^2} r(\mathbf{v}) = -\mathcal{H}_{iii} \times \mathcal{R}(\mathbf{v}) \times_1 \mathbf{u}_i^1 \times_3 \mathbf{u}_i^3$
- $\nabla_{\mathbf{u}_i^3} r(\mathbf{v}) = -\mathcal{H}_{iii} \times \mathcal{R}(\mathbf{v}) \times_1 \mathbf{u}_i^1 \times_2 \mathbf{u}_i^2$

Next we show that by using the forward-backward splitting steps in Algorithm 2 there are lower bounds for  $\lambda_1$  and  $\lambda_2$  in which the iterative algorithm converges to a local optimum arbitrarily close to the simplex. For this purpose, we

assume that estimated parameters remain in a compact set during the optimization, then we use the following corollary to bound the gradient of function  $r(\mathbf{v})$ .

**Corollary 5.** *For every  $\mathbf{v}$  which is comprised of the multi-view parameters and is in the compact set  $\mathcal{F} = \{\mathbf{v} \mid \forall i, 0 < i \leq n_s, 1 < t \leq 3 : \|(\mathbf{U}^t)_i\|_2 \leq L, \|\text{diag}(\mathcal{H})\|_2 \leq L\}$ , every element of the gradient of the function  $r(\mathbf{v})$  is bounded as:*

$$\left| \frac{\partial r(\mathbf{v})}{\partial (\mathbf{v})_i} \right| \leq L^3 \|\mathcal{R}(\mathbf{v})\|_F \quad (16)$$

Although, the norm of the residual error can also be bounded by  $L$  in Equation (16), since we initiate the algorithm with method of moments estimation, its value remains considerably smaller than its upper bound during the iterative procedure in Algorithm 2. Let  $\Upsilon > \sup_k \|\mathcal{R}(\mathbf{v}^{(k)})\|_F$ ; the next lemma shows that for a large enough  $\lambda_2$  and after a fixed number of iterations, all of the elements in  $\mathbf{v}^{(k)}$  become non-negative.

**Lemma 6.** *Assuming that sequence  $\{\mathbf{v}^{(k)}\}$  produced by Algorithm 2 is in the set  $\mathcal{F}$ , and  $\lambda_2$  is selected such that:*

$$\lambda_2 > L^3 \Upsilon + \lambda_1 (\sqrt{n_o} L + 1), \quad (17)$$

*there is a constant  $K$  such that for  $k > K$  we have  $|\mathbf{v}^{(k)}|_- = 0$ . Also, for  $k > K$  the proximal operator in Algorithm 2 reduces to the orthogonal projection operator into the convex set  $\mathcal{C} = \mathbb{R}_+^{n_s(3n_o+1)}$ :*

$$\forall k > K : \text{prox}(\tilde{\mathbf{v}}^{(k)}) = \text{proj}_{\mathcal{C}}(\tilde{\mathbf{v}}^{(k)}) \quad (18)$$

The proof is provided in the Appendix. According to the above lemma, after  $K$  iterations of forward-backward splitting steps, all entries of  $\mathbf{v}^{(k)}$  have non-negative values and the optimization algorithm reduces to gradient projection steps (Bertsekas, 1999) into the set  $\mathbb{R}_+^{n_s(3n_o+1)}$  for optimizing non-convex function  $g(\mathbf{v})$ . There is a lot of research on the convergence guarantees of gradient projection methods for non-convex optimization with different line search algorithms (Bertsekas, 1999), which also can be used in Algorithm 2. The only requirement of our method is that stepsize  $\alpha_k$  should be strictly bounded away from zero for  $k \leq K$  which is guaranteed in Algorithm 2 by taking the  $\max\{c, \beta_k\}$  for  $k \leq K$  for an arbitrary constant  $c > 0$ . Finally, the following theorem shows that by choosing large enough  $\lambda_1$  and  $\lambda_2$ , the algorithm ends up with a solution arbitrarily close to the simplex.

**Theorem 7.** *For every  $\epsilon_1 > 0$ , set  $\lambda_1 > \frac{L^3 \Upsilon}{\epsilon_1}$  and  $\lambda_2 > L^3 \Upsilon + \lambda_1 (\sqrt{n_o} L + 1)$ , in Equation (12). For the convergence point of the sequence  $\{\mathbf{v}^{(k)}\} \subset \mathcal{F}$  which is generated by Algorithm 2 we have:*

$$|\mathbf{v}^*|_- = 0, \|\mathbf{s}(\mathbf{v}^*) - \mathbf{1}\|_2 \leq \epsilon_1$$

The proof of Theorem 7 is provided in the Appendix.

To summarize, we initiate our exterior point method with the result of the method of moments estimator in Sec-

tion 2.1. By choosing large enough  $\lambda_1$ , and  $\lambda_2$ , the convergence point of the exterior point method will be at a local optimum of  $g(\mathbf{v})$  with the constraint  $\mathbf{v} \in \mathbb{R}_+^{n_s(3n_o+1)}$  in which the column sum of parameters set is arbitrarily close to 1. It is important to note that the proven lower bounds for  $\lambda_1$ , and  $\lambda_2$  are sufficient condition for the convergence. In practice, cross-validation can find the best parameter to balance the speed of mapping to the simplex with optimizing the residual function.

### 3.2 HIDDEN MARKOV MODELS

In Section 2.2 we showed that method of moments parameter estimation for HMMs essentially reduces to parameter estimation of multi-view models. After finding parameters from the method of moments algorithm, Algorithm 2 can be used to further refine the solution. In order to use this algorithm, we just need to define the residual estimation term for HMMs, define the function  $g(\cdot)$ , and compute its gradient. Assuming the parameters of the HMM  $\mathbf{T}$ ,  $\mathbf{O}$ , and  $\boldsymbol{\pi}$  are as defined in Section 2.2, let vector  $\mathbf{z}$  be comprised of these parameters. Similar to the multi-view case when the estimated moments are not exact, the equality in Equation (10) does not hold, and we define the residual prediction error of the model for the triples  $(\mathbf{e}_i, \mathbf{e}_j, \mathbf{e}_k)$  as  $(\mathcal{R}(\mathbf{z}))_{ijk} = (\hat{\mathcal{M}})_{ijk} - f((\mathbf{e}_i, \mathbf{e}_j, \mathbf{e}_k); [\mathbf{O}, \mathbf{T}, \boldsymbol{\pi}])$ . Thus, the optimization problem is:

$$\text{minimize } g(\mathbf{z}) + \lambda_2 \|\mathbf{z}\|_-, \quad (19)$$

where  $g(\mathbf{z})$  is defined as:

$$g(\mathbf{z}) = \frac{1}{2} \|\mathcal{R}(\mathbf{z})\|_F^2 + \frac{\lambda_1}{2} \|\mathbf{s}(\mathbf{z}) - \mathbf{1}\|_2^2. \quad (20)$$

The following lemma shows that the gradient of the first term in above equation can be represented by forward and backward variables in Equation (8) efficiently.

**Lemma 8.** *Let  $r(\mathbf{z}) = \frac{1}{2} \|\mathcal{R}(\mathbf{z})\|_F^2$ , for all  $0 < a, b \leq n_s$  and  $0 < c \leq n_o$  following holds:*

- a.  $\frac{\partial r(\mathbf{z})}{\partial (\boldsymbol{\pi})_a} = \sum (\mathcal{R}(\mathbf{z}))_{ijk} (\mathbf{O})_a^\top \mathbf{x}_1 \beta_1(a)$
- b.  $\frac{\partial r(\mathbf{z})}{\partial (\mathbf{T})_{ab}} = \sum (\mathcal{R}(\mathbf{z}))_{ijk} \sum_{t=1}^2 \alpha_t(a) (\mathbf{O})_b^\top \mathbf{x}_{t+1} \beta_{t+1}(b)$
- c.  $\frac{\partial r(\mathbf{z})}{\partial (\mathbf{O})_{cb}} = \frac{1}{(\mathbf{O})_{cb}} \sum (\mathcal{R}(\mathbf{z}))_{ijk} \sum_{t: \mathbf{x}_t = \mathbf{e}_c} \alpha_t(b) \beta_t(b)$

where the outer sums are over  $0 < i, j, k < n_o$  and  $\mathbf{x}_1 = \mathbf{e}_i$ ,  $\mathbf{x}_2 = \mathbf{e}_j$ , and  $\mathbf{x}_3 = \mathbf{e}_k$  ( $\mathbf{e}_i$  is the  $i^{\text{th}}$  canonical basis).

To summarize: to estimate the parameters of a HMM, we initialize Algorithm 2 with the method of moments estimate of the parameters. Then, using lemma 8, we compute  $\nabla g(\mathbf{z})$  at each iteration to solve the optimization (Equation (19)).

## 4 EXPERIMENTAL RESULTS

We evaluate the performance of our proposed method (EX&SVD) on both synthetic and real world datasets. We compare our approach to several state-of-the-art alternatives including EM initialized with 10 random seeds (EM), EM initialized with the method of moments result described in Section 2 after projecting the estimated parameters into simplex (EM&SVD), and the recently published symmetric tensor decomposition method (STD) (Anandkumar et al., 2012b). To evaluate the performance gain due to exterior point algorithm, we also included results from method of moments without the additional optimization (SVD) Section 2.

To ensure a fair time comparison, all of the methods were implemented in Matlab. In all methods, the iteration was stopped whenever the change in  $\frac{obj^{(t-1)} - obj^{(t)}}{[avg(obj^{(t)}, obj^{(t-1)})]}$  was less than  $\delta$ . We set parameter  $\delta$  in EM-based approaches, and exterior point algorithm to  $10^{-4}$  (Murphy; Parikh et al., 2012), and  $10^{-3}$  respectively.

Parameters  $\lambda_1$ , and  $\lambda_2$  controls the speed of mapping parameters into the simplex while estimation error term is optimized simultaneously. We find the best parameters using cross-validation. In our experiments, we sample  $N$  training and  $M$  testing points from each model. For the evaluation we use  $M = 2000$  test samples and calculate normalized  $\ell_1$  error =  $\frac{1}{M} \sum_{i=1}^M \frac{|\mathbb{P}(X_i) - \hat{\mathbb{P}}(X_i)|}{\mathbb{P}(X_i)}$ .

We found that, empirically, spectral methods and exterior point algorithm outperform EM for small sample sizes. In these situations, we believe that EM is overfitting, resulting in poor performance on the test dataset. Similar results are also reported in (Parikh et al., 2012). As the number of training data points increases, EM begins to outperform the spectral methods. However, our experiments show that EX&SVD constantly outperforms other methods in terms of estimation error while remaining an order of magnitude faster than EM.

It is important to note that the gap between estimation error of EX&SVD and EM&SVD is considerably larger in the situations where the number of training data points is relatively small compared to the number of model parameters. In these situations, estimation error in the SVD method is not accurate and the error of projection into the simplex is relatively high in EM&SVD method. However, when the SVD parameter estimates are used to initialize our exterior point algorithm we get considerably better parameter estimates. When the SVD estimate of the parameters is accurate (due to the large training set and small number of parameters) EM&SVD and EX&SVD estimations are close to each other. We believe that this observation strongly supports our approach to use exterior point method to find a set of parameters in the valid set of models (rather than a naive projection).

## 4.1 MULTI-VIEW MODEL EXPERIMENTS

To test the performance of the proposed method on learning multi-view models in different settings, we generate observations from randomly sampled models. The first set of models has 5 hidden states and 10 discrete observations per view, and the second set of models has 10 hidden states and 20 observations per view.

Figure 3 shows the average error of the implemented algorithms run on 10 different datasets generated by *i.i.d* sampled models. Each dataset consisted of up to 100,000 triples of observations sampled from each model. We used log-log scale for better demonstration of results. In these experiments, EM is initialized with 10 different random seeds and the best model is reported. Both EM&SVD and EX&SVD are initialized with 1 sample from our SVD decomposition method. As discussed earlier, EM outperforms SVD and the tensor decomposition method with respect to estimation error as the number of training samples increases. However, both EX&SVD and EM&SVD outperform EM, which shows the effectiveness of using the method of moments result as an initial seed for optimization. The performance of the EX&SVD method is significantly better especially in the small sample size region where the method of moments result is far from the simplex and projection step in EM&SVD method change the value of initial seed a lot. As the number of training samples increases, the error induced by the projection decreases and the results of the two methods converge.

Comparing the results from the two model classes, we see that the difference between the performance of EX&SVD and other methods is more pronounced as the number of parameters increases. This is due to the fact that the error of SVD increases as the number of parameters increases; which, in turn, is due to poor population estimates of the moments. The error of projecting the SVD result into the simplex is also high in the EM&SVD method. As illustrated in Figure 3, the result of SVD is comparable to STD while SVD is orders of magnitude faster. Considering the large number of parameters in this experiment, it is not strange that both method of moments algorithms (STD and SVD) do not show a good performance, however, both EM&SVD and EX&SVD outperform EM which shows the method of moments estimation are a better initialization point than a random selection.

To study the performance of different methods under different parameter set sizes in more detail, we investigate the performance of the different algorithms in estimating parameters of models with different numbers of hidden states. To this end, we sample  $N = 4000$  training points from models with different numbers of hidden states and evaluate the performance of different method in estimating these models parameters. The average error of 10 independent runs is reported in figure 4 for different values of  $n_s$ . In

Figure 3: Error vs. #training (first column), and Time vs. #training (second column) for multi-view models.  $n_s = 5$ ,  $n_o = 10$  in the first row, and  $n_s = 10$ ,  $n_o = 20$  in the second row.

each case we set  $n_o$  to twice the value of  $n_s$ . As  $n_s$  increases, the number of model parameters also increases while the number of training points remains fixed. This results in the estimation error increasing as the models get larger for all of the methods. However, the difference between the performance of EX&SVD and other methods becomes more pronounced with  $n_s$ , which shows the effectiveness of our method in learning models with large state spaces and relatively smaller datasets.

Figure 4: Error vs.  $n_s$  (left), time vs.  $n_s$  (right) for multi-view model for #training = 4000.

## 4.2 HIDDEN MARKOV MODEL EXPERIMENTS

We also evaluate the performance of our algorithm by estimating the parameters of HMMs on synthetic and real-world datasets. Similar to the multi-view case, we randomly sample parameters from two different classes of models to generate synthetic datasets. The first set of models again has 5 hidden states and 10 discrete observations, and the second set of models has 10 hidden states and 20 observations. Figure 5 shows the average error of the implemented algorithms run on 10 different datasets generated by *i.i.d* sampled models. Each dataset consisted of

Figure 5: Error vs. #training (first column), and time vs. #training (second column) for HMM models.  $n_s = 5$ ,  $n_o = 10$  (first row), and  $n_s = 10$ ,  $n_o = 20$  (second row).

up to 100,000 triples of observations sampled from each model. Although, estimated parameters in the SVD method do not have good performance in terms of normalized  $l_1$  error, using them to initiate an iterative optimization procedure improves performance as demonstrated by both the EM&SVD and the EX&SVD methods. On the other hand, our algorithm can also outperform EM&SVD, especially in the low and medium sample size regions when the error of projection step is relatively high. For medium and large training set sizes, EM&SVD and EX&SVD are almost the same speed, and both are considerably faster than EM alone.

#### 4.2.1 Splice Dataset

In this experiment we consider the task of recognizing splice sites on a DNA sequence (Bache and Lichman, 2013). The dataset consist of 3190 examples. Each example is a sequence of 60 fields in which every field is filled by either A,T,C, or G. The label of each example could be Intron/Exon site, Exon/Intron site, or neither. For training, we train a HMM with  $n_s = 4$  for each class using different methods and use the rest of examples for testing. For each test example we compute the probability of the sequence for each model, and choose the label corresponding to the model with the highest test probability. For each test example in our method, we compute the histogram of triples in the test sequence, and choose the label corresponding to the model whose probability distribution over different triples has the lowest  $\ell_1$  distance to the computed histogram. This method of classification is a natural fit for our method, since our optimization method finds model parameters such that its probability distribution over different triples has minimum distance to the empirically estimated distribution of tripes  $\hat{\mathcal{M}}$ . Figure 6 shows the average classification error of each method for 10 randomly

Figure 6: Error vs. #training (left), time vs. #training (right) for splice dataset.

chosen training set with several different sized training sets. The results are consistent with the experiments on the synthetic datasets in terms of speed and accuracy, despite EM outperforms EM&SVD in real world dataset. However, our method performs considerably better than EM.

## 5 CONCLUSION

We present a new approach to learning latent variable models such as multi-view models and HMMs. Recent work on learning such models by method of moments has produced exciting theoretical results that explicitly bound the error in the learned model parameters. Unfortunately, these results have failed to translate into accurate and numerically robust algorithms in practice. In particular, the parameters learned by method of moments may lie outside of the feasible set of models. This is especially likely to happen when the population moments are estimated inaccurately from small quantities of training data. To overcome this problem, we propose a two-stage algorithm for learning the parameters of latent variable models. In the first stage, we learn an initial estimate of the parameters by method of moments. In the second stage, we use an exterior point algorithm that incrementally refines the solution until the parameters are at a local optima and arbitrarily close to valid model parameters. We prove convergence of the method and perform several experiments to compare our method to previous work. An empirical evaluation on both synthetic and real-world datasets demonstrates that our algorithm learns models that are generally more accurate than method of moments or EM alone. By elegantly contending with parameters that may be outside of the model class, we are able to learn models that are much more accurate than EM initialized with method of moments when only a limited amount of training data is available.

## Abstract

Causal inference is often phrased as a missing data problem – for every unit, only the response to observed treatment assignment is known, the response to other treatment assignments is not. In this paper, we extend the converse approach of [7] of representing missing data problems to causal models where only interventions on missingness indicators are allowed. We further use this representation to leverage techniques developed for the problem of identification of causal effects to give a general criterion for cases where a joint distribution containing missing variables can be recovered from data actually observed, given assumptions on missingness mechanisms. This criterion is significantly more general than the commonly used “missing at random” (MAR) criterion, and generalizes past work which also exploits a graphical representation of missingness. In fact, the relationship of our criterion to MAR is not unlike the relationship between the **ID** algorithm for identification of causal effects [22, 18], and conditional ignorability [13].

## 1 INTRODUCTION

Missing data is a ubiquitous problem in data analysis, and can arise due to imperfect data collection, or various types of censoring, for instance via loss to followup, or death. In addition, causal inference can be viewed as a missing data problem, since the fundamental problem of causal inference [4] is that for every unit only the response to observed treatment assignment is known, the responses to other, hypothetical treatment assignments are not known.

Handling missing data entails either dealing with a latent variable model or finding plausible assumptions under which *recoverability*, that is unbiased inferences about *all* cases from the *observed* cases, is possible. Well-known approaches of the former type include fitting a latent variable

model via gradient descent [17], the EM algorithm [1], or performing Monte Carlo averaging via multiple imputation [16]. Well-known approaches of the latter type include the Kaplan-Meier estimator in survival analysis [5], and adjustments based on Missing Completely At Random (MCAR), and Missing At Random (MAR) assumptions [15].

While methods based on inference in a latent variable model are more generally applicable, they are also methodologically and computationally challenging. At the same time, recoverability methods based on MCAR and MAR rely on strong assumptions on how missingness comes about. When neither MCAR nor MAR holds, data is said to be Missing Not At Random (MNAR), and in this case a characterization of recoverability is an open problem, although many sufficient conditions for recoverability are known [7, 6].

In this paper, we take the *converse* view to “causality as missing data,” and view missing data as a particular type of partly causal, and partly probabilistic inference problem [2, 7]. We then represent this problem using partly causal, and partly probabilistic graphical models, and exploit techniques developed for similar models in the context of identification of causal effects to develop a general algorithm for recoverability under MNAR. In fact, the relationship between our algorithm and MAR is not unlike the relationship between the **ID** algorithm for identification of causal effects [22, 18, 19], and the conditional ignorability assumption in causal inference [13].

The paper is organized as follows. We introduce the notation and concepts we will need in section 2. In section 3, we use missingness graphs and missingness models to formally define missing data as a type of causal inference problem where only interventions on certain variables are allowed. We introduce recoverability and give examples of where recoverability is possible in MNAR settings in section 4. We introduce a general algorithm for recoverability we call **MID** in section 5, and show it is sound. Section 6 illustrates a complex case where the entire recursive structure of **MID** is necessary. Section 7 discusses non-recoverability, and section 8 contains our conclusions.

## 2 PRELIMINARIES

Variables are capital letters, values are small letters. Variable sets are bold capital letters, value sets are bold small letters. A state space for a variable  $A$  is  $\mathfrak{X}_A$ . A state space for a set of variables  $\mathbf{A}$  is the Cartesian product of the individual state spaces:  $\mathfrak{X}_{\mathbf{A}} \equiv \times_{A \in \mathbf{A}} \mathfrak{X}_A$ . For a set of values  $\mathbf{a}$ , and  $\mathbf{B} \subseteq \mathbf{A}$ , denote by  $\mathbf{a}_{\mathbf{B}}$  a projection of  $\mathbf{a}$  to  $\mathbf{B}$ . Denote  $\mathbf{a}_{\mathbf{B}}$  as a shorthand for  $\mathbf{a}_{\{\mathbf{B}\}}$ . We will denote a vector of 0s as  $\mathbf{0}$ .  $\mathbf{0}_{\mathbf{B}}$  means “a set of 0 values to  $\mathbf{B}$ .”

### 2.1 GRAPH THEORY AND NOTATION

A directed graph consists of a set of nodes and directed arrows ( $\rightarrow$ ) connecting pairs of nodes. A mixed graph consists of a set of nodes and directed and/or bidirected arrows ( $\leftrightarrow$ ) connecting pairs of nodes. A path is a sequence of distinct edges where any edge in a sequence that ends in a node  $A$  implies the subsequent edge must start with  $A$ , and each such node  $A$  may only occur at most once in this way in the sequence. A directed path from a node  $X$  to a node  $Y$  is a path consisting of directed edges where all edges on the path point away from  $X$  and towards  $Y$ .

If the edge  $X \rightarrow Y$  exists in a graph  $\mathcal{G}$ , we say  $X$  is a parent of  $Y$  and  $Y$  is a child of  $X$ . If a directed path from  $X$  to  $Y$  exists in  $\mathcal{G}$ , we say  $X$  is an ancestor of  $Y$ , and  $Y$  is a descendant of  $X$ . We denote by  $\text{pa}_{\mathcal{G}}(A)$ ,  $\text{ch}_{\mathcal{G}}(A)$ ,  $\text{de}_{\mathcal{G}}(A)$ ,  $\text{an}_{\mathcal{G}}(A)$ ,  $\text{nd}_{\mathcal{G}}(A)$  the sets of parents, children, descendants, ancestors, and non-descendants of  $A$  in  $\mathcal{G}$ , respectively. These are defined disjunctively for sets, e.g.  $\text{pa}_{\mathcal{G}}(\mathbf{A}) = \bigcup_{A \in \mathbf{A}} \text{pa}_{\mathcal{G}}(A)$ . Let  $\text{fa}_{\mathcal{G}}(A) = \text{pa}_{\mathcal{G}}(A) \cup \{A\}$ ,  $\text{pa}_{\mathcal{G}}^s(\mathbf{A}) = \text{pa}_{\mathcal{G}}(\mathbf{A}) \setminus \mathbf{A}$ ,  $\text{ndp}_{\mathcal{G}}(A) = \text{nd}_{\mathcal{G}}(A) \setminus \text{pa}_{\mathcal{G}}(A)$ . Given a graph  $\mathcal{G}$ , we say a vertex set  $\mathbf{A}$  is *ancestral* if  $\text{an}_{\mathcal{G}}(\mathbf{A}) = \mathbf{A}$ . By convention, in any directed graph,  $A \in \text{an}_{\mathcal{G}}(A) \cap \text{de}_{\mathcal{G}}(A)$ . A directed graph is said to have a directed cycle if there is  $X, Y$  such that  $X \in \text{an}_{\mathcal{G}}(Y) \cap \text{ch}_{\mathcal{G}}(Y)$ . A directed graph without such cycles is called a directed acyclic graph (DAG).

A *conditional DAG* (CDAG)  $\mathcal{G}(\mathbf{V} \mid \mathbf{W})$  is a DAG with vertices  $\mathbf{V} \cup \mathbf{W}$  with the property that  $\text{pa}_{\mathcal{G}}(\mathbf{W}) = \emptyset$ . We will denote vertices in  $\mathbf{V}$  as circles, and vertices in  $\mathbf{W}$  as squares. Note that we do not require that all  $V \in \mathbf{V}$  must have parents. We simply distinguish certain parentless nodes in  $\mathcal{G}$  as  $\mathbf{W}$ . We will interpret vertices in  $\mathbf{V}$  as associated with *random variables* and vertices in  $\mathbf{W}$  as associated with variables that have been “set to a constant” in some way. One example of a CDAG is a *mutilated graph* that arises in the analysis of interventional distributions. When considering d-separation on vertices in  $\mathbf{V}$  in a CDAG [9], we will treat it as ordinary d-separation in a DAG, except all nodes in  $\mathbf{W}$  are implicitly conditioned on.

If vertices not in  $\mathbf{W}$  in a CDAG correspond to a variable partition into observed and missing variables, we will explicitly denote the set of vertices corresponding to miss-

ing variables as  $\mathbf{M}$ , and the other vertices as  $\mathbf{O}$ , like so:  $\mathcal{G}(\mathbf{O}, \mathbf{M} \mid \mathbf{W})$ . A CDAG where  $\mathbf{W}$  is empty is written as  $\mathcal{G}(\mathbf{V})$  or  $\mathcal{G}(\mathbf{O}, \mathbf{M})$  as a shorthand.

A conditional acyclic directed mixed graph (CADMG)  $\mathcal{G}(\mathbf{V} \mid \mathbf{W})$  is a mixed graph with two types of edges  $\rightarrow$  and  $\leftrightarrow$  with no directed cycles, where no arrowhead may point to an element of  $\mathbf{W}$ . We will sometimes omit variables from CDAGs and CADMGs if they are obvious to avoid notation clutter, e.g. we will write  $\mathcal{G}(\mathbf{V} \mid \mathbf{W})$  simply as  $\mathcal{G}$ . Given a CDAG  $\mathcal{G}(\mathbf{O}, \mathbf{M} \mid \mathbf{W})$ , define  $\mathcal{G}_{\mathbf{B}}(\mathcal{G})$  to be an edge subgraph obtained from  $\mathcal{G}$  by removing all arrows pointing away from  $\mathbf{B}$ .

Define a *latent projection* of  $\mathcal{G}(\mathbf{O}, \mathbf{M} \mid \mathbf{W})$  onto  $\mathbf{O} \cup \mathbf{W}$  [23] to be a CADMG  $\mathcal{G}_{(\mathbf{O})}(\mathbf{O}, \mathbf{M} \mid \mathbf{W}) \equiv \mathcal{G}^{\dagger}(\mathbf{O} \mid \mathbf{W})$  such that for any  $V_1, V_2 \in \mathbf{O} \cup \mathbf{W}$ :

- There is an edge  $V_1 \rightarrow V_2$  if and only if there is a directed path  $V_1 \rightarrow \dots \rightarrow V_2$  in  $\mathcal{G}(\mathbf{O}, \mathbf{M} \mid \mathbf{W})$  with all intermediate nodes in  $\mathbf{M}$ .
- There is an edge  $V_1 \leftrightarrow V_2$  if and only if there is a marginally d-connected path  $V_1 \leftarrow \dots \rightarrow V_2$  in  $\mathcal{G}(\mathbf{O}, \mathbf{M} \mid \mathbf{W})$  with all intermediate nodes in  $\mathbf{M}$ .

Latent projections are a simplified representation of an infinitely large class of hidden variable CDAGs with structural features in common. In this paper, we use them only to simplify the statements and proofs of our results. The results themselves will always be about models represented by DAGs (and CDAGs).

Given a CDAG  $\mathcal{G}(\mathbf{V} \mid \mathbf{W})$ , and  $\mathbf{A} \subseteq \mathbf{V} \cup \mathbf{W}$ , define  $\mathcal{G}_{\mathbf{A}}(\mathbf{V} \mid \mathbf{W}) \equiv \mathcal{G}(\mathbf{V} \cap \mathbf{A} \mid \mathbf{W} \cap \mathbf{A})$  be a subgraph of  $\mathcal{G}$  containing the vertex set  $\mathbf{A}$  and any edge in  $\mathcal{G}$  between elements in  $\mathbf{A}$ .

Given a CADMG  $\mathcal{G}(\mathbf{V} \mid \mathbf{W})$ , and  $V \in \mathbf{V}$ , define the *district* (or *c-component* [22, 18]) of  $V$  in  $\mathcal{G}(\mathbf{V} \mid \mathbf{W})$  to be  $\text{dis}_{\mathcal{G}}(V) = \{A \in \mathbf{V} \mid V \leftrightarrow \dots \leftrightarrow A\}$ . The set of districts of  $\mathcal{G}(\mathbf{V} \mid \mathbf{W})$  is denoted by  $\mathcal{D}(\mathcal{G}(\mathbf{V} \mid \mathbf{W}))$ , and it partitions  $\mathbf{V}$ .

For any  $V \in \mathbf{O}$  in a CDAG  $\mathcal{G}(\mathbf{O}, \mathbf{M} \mid \mathbf{W})$  where for every  $M \in \mathbf{M}$ ,  $\text{de}_{\mathcal{G}}(M) \cap \mathbf{O} \neq \emptyset$ , define the *clan* of  $V$  as  $\text{cl}_{\mathcal{G}}(V) \equiv \text{an}_{\mathcal{G}_{\mathbf{D}_{\mathbf{V} \cup \mathbf{M}}}}(\mathbf{D}_V)$ , where  $\mathbf{D}_V = \text{dis}_{\mathcal{G}_{(\mathbf{O})}}(V)$ . For example, in  $\mathcal{G}$  shown in Fig. 1 (c), where  $\{X, W\}$  are missing,  $\text{cl}_{\mathcal{G}}(R_X) = \text{cl}_{\mathcal{G}}(S_W) = \{W, R_X, S_W\}$ , and  $\text{cl}_{\mathcal{G}}(R_W) = \text{cl}_{\mathcal{G}}(S_X) = \{X, R_W, S_X\}$ .

For any  $\mathbf{D} \in \mathcal{D}(\mathcal{G}_{(\mathbf{O})}(\mathbf{O}, \mathbf{M} \mid \mathbf{W}))$ , and  $D_1, D_2 \in \mathbf{D}$ ,  $\text{cl}_{\mathcal{G}}(D_1) = \text{cl}_{\mathcal{G}}(D_2)$ . Thus we will write  $\text{cl}_{\mathcal{G}}(\mathbf{D}) \equiv \text{cl}_{\mathcal{G}}(D)$ , for any  $D \in \mathbf{D}$ . In fact, the set of clans partitions  $\mathbf{O} \cup \mathbf{M}$  in  $\mathcal{G}$  with the property above.

Given a CDAG  $\mathcal{G}$ , a total ordering  $\prec$  on vertices in  $\mathcal{G}$  is *topological given  $\mathcal{G}$*  if  $A \prec B$  implies  $A \notin \text{de}_{\mathcal{G}}(B)$ . Given an ordering  $\prec$  topological given  $\mathcal{G}$ , define for any vertex  $V$

in  $\mathcal{G}$ ,  $\text{pre}_{\mathcal{G}, \prec}(V) = \{W \neq V \mid W \prec V\}$ . Given  $\prec$  topological for  $\mathcal{G}$  with a vertex set  $\mathbf{V}$ , if there is a subgraph  $\mathcal{G}'$  of  $\mathcal{G}$  with a vertex set  $\mathbf{V}' \subset \mathbf{V}$ , we will view  $\prec$  with respect to  $\mathcal{G}'$  as the natural subordering restricted to  $\mathbf{V}'$ . Note that this subordering will also be topological with respect to  $\mathcal{G}'$ .

A counterfactual (potential outcome)  $Y(\mathbf{a})$  [8, 14] is a response  $Y$  to a hypothetical assignment of a set of treatments  $\mathbf{A}$  to values  $\mathbf{a}$ . Given a set of potential outcomes  $Y_1(\mathbf{a}), \dots, Y_k(\mathbf{a})$ , where  $\mathbf{Y} = \{Y_1, \dots, Y_k\}$ , we may consider a joint distribution

$$p(\{Y_1, \dots, Y_k\}(\mathbf{a})) \equiv p(\mathbf{Y}(\mathbf{a})) \equiv p(\mathbf{Y} \mid \text{do}(\mathbf{a})).$$

The  $\text{do}(\cdot)$  notation is discussed extensively in [10].

### 3 MISSING GRAPHS AND MISSINGNESS MODELS

Given a CDAG  $\mathcal{G}(\mathbf{V} \mid \mathbf{W})$ , we say  $p_{\mathbf{W}}(\mathbf{V})$  (a mapping from  $\mathfrak{X}_{\mathbf{W}}$  to  $p(\mathbf{V})$ ) is Markov relative to  $\mathcal{G}$  if

$$p_{\mathbf{W}}(\mathbf{V}) = \prod_{V \in \mathbf{V}} p_{\mathbf{W}}(V \mid \text{pa}_{\mathcal{G}}(V) \setminus \mathbf{W}), \quad (1)$$

and each term  $p_{\mathbf{W}}(V \mid \text{pa}_{\mathcal{G}}(V) \setminus \mathbf{W})$  only depends on  $\mathbf{W} \cap \text{pa}_{\mathcal{G}}(V)$ .

**Definition 1 (missingness graph)** *Given a DAG  $\mathcal{G}(\mathbf{O}, \mathbf{M})$ , a DAG  $\mathcal{G}^m$  is called a missingness graph for  $\mathcal{G}$  if  $\mathcal{G}^m$  has the vertex set  $\mathbf{O} \cup \mathbf{M} \cup \mathbf{R}_{\mathbf{M}} \cup \mathbf{S}_{\mathbf{M}}$ , where  $\mathbf{R}_{\mathbf{M}} = \{R_M \mid M \in \mathbf{M}\}$ ,  $\mathbf{S}_{\mathbf{M}} = \{S_M \mid M \in \mathbf{M}\}$ ,  $\mathcal{G} = \mathcal{G}_{\mathbf{O} \cup \mathbf{M}}^m$ , and for all  $M$  in  $\mathbf{M}$ ,  $\text{pa}_{\mathcal{G}^m}(S_M) = \{M, R_M\}$ ,  $\text{ch}_{\mathcal{G}^m}(S_M) = \emptyset$ , and  $\text{ch}_{\mathcal{G}^m}(R_M) \cap (\mathbf{O} \cup \mathbf{M}) = \emptyset$ .*

By convention, if  $\mathbf{M} = \emptyset$ , then  $\mathbf{S}_{\emptyset} = \mathbf{R}_{\emptyset} = \emptyset$ . We will refer to  $\mathbf{O} \cup \mathbf{R}_{\mathbf{M}} \cup \mathbf{S}_{\mathbf{M}}$  as  $\mathbf{V}$ , and to  $\mathbf{V} \cup \mathbf{M}$  as  $\mathbf{A}$ . We call elements of  $\mathbf{R}_{\mathbf{M}}$  indicators, and elements of  $\mathbf{S}_{\mathbf{M}}$  proxies.

Define  $\mathcal{M}(\mathcal{G}^m(\mathbf{A}))$  to be the *missingness model* for a missingness graph  $\mathcal{G}^m(\mathbf{A})$  as a set of distributions  $\{p(\mathbb{A})\}$  over the following set of counterfactuals  $\mathbb{A} \equiv \{\mathbf{A}(\mathbf{r}) \mid \mathbf{R} \subseteq \mathbf{R}_{\mathbf{M}}, \mathbf{r} \in \mathfrak{X}_{\mathbf{R}}\}$ , such that  $(\forall M \in \mathbf{M}) \mathfrak{X}_{R_M} = \{0, 1\}$ ,  $\mathfrak{X}_{S_M} = \mathfrak{X}_M \cup \{\text{missing}\}$ , and the missingness mechanism that determines the value of  $S_M$  is as follows:  $S_M(0_{R_M}) = M$  and  $S_M(1_{R_M}) = \text{missing}$ . In addition:  $(\forall \mathbf{R} \subseteq \mathbf{R}_{\mathbf{M}}, \mathbf{r} \in \mathfrak{X}_{\mathbf{R}}, V \in \mathbf{A})$ ,

$$V(\mathbf{r}) \perp\!\!\!\perp \{\text{ndp}_{\mathcal{G}^m_{\mathbf{R}}}(V)\}(\mathbf{r}) \mid \{\text{pa}_{\mathcal{G}^m_{\mathbf{R}}}(V)\}(\mathbf{r}). \quad (2)$$

To obtain the set  $\mathbb{A}$ , we first define

$$\{\mathbf{A}(\mathbf{r}) \mid \mathbf{r} \in \mathfrak{X}_{\mathbf{R}_{\mathbf{M}}}\} \equiv \{\mathbf{S}_{\mathbf{M}}(\mathbf{r}), \mathbf{O}, \mathbf{M} \mid \mathbf{r} \in \mathfrak{X}_{\mathbf{R}_{\mathbf{M}}}\},$$

and obtain the others via modified recursive substitution as in definition 43 in [11], pp. 100-101.

A missingness model is thus really a particular type of a graphical causal model where we only define interventions on a subset of variables [11]. In particular, we allow

$\mathcal{G}(\mathbf{O}, \mathbf{M})$  to represent an ordinary hidden variable statistical model. (2) is just the DAG local Markov property linking  $p(\mathbf{A}(\mathbf{r}))$  and  $\mathcal{G}_{\mathbf{R}}^m$ , for every  $\mathbf{r}$ . If we had chosen to split variables in  $\mathbf{R}$  into random and intervened versions, and display both explicitly in the graph rather than only displaying the random version of variables, and keeping intervened versions implicit, as we do in  $\mathcal{G}_{\mathbf{R}}^m$ , we would end up with Single World Intervention Graphs (SWIGs), and the appropriate local Markov property for those graphs, as discussed in [11].

Standard results on DAG models imply (2) is equivalent to (1) for  $p(\mathbf{A}(\mathbf{r}))$  and  $\mathcal{G}_{\mathbf{R}}^m$  (if we let  $\mathbf{W} = \emptyset$ , and keep fixed versions of  $\mathbf{R}$  implicit in the graph). We may also let  $\mathbf{W} = \mathbf{R}$ , and treat  $\mathbf{R}$  as a split node as in a SWIG.

### 4 RECOVERABILITY

We call  $p(\mathbf{V})$  the *manifest distribution*. A functional of  $p(\mathbb{A})$ ,  $f(p(\mathbb{A}))$  is said to be *recoverable* given  $p(\mathbf{V})$  in  $\mathcal{G}^m$  if there is a functional  $g$  of  $p(\mathbf{V})$ , such that  $f(p(\mathbb{A})) = g(p(\mathbf{V}))$  for every element of  $\mathcal{M}(\mathcal{G}^m)$ . In this paper, we will concentrate on recoverability of  $p(\mathbf{O} \cup \mathbf{M})$ , although many other kinds of recoverability problems are also interesting, for instance recovering the causal effect in a causal model with missingness.

We explicitly represent missingness as a causal inference problem because this allows us to rephrase recoverability as identifiability of causal effects. If we were allowed to assign  $\mathbf{R}_{\mathbf{M}}$  without affecting other variables, we could use proxies  $\mathbf{S}_{\mathbf{M}}$  to recover the behavior of the underlying missing variables  $\mathbf{M}$ , due to the following result.

**Lemma 1** *In a DAG  $\mathcal{G}$  where  $\mathbf{M} \neq \emptyset$ , for any  $p(\mathbb{A}) \in \mathcal{M}(\mathcal{G}^m(\mathbf{V}, \mathbf{M}))$ , and  $R_M \in \mathbf{R}_{\mathbf{M}}$ ,  $p(\mathbb{Y}) \in \mathcal{M}(\mathcal{G}^m(\mathbf{V} \cup \{M\}, \mathbf{M} \setminus \{M\})_{\mathbf{V} \cup \mathbf{M} \setminus \{S_M, R_M\}})$ , where  $\mathbb{Y}$  is*

$$\{\{\mathbf{V} \cup \mathbf{M} \setminus \{R_M\}\}(\mathbf{r}, 0_{R_M}) \mid \mathbf{R} \subseteq \mathbf{R}_{\mathbf{M} \setminus \{M\}}, \mathbf{r} \in \mathfrak{X}_{\mathbf{R}}\}.$$

*Proof:*  $\{\mathbf{V} \cup \mathbf{M}\}(\mathbf{r}, 0_{R_M})$  obeys (2) for  $\mathcal{G}_{\mathbf{R} \cup \{R_M\}}^m$ . Since  $\mathbf{A} \setminus \{R_M\}$  is ancestral in  $\mathcal{G}_{\mathbf{R} \cup \{R_M\}}^m$ ,  $\{\mathbf{V} \cup \mathbf{M} \setminus \{R_M\}\}(\mathbf{r}, 0_{R_M})$  obeys (2) for  $(\mathcal{G}_{\mathbf{R} \cup \{R_M\}}^m)_{\mathbf{A} \setminus \{R_M\}}$ . Our conclusion follows since  $M = S_M(0_{R_M})$ .  $\square$

In other words, fixing  $R_M$  to 0 gives a new model where  $M$  is effectively observed since  $M = S_M(0_{R_M})$ . This implies that if we were able to fix all of  $\mathbf{R}_{\mathbf{M}}$ , we could recover  $p(\mathbf{O} \cup \mathbf{M})$ .

**Corollary 1**  $p(\{\mathbf{O}, \mathbf{S}_{\mathbf{M}}\}(\mathbf{0}_{\mathbf{R}_{\mathbf{M}}})) = p(\mathbf{O} \cup \mathbf{M})$  for any  $\mathcal{G}^m$ , and any  $p(\mathbb{A}) \in \mathcal{M}(\mathcal{G}^m)$ .

This corollary implies that our recoverability problem is solved by expressing a particular interventional distribution

as a function of the manifest in a restricted causal model. We will attack this problem via two standard results for causal models that hold in restricted causal models as well, as shown in [11], propositions 45 and 46.

**Theorem 1** For any  $p(\mathbb{A}) \in \mathcal{M}(\mathcal{G}^m(\mathbf{V}, \mathbf{M}))$ , and  $(\forall \mathbf{R} \subseteq \mathbf{R}_M, \mathbf{r} \in \mathfrak{X}_R)$ ,

$$p(\mathbf{A}(\mathbf{r})) = \prod_{V \in \mathbf{A}} p(V \mid \text{pa}_{\mathcal{G}^m}(V) \setminus \mathbf{R}, \mathbf{r}_{\text{pa}_{\mathcal{G}^m}(V) \cap \mathbf{R}}). \quad (3)$$

**Theorem 2** For any  $p(\mathbb{A}) \in \mathcal{M}(\mathcal{G}^m(\mathbf{V}, \mathbf{M}))$ , and  $(\forall \mathbf{R} \subseteq \mathbf{R}_M, \mathbf{r} \in \mathfrak{X}_R)$ ,

$$p(\{(\mathbf{V} \cup \mathbf{M}) \setminus \mathbf{R}\}(\mathbf{r}) \mid \mathbf{r}) = p((\mathbf{V} \cup \mathbf{M}) \setminus \mathbf{R} \mid \mathbf{r}). \quad (4)$$

(3) is known as the truncated factorization [10], manipulated distribution [21], or the g-formula [12]. (4) is known as the *consistency* property.

We now illustrate how constraints of the missingness model encoded by  $\mathcal{G}^m$ , as well as (3) and (4) lead to recoverability.

#### 4.1 EXAMPLES OF RECOVERABILITY

Consider Fig. 1, where  $X, C, W$  may possibly be high-dimensional. In Fig. 1 (a),  $X$  is missing according to a mechanism governed by an independent proxy  $R_X$ , so

$$p(X) = p(S_X(0_{R_X})) = p(S_X \mid R_X = 0).$$

The assumption present in this model which allows us to recover the underlying missing variable, namely  $(S_X(0_{R_X}) \perp\!\!\!\perp R_X)$  is known as *missing completely at random* (MCAR) assumption.<sup>1</sup> This assumption is the missingness analogue of *ignorability* (lack of confounding between the missingness indicator  $R_X$  and the proxy  $S_X(r)$  under assignment  $r$  to  $R_X$ ).

In Fig. 1 (b),  $X$  is missing according to a mechanism governed by a proxy  $R_X$  which has a (statistical) dependence on  $X$  through  $C$ , which is a fully observed variable. In this case,

$$p(X, C) = p(S_X(0_{R_X}) \mid C)p(C) = p(S_X \mid R_X = 0, C)p(C).$$

The assumption present in this model which allows us to recover the underlying missing variable, namely  $(S_X(0_{R_X}) \perp\!\!\!\perp R_X \mid C)$  is known as the *missing at random* (MAR) assumption. This assumption is the missingness analogue of *conditional ignorability* (lack of confounding between the indicator  $R_X$  and the proxy  $S_X(r)$  under assignment  $r$  to  $R_X$  given that we conditioned on a set of variables  $C$ ).

In Fig. 1 (c), it is not the case that

$$\{S_W(0_{R_W}), S_X(0_{R_X})\} \perp\!\!\!\perp \{R_X, R_W\}.$$

<sup>1</sup>  $\perp\!\!\!\perp$  is the independence symbol.

Figure 1: (a) A missingness model satisfying the *missing completely at random* (MCAR) assumption. (b) A missingness model satisfying the *missing at random* (MAR) assumption. (c) A missingness model where missingness is *not at random* (MNAR), but where recoverability is nevertheless possible.

That is, data on  $X, W$  is not missing completely at random (nor at random, since there is no fully observed variable to screen off the dependence of proxies under indicator assignment from indicators.) Nevertheless, despite the fact that data on  $p(X, W)$  is missing not at random (MNAR), we now show that  $p(X, W)$  is recoverable. We will exploit the fact that the missingness model implies

$$\{S_W(0_{R_W}), R_X(0_{R_X})\} \perp\!\!\!\perp \{S_X(0_{R_X}), R_W\}. \quad (5)$$

It is not difficult to show that  $p(R_W, R_X, S_W, S_X)$  is equal to

$$p(\{S_W, R_X\}(R_W)) \cdot p(S_X(R_X), R_W) = (p(S_W \mid R_X, R_W)p(R_X \mid R_W)) \cdot (p(S_X \mid R_X, R_W)p(R_W))$$

This implies  $p(X, W) = p(X)p(W)$  is equal to

$$\left( \sum_{R_X} p(\{S_W, R_X\}(0_{R_W})) \right) \cdot \left( \sum_{R_W} p(S_X(0_{R_X}), R_W) \right) = p(S_W \mid 0_{R_W}) \cdot \left( \sum_{R_W} p(S_X \mid 0_{R_X}, R_W)p(R_W) \right)$$

The key to this example is the joint independence (5); independences of this type arise in hidden variable DAG models. We give an example later where recoverability is based not on an ordinary independence, but on a generalized independence, or Verma constraint [23, 20]. In the following sections, we give a general recursive scheme for solving recoverability problems under MNAR using these types of constraints.

#### 4.2 KNOWN RESULTS FOR MISSINGNESS GRAPHS

Recently [7] and [6] have used missingness graphs to derive conditions for recoverability when data is MNAR. In particular, the following characterization appears in [7] (as theorem 2).

**Theorem 3** For any  $p(\mathbb{A}) \in \mathcal{M}(\mathcal{G}^m(\mathbf{V}, \mathbf{M}))$ , if no elements of  $\mathbf{R}_M$  are adjacent in  $\mathcal{G}^m(\mathbf{V}, \mathbf{M})$ , then  $p(\mathbf{O} \cup \mathbf{M})$  is recoverable from  $p(\mathbf{O}, \mathbf{S}_M, \mathbf{0}_{\mathbf{R}_M})$  if and only if  $M \notin \text{pa}_{\mathcal{G}}(R_M)$  for any  $M \in \mathbf{M}$ . Moreover,  $p(\mathbf{O} \cup \mathbf{M})$  is equal to

$$\frac{p(\mathbf{O}, \mathbf{S}_M, \mathbf{0}_{\mathbf{R}_M})}{\prod_{R_M \in \mathbf{R}_M} p(0_{R_M} \mid \text{pa}_{\mathcal{G}}(R_M) \setminus \mathbf{M}, \mathbf{S}_{\text{pa}_{\mathcal{G}}(R_M) \cap \mathbf{M}}, \mathbf{0}_{\text{pa}_{\mathcal{G}}(R_M) \cap \mathbf{M}})}$$

This result can be generalized in three directions. We may consider cases where variables are unobserved and no missingness mechanism exists. We may consider recoverability of other queries than  $p(\mathbf{O} \cup \mathbf{M})$ , for instance causal effects or marginal distributions. Finally, we may consider cases where elements of  $\mathbf{R}_M$  are adjacent. This case is important because it represents important classes of missingness such as monotonic missingness due to loss to followup. A unit that drops out of a longitudinal study at time  $t$  often remains dropped out at times  $t+1, \dots$ . In our framework, we would code this by requiring that for all  $t' > t$ ,  $R_{M_{t'}} = 1$  if  $R_{M_{t'-1}} = 1$ , where  $M_t$  is unit's status at time  $t$ . But this coding is only possible if indicators are allowed to be adjacent in the graph. In addition, allowing indicators to be adjacent allows us to model *non-monotone missing data*, where a unit may be missing at a particular time  $t$ , but then becomes observed at a later time  $t+k$ .

In this paper, we consider the problem of recovering  $p(\mathbf{O} \cup \mathbf{M})$  given that every missing variable has an indicator and a proxy (e.g. no completely hidden variables), and that indicators  $\mathbf{R}_M$  are allowed to be adjacent. We give a recoverability algorithm that generalizes earlier work in this setting.

## 5 A GENERAL RECOVERABILITY ALGORITHM

The algorithm, which we call **MID**, work as follows. It tries, for every  $R_M \in \mathbf{R}_M$ , to recover

$$p(0_{R_M} \mid \text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{R}_M, \mathbf{0}_{\text{pa}_{\mathcal{G}^m}(R_M) \cap \mathbf{R}_M})$$

via a subroutine **DIR**. If every such conditional distribution is recovered, **MID** recovers  $p(\mathbf{O} \cup \mathbf{M})$  via (3), otherwise **MID** fails.

The subroutine **DIR** (so named for its resemblance to the way the **ID** algorithm operates when identifying controlled direct effects) has three cases. The first case, which is sufficient for obtaining the soundness part of Theorem 3, attempts to check if indicators for missing parents of  $R_M$  are non-parental non-descendants of  $R_M$ , in which case recoverability of the conditional distribution for  $R_M$  is immediate.

Otherwise, **DIR** uses the other two cases to isolate  $R_M$  and its parents into smaller subproblems based on a particular type of ancestral set  $\mathbf{A}^\dagger$ , or the clan  $\mathbf{D}^\dagger$  of  $R_M$ . **DIR**

is recursive, which means the input must also keep track of a set  $\mathbf{W}$  representing variables the clan subproblem ends up depending on.

The situation is somewhat analogous to the way in which the **ID** algorithm attempts to identify controlled direct effects  $p(Y \mid \text{do}(\mathbf{v}_{\text{pa}_{\mathcal{G}}(Y)})) = p(Y(\mathbf{v}_{\text{pa}_{\mathcal{G}}(Y)}))$ , with three major differences. First, we are attempting identification in a setting where some variables start off being treated as hidden, but in the course of the recursion of **DIR** become observed due to fixing indicators to 0. In **ID** variables are always either hidden or observed and do not change status. Second, since we are only allowed to intervene on indicators, we are attempting to identify

$$p(R_M(\mathbf{0}_{\mathbf{R}_M \cap \text{pa}_{\mathcal{G}}(R_M)} \mid \{\text{pa}_{\mathcal{G}}(R_M) \setminus \mathbf{R}_M\}(\mathbf{0}_{\mathbf{R}_M \cap \text{pa}_{\mathcal{G}}(R_M)}))).$$

Finally, there is not necessarily a fully interventional interpretation for the intermediate objects  $p_{\mathbf{W}}(\cdot)$  that arise during the execution of **DIR**, since  $\mathbf{W}$  may contain elements outside  $\mathbf{R}_M$ . This is a necessary consequence of our insistence on not imposing a causal model on  $p(\mathbf{M} \cup \mathbf{O})$ . Intermediate objects that arise during the execution of **ID** can always be interpreted as interventional distributions.

### 5.1 SOUNDNESS

**MID** and its subroutine **DIR** appear below as algorithm 1. In this section, we prove that **MID** is sound.

Corollary 1 implies that if we were able to express  $p(\{\mathbf{O}, \mathbf{S}_M\}(\mathbf{0}_{\mathbf{R}_M}))$  as a function of the manifest distribution, we would solve the recoverability problem for  $p(\mathbf{O} \cup \mathbf{M})$ . If we happen to know

$$p(0_{R_M} \mid \text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{R}_M, \mathbf{0}_{\text{pa}_{\mathcal{G}^m}(R_M) \cap \mathbf{R}_M})$$

for every  $R_M \in \mathbf{R}_M$  as a function of the manifest, this would suffice due to the following result.

**Lemma 2** Under  $\mathcal{M}(\mathcal{G}^m)$ , if for every  $R_M \in \mathbf{R}_M$ ,

$$p(0_{R_M} \mid \text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{R}_M, \mathbf{0}_{\text{pa}_{\mathcal{G}^m}(R_M) \cap \mathbf{R}_M})$$

is a functional  $f_{R_M}(\cdot)$  of  $p(\mathbf{O}, \mathbf{S}_M, \mathbf{0}_{\mathbf{R}_M})$ , then

$$p(\{\mathbf{O}, \mathbf{S}_M\}(\mathbf{0}_{\mathbf{R}_M})) = \frac{p(\mathbf{O}, \mathbf{S}_M, \mathbf{0}_{\mathbf{R}_M})}{\prod_{R_M \in \mathbf{R}_M} f_{R_M}(p(\mathbf{O}, \mathbf{S}_M, \mathbf{0}_{\mathbf{R}_M}))}.$$

*Proof:*  $p(\{\mathbf{O}, \mathbf{S}_M\}(\mathbf{0}_{\mathbf{R}_M})) = \sum_{\mathbf{M}} p(\{\mathbf{A} \setminus \mathbf{R}_M\}(\mathbf{0}_{\mathbf{R}_M}))$ .

$$p(\{\mathbf{A} \setminus \mathbf{R}_M\}(\mathbf{0}_{\mathbf{R}_M})) = \frac{p(\mathbf{A} \setminus \mathbf{R}_M, \mathbf{0}_{\mathbf{R}_M})}{\prod_{R_M \in \mathbf{R}_M} f_{R_M}(p(\mathbf{O}, \mathbf{S}_M, \mathbf{0}_{\mathbf{R}_M}))}$$

is implied by (3). But no denominator is a function of  $\mathbf{M}$ , so we can apply the sum to the numerator first.  $\square$  Finding functionals  $f_{R_M}(\cdot)$  for every  $R_M$  in order to apply Lemma 2 is the job of the subroutine **DIR**.

**Algorithm 1**  $\mathcal{G}^m(\mathbf{V}, \mathbf{M})$  a missingness graph,  $p(\mathbf{V})$  a manifest distribution from  $p(\mathbb{A}) \in \mathcal{M}(\mathcal{G}^m(\mathbf{V}, \mathbf{M}))$ ,  $p_{\mathbf{W}}(\mathbf{V})$  a family of manifest distributions from elements of  $p(\mathbb{A}) \in \mathcal{M}(\mathcal{G}^m(\mathbf{V}, \mathbf{M}))$ ,  $\prec$  a topological order on  $\mathcal{G}^m$ .

**procedure** MID( $\mathcal{G}^m(\mathbf{V}, \mathbf{M}), p(\mathbf{V})$ )

**for each**  $R_M \in \mathbf{R}_M$ ,

$\tilde{p}(0_{R_M} \mid \text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{R}_M, \mathbf{0}_{\text{pa}_{\mathcal{G}^m}(R_M) \cap \mathbf{R}_M})$   
 $\leftarrow \text{DIR}(\mathcal{G}^m, p, R_M)$

**if**  $(\exists R_M \in \mathbf{R}_M)$ , s.t.  $\text{DIR}(\mathcal{G}^m, p, R_M) = \emptyset$ ,

**return** “cannot recover.”

**else return**

$$\frac{p(\mathbf{O}, \mathbf{S}_M, \mathbf{0}_{\mathbf{R}_M})}{\prod_{R_M \in \mathbf{R}_M} \tilde{p}(0_{R_M} \mid \text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{R}_M, \mathbf{0}_{\text{pa}_{\mathcal{G}^m}(R_M) \cap \mathbf{R}_M})}.$$

**end procedure**

**procedure** DIR( $\mathcal{G}^m(\mathbf{V}, \mathbf{M} \mid \mathbf{W}), p_{\mathbf{W}}(\mathbf{V}), R_M$ )

**if**  $\mathbf{R}_M \cap (\text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{W}) \subseteq \text{ndp}_{\mathcal{G}^m}(R_M)$ , **return**

$$p_{\mathbf{W}} \left( 0_{R_M} \mid \begin{array}{l} \text{pa}_{\mathcal{G}^m}(R_M) \setminus (\mathbf{M} \cup \mathbf{W} \cup \mathbf{R}_M) \\ \mathbf{0}_{\mathbf{R}_M \cap \text{pa}_{\mathcal{G}^m}(R_M)}, \mathbf{S}_{\mathbf{M} \cap \text{pa}_{\mathcal{G}^m}(R_M)} \\ \mathbf{0}_{\mathbf{R}_M \cap (\text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{W})} \end{array} \right).$$

**else**  $\mathbf{A}^\dagger \leftarrow \{R_M\}$ .

**while**  $(\text{an}_{\mathcal{G}^m}(\mathbf{A}^\dagger) \cup \mathbf{S}_{\text{an}_{\mathcal{G}^m}(\mathbf{A}^\dagger) \cap \mathbf{M}} \not\subseteq \mathbf{A}^\dagger)$  **do**

$\mathbf{A}^\dagger \leftarrow \text{an}_{\mathcal{G}^m}(\mathbf{A}^\dagger) \cup \mathbf{S}_{\text{an}_{\mathcal{G}^m}(\mathbf{A}^\dagger) \cap \mathbf{M}}$ .

**if**  $\mathbf{A}^\dagger \subset \mathbf{A}$ ,

**return** DIR( $\mathcal{G}_{\mathbf{A}^\dagger}^m, p_{\mathbf{W} \cap \mathbf{A}^\dagger}(\mathbf{V} \cap \mathbf{A}^\dagger), R_M$ ).

$\mathbf{D} \leftarrow \text{dis}_{\mathcal{G}^m(\mathbf{V})}(R_M)$ ,  $\mathbf{D}^\dagger \leftarrow \text{cla}_{\mathcal{G}^m}(R_M)$ .

**if**  $\mathbf{D} \subset \mathbf{V}$ ,

$\mathbf{Z}^\dagger \leftarrow \text{pa}_{\mathcal{G}^m(\mathbf{V})}^s(\mathbf{D}) \cap \mathbf{R}_M$

$\mathbf{Y}^\dagger \leftarrow \text{pa}_{\mathcal{G}^m(\mathbf{V})}^s(\mathbf{D}) \setminus \mathbf{R}_M$

$\mathbf{M}_{\mathbf{D}^\dagger}^o \leftarrow \{M \in (\mathbf{M} \cap \mathbf{D}^\dagger) \mid R_M \in \mathbf{Z}^\dagger\}$

$\mathbf{M}_{\mathbf{D}^\dagger}^h \leftarrow (\mathbf{M} \cap \mathbf{D}^\dagger) \setminus \mathbf{M}_{\mathbf{D}^\dagger}^o$

$\mathbf{V}^\dagger \leftarrow \mathbf{D} \cup \mathbf{M}_{\mathbf{D}^\dagger}^o$

$\tilde{\mathcal{G}}^m \leftarrow \mathcal{G}_{\mathbf{D}^\dagger}^m(\mathbf{V}^\dagger, \mathbf{M}_{\mathbf{D}^\dagger}^h \mid \mathbf{Y}^\dagger)$

$$p_{\mathbf{Y}^\dagger}(\mathbf{D}) \leftarrow \prod_{V \in \mathbf{D}} p_{\mathbf{W}} \left( V \mid \begin{array}{l} \text{pre}_{\mathcal{G}^m(\mathbf{V}), \prec}(V) \setminus \mathbf{Z}^\dagger, \\ \mathbf{0}_{\text{pre}_{\mathcal{G}^m(\mathbf{V}), \prec}(V) \cap \mathbf{Z}^\dagger} \end{array} \right)$$

**return** DIR( $\tilde{\mathcal{G}}^m, p_{\mathbf{Y}^\dagger}(\mathbf{D}), R_M$ )

**end if**

**return**  $\emptyset$ .

**end procedure**

## Soundness of DIR

The subroutine **DIR** invoked by **MID** aims to recover  $f_{R_M}(p) = p(0_{R_M} \mid \text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{R}_M, \mathbf{0}_{\text{pa}_{\mathcal{G}^m}(R_M) \cap \mathbf{R}_M})$  by recursively attempting to restrict  $R_M$  and  $\text{pa}_{\mathcal{G}^m}(R_M)$  to either an appropriate ancestral subset containing these vertices, or an appropriate clan of  $\mathcal{G}^m$ , and, in the base case, exploiting the independence structure, and properties of the subproblem that is left.

To prove the soundness of **DIR**, we must establish, by induction on algorithm structure, certain results about the subproblems it considers. We will represent subproblems as a pair consisting of a CDAG  $\tilde{\mathcal{G}}^m$  that is a subgraph of the original graph  $\mathcal{G}^m$ , and a *conditional fragment* of the missingness model which can be viewed as a set of all interventional distributions relevant to the subproblem, which also possibly depend on variables  $\mathbf{W}$  from larger subproblems.

Given an element  $p(\mathbb{A})$  of  $\mathcal{M}(\mathcal{G}^m(\mathbf{A}))$ ,  $\mathbf{B} \subseteq \mathbf{A}$ , and  $\mathbf{W} \subseteq \mathbf{A} \setminus \mathbf{B}$ , a *conditional fragment of  $p(\mathbb{A})$  with respect to  $\mathbf{B}$  and  $\mathbf{W}$* , denoted by  $\mathcal{F}_{\mathbf{W}, \mathbf{B}}$ , is a mapping from elements  $\mathbf{w}$  in  $\mathfrak{X}_{\mathbf{W}}$  to

$$\mathcal{F}_{\mathbf{w}, \mathbf{B}} \equiv \{p_{\mathbf{w}}(\mathbf{B}(\mathbf{r})_{\mathbf{w}}) \mid \mathbf{R} \subseteq \mathbf{R}_M \cap \mathbf{B}, \mathbf{r} \in \mathfrak{X}_{\mathbf{R}}\}.$$

Note that we cannot view  $p_{\mathbf{w}}(\mathbf{B}(\mathbf{r})_{\mathbf{w}})$  as a joint response of  $\mathbf{B}$  to an intervention setting  $\mathbf{R} \cup \mathbf{W}$  to  $\mathbf{r} \cup \mathbf{w}$ , because  $\mathbf{W}$  may contain elements outside  $\mathbf{R}$  that we are not allowed to intervene on.

For each call to **DIR**, we want to show that all interventional distributions in the input fragment are Markov with respect to the appropriately modified input graph, that we have enough information in the subproblem to possibly obtain  $f_{R_M}(p)$ , and that the manifest distribution of the fragment for the current (inner) call can be obtained from the manifest distribution of the fragment for the previous (outer) call.

**Definition 2**  $\mathcal{F}_{\mathbf{W}, \mathbf{B}}$  is causal Markov relative to a CDAG  $\mathcal{G}^m(\mathbf{B} \mid \mathbf{W})$  if  $(\forall \mathbf{w} \in \mathfrak{X}_{\mathbf{W}}, p_{\mathbf{w}}(\mathbf{B}(\mathbf{r})_{\mathbf{w}}) \in \mathcal{F}_{\mathbf{w}, \mathbf{B}})$ ,  $p_{\mathbf{w}}(\mathbf{B}(\mathbf{r})_{\mathbf{w}})$  is Markov relative to  $\mathcal{G}^m(\mathbf{B} \mid \mathbf{W})_{\mathbf{R}}$ .

This definition is how we will relate fragments and corresponding subgraphs, and the following two results establish this relationship for the two recursive cases relevant for **DIR**.

**Lemma 3** For  $\mathcal{F}_{\mathbf{W}, \mathbf{A}}$  causal Markov relative to  $\mathcal{G}^m(\mathbf{A} \mid \mathbf{W})$ , let  $\mathbf{D} \in \mathcal{D}(\mathcal{G}_{\mathbf{V}}^m)$ ,  $\mathbf{D}^\dagger \equiv \text{cla}_{\mathcal{G}^m}(\mathbf{D})$ ,  $\mathbf{W}^\dagger \equiv \text{pa}_{\mathcal{G}_{\mathbf{V}}^m}^s(\mathbf{D})$ ,  $\mathbf{W}^* \equiv \mathbf{W}^\dagger \setminus \mathbf{W}$ . Then for any  $\mathbf{w}^\dagger \in \mathfrak{X}_{\mathbf{W}^\dagger}$ ,  $\mathcal{F}_{\mathbf{w}^\dagger, \mathbf{D}^\dagger} \equiv \{\tilde{p}_{\mathbf{w}^\dagger}(\mathbf{D}^\dagger(\mathbf{r})_{\mathbf{w}^\dagger}) \mid \mathbf{r} \in \mathfrak{X}_{\mathbf{R}}, \mathbf{R} \subseteq \mathbf{R}_M \cap \mathbf{D}\}$  is causal Markov relative to  $\mathcal{G}_{\text{fa}_{\mathcal{G}^m}(\mathbf{D}^\dagger)}^m(\mathbf{D}^\dagger \mid \mathbf{W}^\dagger)$ , where for any  $\mathbf{w}$  consistent with  $\mathbf{w}^\dagger$ ,  $\tilde{p}_{\mathbf{w}^\dagger}(\mathbf{D}^\dagger(\mathbf{r})_{\mathbf{w}^\dagger})$  is

$$\prod_{V \in \mathbf{D}^\dagger} p_{\mathbf{w}}(V \mid (\mathbf{r} \cup \mathbf{w}^\dagger)_{\text{pa}_{\mathcal{G}^m}(V) \cap (\mathbf{R} \cup \mathbf{W}^*)}, \text{pa}_{\mathcal{G}^m}(V) \setminus (\mathbf{R} \cup \mathbf{W}^\dagger))$$

*Proof:* For any CDAG  $\mathcal{G}(\mathbf{O}, \mathbf{M} \mid \mathbf{W})$ ,  $\text{fa}_{\mathcal{G}}(\text{cla}_{\mathcal{G}}(\mathbf{D}))$  is equal to  $\text{cla}_{\mathcal{G}}(\mathbf{D}) \cup \text{pa}_{\mathcal{G}(\mathbf{O})}^s(\mathbf{D})$  for any  $\mathbf{D} \in \mathcal{D}(\mathcal{G}(\mathbf{O}))$ . The proof is now immediate. Elements  $\tilde{p}_{\mathbf{w}^\dagger}(\mathbf{D}^\dagger(\mathbf{r})_{\mathbf{w}^\dagger})$  of each  $\mathcal{F}_{\mathbf{w}^\dagger, \mathbf{D}^\dagger}$  are Markov relative to  $(\mathcal{G}_{\text{fa}_{\mathcal{G}}(\mathbf{D}^\dagger)}^m)_{\mathbf{R}}$  by construction. The definition of  $\tilde{p}_{\mathbf{w}^\dagger}(\mathbf{D}^\dagger(\mathbf{r})_{\mathbf{w}^\dagger})$  implies it is the same object for any  $\mathbf{w}$  consistent with  $\mathbf{w}^\dagger$ .  $\square$

**Lemma 4** For  $\mathcal{F}_{\mathbf{W}, \mathbf{A}}$  causal Markov relative to  $\mathcal{G}^m(\mathbf{A} \mid \mathbf{W})$ , let  $\mathbf{V}^\dagger \subseteq \mathbf{A} \cup \mathbf{W}$  be ancestral,  $\mathbf{W}^\dagger \equiv \mathbf{W} \cap \mathbf{V}^\dagger$ ,  $\mathbf{A}^\dagger \equiv \mathbf{A} \cap \mathbf{V}^\dagger$ . Then for any  $\mathbf{w}^\dagger \in \mathfrak{X}_{\mathbf{W}^\dagger}$ ,  $\mathcal{F}_{\mathbf{w}^\dagger, \mathbf{D}^\dagger} \equiv \{\tilde{p}_{\mathbf{w}^\dagger}(\mathbf{A}^\dagger(\mathbf{r})_{\mathbf{w}^\dagger}) \mid \mathbf{r} \in \mathfrak{X}_{\mathbf{R}}, \mathbf{R} \subseteq \mathbf{R}_{\mathbf{M}} \cap \mathbf{A}^\dagger\}$  is causal Markov relative to  $\mathcal{G}_{\mathbf{A}^\dagger}^m(\mathbf{A}^\dagger \mid \mathbf{W}^\dagger)$ , where for any  $\mathbf{w}$  consistent with  $\mathbf{w}^\dagger$ ,  $\tilde{p}_{\mathbf{w}^\dagger}(\mathbf{A}^\dagger(\mathbf{r})_{\mathbf{w}^\dagger})$  is

$$\prod_{V \in \mathbf{A}^\dagger} p_{\mathbf{w}}(V \mid \mathbf{r}_{\text{pa}_{\mathcal{G}^m}(V) \cap \mathbf{R}}, \text{pa}_{\mathcal{G}^m}(V) \setminus (\mathbf{R} \cup \mathbf{W}^\dagger))$$

*Proof:* Immediate. Elements  $p_{\mathbf{w}^\dagger}(\mathbf{A}^\dagger(\mathbf{r})_{\mathbf{w}^\dagger})$  of each  $\mathcal{F}_{\mathbf{w}^\dagger, \mathbf{A}^\dagger}$  are Markov relative to  $(\mathcal{G}_{\mathbf{A}^\dagger}^m)_{\mathbf{R}}$  by construction. The definition of  $\tilde{p}_{\mathbf{w}^\dagger}(\mathbf{D}^\dagger(\mathbf{r})_{\mathbf{w}^\dagger})$  implies it is the same object for any  $\mathbf{w}$  consistent with  $\mathbf{w}^\dagger$ .  $\square$

The next two results re-express  $p(R_M \mid \text{pa}_{\mathcal{G}^m}(R_M))$  from a function of the larger fragment of the outer recursive call to a function of the smaller fragment of the inner call.

**Lemma 5** Assume  $\mathcal{F}_{\mathbf{W}, \mathbf{A}}$  is causal Markov relative to  $\mathcal{G}^m(\mathbf{A} \mid \mathbf{W})$ , and  $\mathcal{F}_{\mathbf{W}^\dagger, \mathbf{D}^\dagger}$  is defined as in Lemma 3. Then for any  $R_M \in \mathbf{D}^\dagger$ ,  $p_{\mathbf{W}}(R_M \mid \text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{W})$  is equal to  $p_{\mathbf{W}^\dagger}(R_M \mid \text{pa}_{\mathcal{G}^m(\mathbf{D}^\dagger)}(R_M) \setminus \mathbf{W}^\dagger)$ .

*Proof:* Since  $R_M \in \mathbf{D}^\dagger$ , this follows by Lemma 3. That is,  $p_{\mathbf{W}^\dagger}(R_M \mid \text{pa}_{\mathcal{G}^m(\mathbf{D}^\dagger)}(R_M) \setminus \mathbf{W}^\dagger)$  is equal to  $p_{\mathbf{W}}(R_M \mid \mathbf{W}^\dagger_{\text{pa}_{\mathcal{G}^m}(R_M) \cap (\mathbf{W}^\dagger \setminus \mathbf{W})}, \text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{W}^\dagger)$ , which is equal to  $p_{\mathbf{W}}(R_M \mid \text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{W})$ .  $\square$

**Lemma 6** Assume  $\mathcal{F}_{\mathbf{W}, \mathbf{A}}$  is causal Markov relative to  $\mathcal{G}^m(\mathbf{A} \mid \mathbf{W})$ , and  $\mathcal{F}_{\mathbf{W}^\dagger, \mathbf{A}^\dagger}$  is defined as in Lemma 4. Then for any  $R_M \in \mathbf{A}^\dagger$ ,  $p_{\mathbf{W}}(R_M \mid \text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{W})$  is equal to  $p_{\mathbf{W}^\dagger}(R_M \mid \text{pa}_{\mathcal{G}^m(\mathbf{A}^\dagger)}(R_M) \setminus \mathbf{W}^\dagger)$ .

*Proof:* Since  $R_M \in \mathbf{A}^\dagger$ , this follows by Lemma 4. That is,  $p_{\mathbf{W}^\dagger}(R_M \mid \text{pa}_{\mathcal{G}^m(\mathbf{A}^\dagger)}(R_M) \setminus \mathbf{W}^\dagger)$  is equal to  $p_{\mathbf{W}}(R_M \mid \text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{W})$ .  $\square$

The next two results express the analogue of the manifest distribution of the smaller fragment as a function of the manifest distribution of the larger fragment. We assume  $\mathbf{M}_{\mathbf{D}^\dagger}^o, \mathbf{M}_{\mathbf{D}^\dagger}^h, \mathbf{V}^\dagger, \mathbf{Z}^\dagger, \mathbf{Y}^\dagger$ , and  $\mathcal{G}^m$  are defined as in the district case of **DIR**. Let  $\mathbf{W}^\dagger = \mathbf{Y}^\dagger \cup \mathbf{Z}^\dagger$ , and  $\mathbf{O}^\dagger = \mathbf{D} \cap \mathbf{O}$ .

**Lemma 7** Assume  $\mathcal{F}_{\mathbf{W}, \mathbf{A}}$  is causal Markov relative to  $\mathcal{G}^m(\mathbf{A} \mid \mathbf{W})$ , and  $\mathcal{F}_{\mathbf{W}^\dagger, \mathbf{D}^\dagger}$  is defined as in Lemma 3.

Then the marginal  $p_{\mathbf{Y}^\dagger, \mathbf{O}_{\mathbf{Z}^\dagger}}(\mathbf{O}^\dagger, \mathbf{M}_{\mathbf{D}^\dagger}^o, \mathbf{S}_{\mathbf{M}_{\mathbf{D}^\dagger}^h}, \mathbf{R}_{\mathbf{M}_{\mathbf{D}^\dagger}^h})$  of  $p_{\mathbf{W}^\dagger}(\mathbf{D}^\dagger) \in \mathcal{F}_{\mathbf{W}^\dagger, \mathbf{D}^\dagger}$  is equal to  $\prod_{V \in \mathbf{V}^\dagger} p_{\mathbf{W}}(V \mid \text{pre}_{\mathcal{G}^m(\mathbf{V}), \prec}(V) \setminus \mathbf{Z}^\dagger, \mathbf{0}_{\text{pre}_{\mathcal{G}^m(\mathbf{V}), \prec}(V) \cap \mathbf{Z}^\dagger})$ .

*Proof:* Fix  $\mathbf{w}$  and  $\mathbf{w}^\dagger$  consistent with  $\mathbf{w}$ , such that  $\mathbf{w}_{\mathbf{Z}^\dagger}^\dagger = \mathbf{0}$ . We get the following set of equalities, where the first is by assumption on missingness models, the second by (4), (3) and the definition of  $\mathbf{M}_{\mathbf{D}^\dagger}^o$ , the third by definition, the fourth by Lemma 3, and the last by standard results on district factorization of hidden variable DAG models found in [22]. If we range over all possible  $\mathbf{w}_{\mathbf{Y}^\dagger}^\dagger$ , the last expression reduces to  $\prod_{V \in \mathbf{V}^\dagger} p_{\mathbf{W}}(V \mid \text{pre}_{\mathcal{G}^m(\mathbf{V}), \prec}(V) \setminus \mathbf{Z}^\dagger, \mathbf{0}_{\text{pre}_{\mathcal{G}^m(\mathbf{V}), \prec}(V) \cap \mathbf{Z}^\dagger})$ .

$$\begin{aligned} & p_{\mathbf{w}^\dagger}(\mathbf{O}^\dagger, \mathbf{M}_{\mathbf{D}^\dagger}^o, \mathbf{S}_{\mathbf{M}_{\mathbf{D}^\dagger}^h}, \mathbf{R}_{\mathbf{M}_{\mathbf{D}^\dagger}^h}) \\ &= p_{\mathbf{w}^\dagger}(\mathbf{O}^\dagger, \mathbf{S}_{\mathbf{M}_{\mathbf{D}^\dagger}^o}(\mathbf{R}_{\mathbf{M}_{\mathbf{D}^\dagger}^o} = \mathbf{0}), \mathbf{S}_{\mathbf{M}_{\mathbf{D}^\dagger}^h}, \mathbf{R}_{\mathbf{M}_{\mathbf{D}^\dagger}^h}) \\ &= p_{\mathbf{w}^\dagger}(\mathbf{O}^\dagger, \mathbf{S}_{\mathbf{M}_{\mathbf{D}^\dagger}^o}, \mathbf{S}_{\mathbf{M}_{\mathbf{D}^\dagger}^h}, \mathbf{R}_{\mathbf{M}_{\mathbf{D}^\dagger}^h}) \\ &= \sum_{\mathbf{M}_{\mathbf{D}^\dagger}^h} p_{\mathbf{w}^\dagger}(\mathbf{O}^\dagger, \mathbf{S}_{\mathbf{M}_{\mathbf{D}^\dagger}^o}, \mathbf{S}_{\mathbf{M}_{\mathbf{D}^\dagger}^h}, \mathbf{R}_{\mathbf{M}_{\mathbf{D}^\dagger}^h}, \mathbf{M}_{\mathbf{D}^\dagger}^h) \\ &= \sum_{\mathbf{M}_{\mathbf{D}^\dagger}^h} \prod_{V \in \mathbf{D}^\dagger} p_{\mathbf{w}}(V \mid \mathbf{w}_{\text{pa}_{\mathcal{G}^m}(V) \cap (\mathbf{W}^\dagger \setminus \mathbf{W})}^\dagger, \text{pa}_{\mathcal{G}^m}(V) \setminus \mathbf{W}^\dagger) \\ &= \prod_{V \in \mathbf{D}} p_{\mathbf{w}}(V \mid \text{pre}_{\mathcal{G}^m(\mathbf{V}), \prec}(V) \setminus \mathbf{W}^\dagger, \mathbf{w}_{\text{pre}_{\mathcal{G}^m(\mathbf{V}), \prec}(V) \cap \mathbf{W}^\dagger}^\dagger) \end{aligned}$$

$\square$

**Lemma 8** Assume  $\mathcal{F}_{\mathbf{W}, \mathbf{A}}$  is causal Markov relative to  $\mathcal{G}^m(\mathbf{A} \mid \mathbf{W})$ , and  $\mathcal{F}_{\mathbf{W}^\dagger, \mathbf{A}^\dagger}$  is defined as in Lemma 4. Then the element  $p_{\mathbf{W}^\dagger}(\mathbf{V} \cap \mathbf{A}^\dagger)$  of  $\mathcal{F}_{\mathbf{W}^\dagger, \mathbf{A}^\dagger}$  is equal to  $\sum_{\mathbf{V} \setminus \mathbf{A}^\dagger} p_{\mathbf{W}}(\mathbf{V})$ .

*Proof:*  $p_{\mathbf{W}^\dagger}(\mathbf{V} \cap \mathbf{A}^\dagger)$  is equal to  $\sum_{\mathbf{A}^\dagger \setminus \mathbf{V}} p_{\mathbf{W}^\dagger}(\mathbf{A}^\dagger)$  (by definition), which is equal to  $\sum_{\mathbf{A}^\dagger \setminus \mathbf{V}} \sum_{\mathbf{A} \setminus \mathbf{A}^\dagger} p_{\mathbf{W}}(\mathbf{A})$  by Lemma 4. But since both  $\mathbf{V}, \mathbf{A}^\dagger$  are subsets of  $\mathbf{A}$ , this is just  $\sum_{\mathbf{A} \setminus (\mathbf{V} \cap \mathbf{A}^\dagger)} p_{\mathbf{W}}(\mathbf{A})$ , which is equal to  $\sum_{\mathbf{V} \setminus \mathbf{A}^\dagger} \sum_{\mathbf{A} \setminus \mathbf{V}} p_{\mathbf{W}}(\mathbf{A}) = \sum_{\mathbf{V} \setminus \mathbf{A}^\dagger} p_{\mathbf{W}}(\mathbf{V})$ .  $\square$

The following result establishes the validity of the base case of **DIR**, where  $p_{\mathbf{W}}(R_M \mid \text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{W})$  is expressed in terms of the manifest distribution for the current fragment.

**Lemma 9** Assume  $\mathcal{F}_{\mathbf{W}, \mathbf{A}}$  is causal Markov relative to  $\mathcal{G}^m(\mathbf{A} \mid \mathbf{W})$ . Then if  $\mathbf{R}_{\mathbf{M} \cap (\text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{W})} \subseteq \text{ndp}_{\mathcal{G}^m}(R_M)$ , then

$$p_{\mathbf{W}}(0_{R_M} \mid \text{pa}_{\mathcal{G}^m}(R_M) \setminus (\mathbf{W} \cup \mathbf{R}_{\mathbf{M}}), \mathbf{0}_{\mathbf{R}_{\mathbf{M}} \cap (\text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{W})})$$

is equal to  $p_{\mathbf{W}} \left( \begin{array}{c} \text{pa}_{\mathcal{G}^m}(R_M) \setminus (\mathbf{M} \cup \mathbf{W} \cup \mathbf{R}_{\mathbf{M}}) \\ 0_{R_M} \mid \mathbf{0}_{\mathbf{R}_{\mathbf{M}} \cap \text{pa}_{\mathcal{G}^m}(R_M)}, \mathbf{S}_{\mathbf{M} \cap \text{pa}_{\mathcal{G}^m}(R_M)} \\ \mathbf{0}_{\mathbf{R}_{\mathbf{M}} \cap (\text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{W})} \end{array} \right)$ .

*Proof:* We get the following set of equalities, where the first follows by assumption, and the fact that  $p_{\mathbf{W}}(\mathbf{A})$  is Markov relative to  $\mathcal{G}^m$ , the second is by the properties of the missingness model, and the third is by (4):

$$\begin{aligned} p_{\mathbf{W}} \left( 0_{R_M} \middle| \begin{array}{l} \text{pa}_{\mathcal{G}^m}(R_M) \setminus (\mathbf{W} \cup \mathbf{R}_M) \\ \mathbf{0}_{\mathbf{R}_M \cap (\text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{W})} \end{array} \right) &= \\ p_{\mathbf{W}} \left( 0_{R_M} \middle| \begin{array}{l} \text{pa}_{\mathcal{G}^m}(R_M) \setminus (\mathbf{M} \cup \mathbf{W} \cup \mathbf{R}_M) \\ \text{pa}_{\mathcal{G}^m}(R_M) \cap \mathbf{M}, \mathbf{0}_{\mathbf{R}_M \cap \text{pa}_{\mathcal{G}^m}(R_M)} \\ \mathbf{0}_{\mathbf{R}_M \cap (\text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{W})} \end{array} \right) &= \\ p_{\mathbf{W}} \left( 0_{R_M} \middle| \begin{array}{l} \text{pa}_{\mathcal{G}^m}(R_M) \setminus (\mathbf{M} \cup \mathbf{W} \cup \mathbf{R}_M), \\ \mathbf{S}_{\mathbf{M} \cap \text{pa}_{\mathcal{G}^m}(R_M)}, \mathbf{0}_{\mathbf{R}_M \cap \text{pa}_{\mathcal{G}^m}(R_M)} \\ \mathbf{0}_{\mathbf{R}_M \cap \text{pa}_{\mathcal{G}^m}(R_M)}, \mathbf{0}_{\mathbf{R}_M \cap (\text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{W})} \end{array} \right) &= \\ p_{\mathbf{W}} \left( 0_{R_M} \middle| \begin{array}{l} \text{pa}_{\mathcal{G}^m}(R_M) \setminus (\mathbf{M} \cup \mathbf{W} \cup \mathbf{R}_M) \\ \mathbf{0}_{\mathbf{R}_M \cap \text{pa}_{\mathcal{G}^m}(R_M)}, \mathbf{S}_{\mathbf{M} \cap \text{pa}_{\mathcal{G}^m}(R_M)} \\ \mathbf{0}_{\mathbf{R}_M \cap (\text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{W})} \end{array} \right). \end{aligned}$$

□

Before putting all these results together to show soundness of **DIR**, we must prove one additional utility lemma that shows the set  $\mathbf{A}^\dagger$  constructed by **DIR** is ancestral.

Define an automorphism from vertex sets in  $\mathcal{G}^m$ ,  $\rho_{M, \mathcal{G}^m}(\mathbf{B})$ , as  $\text{an}_{\mathcal{G}^m}(\{R_M\} \cup \mathbf{B}) \cup \mathbf{S}_{\text{an}_{\mathcal{G}^m}(\{R_M\} \cup \mathbf{B})}$ . Let  $\mathbf{A}^\dagger$  be the fixed point of  $\rho_{M, \mathcal{G}^m}$  with the starting input of the empty set.

**Lemma 10**  $\mathbf{A}^\dagger$  is an ancestral set in  $\mathcal{G}^m$ .

*Proof:* A simple proof by contradiction follows by definition of  $\rho_{M, \mathcal{G}^m}$ . □

We now show the main result of this paper.

**Theorem 4** **MID** is sound.

*Proof:* Assuming **DIR** returns the answer for every  $R_M \in \mathbf{R}_M$ , Corollary 1, and Lemma 2 ensure that **MID** recovers  $p(\mathbf{M} \cup \mathbf{O})$  from  $p(\mathbf{V})$ .

The soundness of **DIR** follows by induction on the recursive call structure. The inductive hypothesis is that the input conditional fragment  $\mathcal{F}_{\widetilde{\mathbf{W}}, \widetilde{\mathbf{A}}}$  is causal Markov relative to the appropriate graph derived from the input graph  $\widetilde{\mathcal{G}}^m$ , that the input manifest  $\widetilde{p}_{\widetilde{\mathbf{W}}}(\mathbf{V})$  is the function of the original manifest  $p(\mathbf{V})$ , and that  $\widetilde{p}_{\widetilde{\mathbf{W}}}(R_M | \text{pa}_{\widetilde{\mathcal{G}}^m}(R_M) \setminus \widetilde{\mathbf{W}}) = p(R_M | \text{pa}_{\mathcal{G}^m}(R_M))$ .

The base case trivially holds for the original inputs to **DIR**. If the inductive hypothesis is true, and **DIR** returns after the first conditional, soundness follows by Lemma 9.

If **DIR** returns after the second conditional, then Lemma 10 ensures the constructed set  $\mathbf{A}^\dagger$  is ancestral, and the induction for the following recursive call is maintained via Lemmas 4, 8 and 6.

If **DIR** returns after the third conditional, Lemma 3 ensures  $\mathcal{F}_{\widetilde{\mathbf{W}}, \mathbf{D}^\dagger}$  is causal Markov relative to  $\mathcal{G}_{\text{fa}_{\mathcal{G}^m}(\mathbf{D}^\dagger)}^m$

for all values of  $\widetilde{\mathbf{w}}$ , including those that set  $\mathbf{Z}^\dagger$  to  $\mathbf{0}$ . Lemma 5, and the inductive hypothesis ensures  $p_{\mathbf{W}^\dagger}(R_M | \text{pa}_{\mathcal{G}_{\text{fa}_{\mathcal{G}^m}(\mathbf{D}^\dagger)}}^m(R_M) \setminus \mathbf{W}^\dagger)$  is equal to  $p_{\mathbf{W}}(R_M | \text{pa}_{\mathcal{G}^m}(R_M) \setminus \mathbf{W})$ . Finally, Lemma 7 ensures the manifest for the recursive call is a function of the input manifest. In fact, because we set  $\mathbf{Z}^\dagger$  to  $\mathbf{0}$ , properties of missingness models ensure we can treat  $\mathbf{M}_{\mathbf{D}^\dagger}^o$  as observed in subsequent recursive calls, which means we no longer need to consider  $\mathbf{S}_{\mathbf{M}_{\mathbf{D}^\dagger}^o}$ .

Since induction follows for all cases, so does our conclusion. □

## 6 A COMPLEX RECOVERABLE EXAMPLE

We now work through an example where all cases of **MID** and **DIR** are necessary. Consider the graph shown in Fig. 2 (a). Here  $C$  and  $D$  are shown in green to indicate that they are fully observed. This is a more complex version of the example in Fig. 1 (c). Unlike that case, here, there are no conditional independences that hold between proxies and indicators. However, if we were to divide by  $p(D | C)$  and sum out  $C$ , in the resulting distribution  $p_D(S_A, S_B, R_A, R_B, A, B)$ , for any fixed value  $d$  of  $D$ , we would have

$$\left( \{S_A(0_{R_A}), R_B\} \perp\!\!\!\perp \{S_B(0_{R_B}), R_A(0_{R_B})\} \right)_{p_d}$$

This is a type of Verma constraint [23] or generalized independence constraint [20].

Our goal is to recover  $p(A, B, C, D)$  given the missingness model corresponding to this graph, and in particular the above constraint. We must recover  $p(0_{R_B} | A, D)$  and  $p(0_{R_A} | 0_{R_B}, B, D)$  from  $p(R_A, R_B, S_A, S_B, C, D)$ . In either case, we note that  $D$  is not an element of  $\text{cla}_{\mathcal{G}^m}(R_A) = \text{cla}_{\mathcal{G}^m}(R_B)$ , which implies we can use the clan case of **DIR** and consider a subproblem shown in Fig. 2 (b), with the corresponding manifest  $\widetilde{p}_D(R_A, R_B, S_A, S_B, C) = p(S_A, S_B, R_A, R_B | D, C)p(C)$ . In the new subproblem (for either  $R_A$  or  $R_B$ ),  $C$  is not a part of the ancestral set  $\mathbf{A}^\dagger$  constructed by **DIR** in the ancestral case, so we consider a new subproblem shown in Fig. 2 (c), with the corresponding manifest  $\widetilde{p}_D(R_A, R_B, S_A, S_B) = \sum_c \widetilde{p}_D(S_A, S_B, R_A, R_B | D, c)\widetilde{p}_D(c)$ . This new subproblem now resembles the example in Fig. 1 (c), and is solved similarly. In particular, we recover  $p(0_{R_B} | D, A)$  as

$$\frac{\widetilde{p}_D(S_A | 0_{R_A}, 0_{R_B})\widetilde{p}_D(0_{R_B})}{\sum_{R_B} \widetilde{p}_D(S_A | 0_{R_A}, R_B)\widetilde{p}_D(R_B)}$$

and  $p(0_{R_A} | 0_{R_B}, B, D)$  as  $\widetilde{p}_D(0_{R_A} | 0_{R_B}, S_B)$ . We then obtain  $p(A, B, C, D)$  by dividing the manifest distribution for observed cases  $p(0_{R_A}, 0_{R_B}, S_A, S_B, C, D)$  by the above two probabilities.

Figure 2: (a) An example where recoverability is possible via **MID**. (b),(c) Graphs corresponding to subproblems considered by **MID** in recovering  $p(A, B, C, D)$ .

## 7 NONRECOVERABILITY

The generality of **MID** naturally raises the question of whether it is complete, that is whether whenever it outputs “cannot recover” then it is possible to construct two elements of the missingness model that agree on the manifest but disagree on the underlying joint distribution. We leave this difficult question aside in this paper in the interests of space, but note that an approach similar to one used to show completeness for causal effects identification [18] seems promising. That is, use **MID** as a guide for constructing a “zoo” of structures where recoverability does not seem to be possible, and then construct a general method for showing non-recoverability for this “zoo.”

Some results on non-recoverability do exist. For example, it can be shown that  $p(A)$  is not recoverable in the missingness model with the graph in Fig. 3 (a) [7], and similarly that  $p(A, B)$  is not recoverable in the missingness model with the graph in Fig. 3 (b). Characterization of non-recoverability is an open problem.

## 8 DISCUSSION AND CONCLUSIONS

We have represented missing data as a type of a restricted causal inference problem. Using the machinery of graphical causal models, we have given a general algorithm for recoverability of a joint distribution in MNAR settings. Though we do not require this, our formalism allows the joint distribution we recover to come from a statistical, rather than a causal model – all causal assumptions may be restricted to the missingness model governing the behavior of proxies of missing variables under interventions on indicators. We show that the MCAR, MAR, MNAR taxonomy is not sufficiently granular to classify cases where recoverability is possible. In particular, there are MNAR examples where constraints akin to Verma constraints permit recoverability.

Aside from the algorithm, our formalism allows us to seamlessly integrate issues of identification of causal effects, and recoverability. For instance, it is known that in the graph shown in Fig. 3 (c) (where we treat  $\leftrightarrow$  edges as indicating

Figure 3: (a)  $p(A)$  is not recoverable. (b)  $p(A, B)$  is not recoverable. (c) A graph with hidden variables where  $p(Y)$  is not recoverable, but  $p(Y(a))$  is.

the presence of an unobserved parent),  $p(Y)$  is not recoverable. However, if the graph on  $C, A, Y$  represents a causal model, we can show that  $p(Y(a))$  is recoverable. In particular

$$p(Y(a)) = p(S_Y(a, 0_{R_Y})) = \frac{\sum_c p(S_Y, 0_{R_Y} | a, c)p(c)}{\sum_c p(0_{R_Y} | a, c)p(c)}$$

A similar observation appears in [6], example 3.

By explicitly representing missingness via an intervenable indicator, and a proxy as a response to this intervention, our formalism allows us to reason explicitly about the interpretation of censoring by death using the existing language of interventions. That is if  $S_X$  is observed patient history, and  $1_{R_X}$  implies it is missing due to the patient dying, then we may either disallow considering  $S_X(0_{R_X})$  (e.g. “resurrecting the patient”) for that patient, allow  $S_X(0_{R_X})$ , but treat it as making statements about exchangeable but different patients who happened to be alive that transfer over to the dead patient in a hypothetical alternative history where the patient never died, and so on.

Note that if we assume a *known* relationship  $p(S_M(r_{R_M}) | M)$  between  $M$  and  $S_M(r_{R_M})$  other than direct equality, we can use the approach in this paper to address certain *coarsening* [3] and *measurement error* settings. We do not consider these extensions explicitly here for space reasons, but they are straightforward.

## Abstract

Recently we showed that the problem of Maximum Inner Product Search (MIPS) is efficient and it admits provably sub-linear hashing algorithms. In [23], we used asymmetric transformations to convert the problem of approximate MIPS into the problem of approximate near neighbor search which can be efficiently solved using L2-LSH. In this paper, we revisit the problem of MIPS and argue that the quantizations used in L2-LSH is suboptimal for MIPS compared to signed random projections (SRP) which is another popular hashing scheme for cosine similarity (or correlations). Based on this observation, we provide different asymmetric transformations which convert the problem of approximate MIPS into the problem amenable to SRP instead of L2-LSH. An additional advantage of our scheme is that we also obtain LSH type space partitioning which is not possible with the existing scheme. Our theoretical analysis shows that the new scheme is significantly better than the original scheme for MIPS. Experimental evaluations strongly support the theoretical findings. In addition, we also provide the first empirical comparison that shows the superiority of hashing over tree based methods [21] for MIPS.

## 1 Introduction

In this paper, we revisit the problem of *Maximum Inner Product Search (MIPS)*, which was studied in our recent work [23]. In this work we present the first provably fast algorithm for MIPS, which was considered hard [21, 15]. Given an input query point  $q \in \mathbb{R}^D$ , the task of MIPS is to find  $p \in \mathcal{S}$ , where  $\mathcal{S}$  is a giant collection of size  $N$ , which maximizes (approximately) the **inner product**  $q^T p$ :

$$p = \arg \max_{x \in \mathcal{S}} q^T x \quad (1)$$

The MIPS problem is related to the problem of *near neighbor search (NNS)*. For example, L2-NNS

$$p = \arg \min_{x \in \mathcal{S}} \|q - x\|_2^2 = \arg \min_{x \in \mathcal{S}} (\|x\|_2^2 - 2q^T x) \quad (2)$$

or, correlation-NNS

$$p = \arg \max_{x \in \mathcal{S}} \frac{q^T x}{\|q\| \|x\|} = \arg \max_{x \in \mathcal{S}} \frac{q^T x}{\|x\|} \quad (3)$$

These three problems are equivalent if the norm of every element  $x \in \mathcal{S}$  is constant. Clearly, the value of the norm  $\|q\|_2$  has no effect for the argmax. In many scenarios, MIPS arises naturally at places where the norms of the elements in  $\mathcal{S}$  have significant variations [15]. As reviewed in our prior work [23], examples of applications of MIPS include recommender system [16, 5, 15], large-scale object detection with DPM [9, 7, 14, 14], structural SVM [7], and multi-class label prediction [21, 15, 25].

**Asymmetric LSH (ALSH):** Locality Sensitive Hashing (LSH) [13] is popular in practice for efficiently solving NNS. In our prior work [23], the concept of “asymmetric LSH” (ALSH) was formalized and one can transform the input query  $Q(p)$  and data in the collection  $P(x)$  independently, where the transformations  $Q$  and  $P$  are different. In [23] we developed a particular set of transformations to convert MIPS into L2-NNS and then solved the problem by standard hashing i.e. L2-LSH [6]. In this paper, we name the scheme in [23] as **L2-ALSH**. Later we showed in [24] the flexibility and the power of the asymmetric framework developed in [23] by constructing a provably superior scheme for binary data. Prior to our work, asymmetry was applied for hashing higher order similarity [22], sketching [8], hashing different subspaces [3], and data dependent hashing [20] which unlike locality sensitive hashing do not come with provable runtime guarantees. Explicitly constructing asymmetric transformation tailored for a particular similarity, given an existing LSH, was the first observation made in [23] due to which MIPS, a sought after problem, became provably fast and practical.

It was argued in [17] that the quantizations used in traditional L2-LSH is suboptimal and it hurts the variance of the hashes. This raises a natural question that L2-ALSH which uses L2-LSH as a subroutine for solving MIPS could be suboptimal and there may be a better hashing scheme. We provide such a scheme in this work.

**Our contribution:** Based on the observation that the quantizations used in traditional L2-LSH is suboptimal, in this study, we propose another scheme for ALSH, by developing a new set of asymmetric transformations to convert MIPS into a problem of correlation-NNS, which is solved by “signed random projections” (SRP) [11, 4]. The new scheme thus avoids the use of L2-LSH. We name this new scheme as **Sign-ALSH**. Our theoretical analysis and experimental study show that Sign-ALSH is more advantageous than L2-ALSH for MIPS.

For inner products asymmetry is unavoidable. In case of L2-ALSH, due to asymmetry, we loose the capability to generate LSH like random data partitions for efficient clustering [12]. We show that for inner products with Sign-ALSH there is a novel formulation that allows us to generate such partitions for inner products. With existing L2-ALSH such formulation does not work.

Apart from providing a better hashing scheme, we also provide comparisons of the Sign-ALSH with cone trees [21]. Our empirical evaluations on three real datasets show that hashing based methods are superior over the tree based space partitioning methods. Since there is no existing comparison of hashing based methods with tree based methods for the problem of MIPS, we believe that the results shown in this work will be very valuable for practitioners.

## 2 Review: Locality Sensitive Hashing (LSH)

The problem of efficiently finding nearest neighbors has been an active research since the very early days of computer science [10]. Approximate versions of the near neighbor search problem [13] were proposed to break the linear query time bottleneck. The following formulation for approximate near neighbor search is often adopted.

**Definition:** (*c*-Approximate Near Neighbor or *c*-NN) Given a set of points in a *D*-dimensional space  $\mathbb{R}^D$ , and parameters  $S_0 > 0$ ,  $\delta > 0$ , construct a data structure which, given any query point *q*, does the following with probability  $1 - \delta$ : if there exists an  $S_0$ -near neighbor of *q* in  $\mathcal{S}$ , it reports some  $cS_0$ -near neighbor of *q* in  $\mathcal{S}$ .

*Locality Sensitive Hashing* (LSH) [13] is a family of functions, with the property that more similar items have a higher collision probability. LSH trades off query time with extra (one time) preprocessing cost and space. Existence of an LSH family translates into provably sublinear query time algorithm for *c*-NN problems.

**Definition:** (Locality Sensitive Hashing (LSH)) A family  $\mathcal{H}$  is called  $(S_0, cS_0, p_1, p_2)$ -sensitive if, for any two points  $x, y \in \mathbb{R}^D$ , *h* chosen uniformly from  $\mathcal{H}$  satisfies:

- if  $Sim(x, y) \geq S_0$  then  $Pr_{\mathcal{H}}(h(x) = h(y)) \geq p_1$
- if  $Sim(x, y) \leq cS_0$  then  $Pr_{\mathcal{H}}(h(x) = h(y)) \leq p_2$

For efficient approximate nearest neighbor search,  $p_1 > p_2$  and  $c < 1$  is needed.

**Fact 1:** Given a family of  $(S_0, cS_0, p_1, p_2)$  -sensitive hash functions, one can construct a data structure for *c*-NN with  $O(n^\rho \log n)$  query time and space  $O(n^{1+\rho})$ , where  $\rho = \frac{\log p_1}{\log p_2} < 1$ .

LSH is a generic framework and an implementation of LSH requires a concrete hash function.

### 2.1 LSH for L2 distance

[6] presented an LSH family for  $L_2$  distances. Formally, given a fixed window size *r*, we sample a random vector *a* with each component from i.i.d. normal, i.e.,  $a_i \sim N(0, 1)$ , and a scalar *b* generated uniformly at random from  $[0, r]$ . The hash function is defined as:

$$h_{a,b}^{L2}(x) = \left\lfloor \frac{a^T x + b}{r} \right\rfloor \quad (4)$$

where  $\lfloor \cdot \rfloor$  is the floor operation. The collision probability under this scheme can be shown to be

$$\begin{aligned} Pr(h_{a,b}^{L2}(x) = h_{a,b}^{L2}(y)) &= 1 - 2\Phi(-r/d) - \frac{2}{\sqrt{2\pi}(r/d)} \left(1 - e^{-(r/d)^2/2}\right) = F_r(d) \end{aligned} \quad (5)$$

where  $\Phi(x) = \int_{-\infty}^x \frac{1}{\sqrt{2\pi}} e^{-\frac{x^2}{2}} dx$  and  $d = \|x - y\|_2$  is the Euclidean distance between the vectors *x* and *y*.

### 2.2 LSH for correlation

Another popular LSH family is the so-called “sign random projections” [11, 4]. Again, we choose a random vector *a* with  $a_i \sim N(0, 1)$ . The hash function is defined as:

$$h^{Sign}(x) = sign(a^T x) \quad (6)$$

And collision probability is

$$Pr(h^{Sign}(x) = h^{Sign}(y)) = 1 - \frac{1}{\pi} \cos^{-1} \left( \frac{x^T y}{\|x\| \|y\|} \right) \quad (7)$$

This scheme is known as *signed random projections* (SRP).

## 3 Review of ALSH for MIPS and L2-ALSH

In [23], it was shown that the framework of locality sensitive hashing is restrictive for solving MIPS. The inherent assumption of the same hash function for both the transformation as well as the query was unnecessary in the classical LSH framework and it was the main hurdle in finding provable sub-linear algorithms for MIPS with LSH. For the theoretical guarantees of LSH to work there was no requirement of symmetry. Incorporating asymmetry in the hashing schemes was the key in solving MIPS efficiently.

**Definition [23]:** (*Asymmetric* Locality Sensitive Hashing (ALSH)) A family  $\mathcal{H}$ , along with the two vector functions  $Q : \mathbb{R}^D \mapsto \mathbb{R}^{D'}$  (**Query Transformation**) and  $P :$

$\mathbb{R}^D \mapsto \mathbb{R}^{D'}$  (**Preprocessing Transformation**), is called  $(S_0, cS_0, p_1, p_2)$ -sensitive if for a given  $c$ -NN instance with query  $q$ , and the hash function  $h$  chosen uniformly from  $\mathcal{H}$  satisfies the following:

- if  $Sim(q, x) \geq S_0$  then  $Pr_{\mathcal{H}}(h(Q(q)) = h(P(x))) \geq p_1$
- if  $Sim(q, x) \leq cS_0$  then  $Pr_{\mathcal{H}}(h(Q(q)) = h(P(x))) \leq p_2$

Here  $x$  is any point in the collection  $\mathcal{S}$ .

Note that the query transformation  $Q$  is only applied on the query and the pre-processing transformation  $P$  is applied to  $x \in \mathcal{S}$  while creating hash tables. By letting  $Q(x) = P(x) = x$ , we can recover the vanilla LSH. Using different transformations (i.e.,  $Q \neq P$ ), it is possible to counter the fact that self similarity is not highest with inner products which is the main argument of failure of LSH. We just need the probability of the new collision event  $\{h(Q(q)) = h(P(y))\}$  to satisfy the conditions of definition of ALSH for  $Sim(q, y) = q^T y$ .

**Theorem 1** [23] *Given a family of hash function  $\mathcal{H}$  and the associated query and preprocessing transformations  $P$  and  $Q$ , which is  $(S_0, cS_0, p_1, p_2)$ -sensitive, one can construct a data structure for  $c$ -NN with  $O(n^\rho \log n)$  query time and space  $O(n^{1+\rho})$ , where  $\rho = \frac{\log p_1}{\log p_2}$ .*

[23] provided an explicit construction of ALSH, which we call **L2-ALSH**. Without loss of generality, one can assume

$$\|x_i\|_2 \leq U < 1, \quad \forall x_i \in \mathcal{S} \quad (8)$$

for some  $U < 1$ . If this is not the case, then we can always scale down the norms without altering the  $\arg \max$ . Since the norm of the query does not affect the  $\arg \max$  in MIPS, for simplicity it was assumed  $\|q\|_2 = 1$ . This condition can be removed easily (see Section 5 for details). In L2-ALSH, two vector transformations  $P : \mathbb{R}^D \mapsto \mathbb{R}^{D+m}$  and  $Q : \mathbb{R}^D \mapsto \mathbb{R}^{D+m}$  are defined as follows:

$$P(x) = [x; \|x\|_2^2; \|x\|_2^4; \dots; \|x\|_2^{2^m}] \quad (9)$$

$$Q(x) = [x; 1/2; 1/2; \dots; 1/2], \quad (10)$$

where  $[\cdot]$  is the concatenation.  $P(x)$  appends  $m$  scalars of the form  $\|x\|_2^{2^i}$  at the end of the vector  $x$ , while  $Q(x)$  simply appends  $m$  “1/2” to the end of the vector  $x$ . By observing

$$\begin{aligned} \|P(x_i)\|_2^2 &= \|x_i\|_2^2 + \|x_i\|_2^4 + \dots + \|x_i\|_2^{2^m} + \|x_i\|_2^{2^{m+1}} \\ \|Q(q)\|_2^2 &= \|q\|_2^2 + m/4 = 1 + m/4 \\ Q(q)^T P(x_i) &= q^T x_i + \frac{1}{2}(\|x_i\|_2^2 + \|x_i\|_2^4 + \dots + \|x_i\|_2^{2^m}) \end{aligned}$$

one can obtain the following key equality:

$$\|Q(q) - P(x_i)\|_2^2 = (1 + m/4) - 2q^T x_i + \|x_i\|_2^{2^{m+1}} \quad (11)$$

Since  $\|x_i\|_2 \leq U < 1$ , we have  $\|x_i\|_2^{2^{m+1}} \rightarrow 0$  at the tower rate (exponential to exponential). Thus, as long as  $m$  is not

too small (e.g.,  $m \geq 3$  would suffice), we have

$$\arg \max_{x \in \mathcal{S}} q^T x \simeq \arg \min_{x \in \mathcal{S}} \|Q(q) - P(x)\|_2 \quad (12)$$

This scheme is the first connection between solving unnormalized MIPS and approximate near neighbor search. Transformations  $P$  and  $Q$ , when norms are less than 1, provide correction to the L2 distance  $\|Q(q) - P(x_i)\|_2$  making it rank correlate with the (un-normalized) inner product.

### 3.1 Intuition for the Better Scheme : Why Signed Random Projections (SRP)?

Recently in [17, 18], it was observed that the quantization of random projections used by traditional L2-LSH scheme is not desirable when the data is normalized and in fact the shift  $b$  in Eq. (4) hurts the variance leading to less informative hashes. The sub-optimality of L2-LSH hints towards existence of better hashing functions for MIPS.

As previously argued, when the data are normalized then both L2-NNS and correlation-NNS are equivalent to MIPS. Therefore, for normalized data we can use either L2-LSH which is popular LSH for L2 distance or SRP which is popular LSH for correlation to solve MIPS directly. This raises a natural question “Which will perform better?”

If we assume that the data are normalized, i.e., all the norms are equal to 1, then both SRP and L2-LSH are monotonic in the inner product and their corresponding  $\rho$  values for retrieving max inner product can be computed as

$$\rho_{SRP} = \frac{\log\left(1 - \frac{1}{\pi} \cos^{-1}(S_0)\right)}{\log\left(1 - \frac{1}{\pi} \cos^{-1}(cS_0)\right)} \quad (13)$$

$$\rho_{L2-LSH} = \frac{\log\left(F_r(\sqrt{2-2S_0})\right)}{\log\left(F_r(\sqrt{2-2cS_0})\right)} \quad (14)$$

where the function  $F_r(\cdot)$  is given by Eq. (5). The values of  $\rho_{SRP}$  and  $\rho_{L2-LSH}$  for different  $S_0 = \{0.1, 0.2, \dots, 0.9, 0.95\}$  with respect to approximation ratio  $c$  is shown in Figure 1. We use standard recommendation of  $r = 2.5$  for L2-LSH. We can clearly see that  $\rho_{SRP}$  is consistently better than  $\rho_{L2-LSH}$  given any  $S_0$  and  $c$ . Thus, for MIPS with normalized data L2-LSH type of quantization given by equation 5 seems suboptimal. It is clear that when the data is normalized then SRP is always a better choice for MIPS as compared to L2-LSH. This motivates us to explore the possibility of better hashing algorithm for general (unnormalized) instance of MIPS using SRP, which will have impact in many applications as pointed out in [23].

Asymmetric transformations give us enough flexibility to modify norms without changing inner products. The transformations provided in [23] used this flexibility to convert MIPS to standard near neighbor search in  $L_2$  space for which we have standard hash functions. For binary data, [24] showed a strictly superior construction, the asymmetric minwise hashing, which outperforms all ALSHs made for general MIPS.

Figure 1: Values of  $\rho_{SRP}$  and  $\rho_{L2-LSH}$  (Lower is better) for normalized data. It is clear that SRP is more suited for retrieving inner products when the data is normalized

Signed random projections are popular hash functions widely adopted for correlation or cosine similarity. We use asymmetric transformations to convert approximate MIPS into approximate maximum correlation search and thus we avoid the use of sub-optimal L2-LSH. The collision probability of the hash functions is one of the key constituents which determine the efficiency of the obtained ALSH algorithm. We show that our proposed transformation with SRP is better suited for ALSH compared to the existing L2-ALSH for solving general MIPS instance.

## 4 The New Proposal: Sign-ALSH

### 4.1 From MIPS to Correlation-NNS

We assume for simplicity that  $\|q\|_2 = 1$  as the norm of the query does not change the ordering, we show in the next section how to get rid of this assumption. Without loss of generality let  $\|x_i\|_2 \leq U < 1, \forall x_i \in \mathcal{S}$  as it can always be achieved by scaling the data by large enough number. We define two vector transformations  $P : \mathbb{R}^D \mapsto \mathbb{R}^{D+m}$  and  $Q : \mathbb{R}^D \mapsto \mathbb{R}^{D+m}$  as follows:

$$P(x) = [x; 1/2 - \|x\|_2^2; 1/2 - \|x\|_2^4; \dots; 1/2 - \|x\|_2^{2^m}] \quad (15)$$

$$Q(x) = [x; 0; 0; \dots; 0], \quad (16)$$

Using  $\|Q(q)\|_2^2 = \|q\|_2^2 = 1$ ,  $Q(q)^T P(x_i) = q^T x_i$ , and

$$\begin{aligned} & \|P(x_i)\|_2^2 \\ &= \|x_i\|_2^2 + 1/4 + \|x_i\|_2^4 - \|x_i\|_2^2 + 1/4 + \|x_i\|_2^8 - \|x_i\|_2^4 + \dots \\ &+ 1/4 + \|x_i\|_2^{2^{m+1}} - \|x_i\|_2^{2^m} \\ &= m/4 + \|x_i\|_2^{2^{m+1}} \end{aligned}$$

we obtain the following key equality:

$$\frac{Q(q)^T P(x_i)}{\|Q(q)\|_2 \|P(x_i)\|_2} = \frac{q^T x_i}{\sqrt{m/4 + \|x_i\|_2^{2^{m+1}}}} \quad (17)$$

The term  $\|x_i\|_2^{2^{m+1}} \rightarrow 0$ , again vanishes at the tower rate. This means we have approximately

$$\arg \max_{x \in \mathcal{S}} q^T x \approx \arg \max_{x \in \mathcal{S}} \frac{Q(q)^T P(x_i)}{\|Q(q)\|_2 \|P(x_i)\|_2} \quad (18)$$

This provides another solution for solving MIPS using known methods for approximate correlation-NNS. Asymmetric transformations  $P$  and  $Q$  provide a lot of flexibility. Note that transformations  $P$  and  $Q$  are not unique for this task and there are other possibilities [2, 19]. It should be further noted that even scaling data and query differently is asymmetry in a strict sense because it changes the distribution of the hashes. Flexibility in choosing the transformations  $P$  and  $Q$  allow us to use signed random projections and thereby making possible to avoid suboptimal L2-LSH.

### 4.2 Fast MIPS Using Sign Random Projections

Eq. (18) shows that MIPS reduces to the standard approximate near neighbor search problem which can be efficiently solved by sign random projections, i.e.,  $h^{Sign}$  (defined by Eq. (6)). Formally, we can state the following theorem.

**Theorem 2** Given a  $c$ -approximate instance of MIPS, i.e.,  $Sim(q, x) = q^T x$ , and a query  $q$  such that  $\|q\|_2 = 1$  along with a collection  $\mathcal{S}$  having  $\|x\|_2 \leq U < 1 \forall x \in \mathcal{S}$ . Let  $P$  and  $Q$  be the vector transformations defined in Eq. (15) and Eq. (16), respectively. We have the following two conditions for hash function  $h^{Sign}$  (defined by Eq. (6))

- if  $q^T x \geq S_0$  then

$$\begin{aligned} & Pr[h^{Sign}(Q(q)) = h^{Sign}(P(x))] \\ & \geq 1 - \frac{1}{\pi} \cos^{-1} \left( \frac{S_0}{\sqrt{m/4 + U^{2^{m+1}}}} \right) \end{aligned}$$

- if  $q^T x \leq cS_0$  then

$$\begin{aligned} & Pr[h^{Sign}(Q(q)) = h^{Sign}(P(x))] \\ & \leq 1 - \frac{1}{\pi} \cos^{-1} \left( \frac{\min\{cS_0, z^*\}}{\sqrt{m/4 + (\min\{cS_0, z^*\})^{2^{m+1}}}} \right) \end{aligned}$$

$$\text{where } z^* = \left( \frac{m/2}{2^{m+1}-2} \right)^{2^{-m-1}}.$$

**Proof:** When  $q^T x \geq S_0$ , we have, according to Eq. (7)

$$\begin{aligned} & Pr[h^{\text{Sign}}(Q(q)) = h^{\text{Sign}}(P(x))] \\ &= 1 - \frac{1}{\pi} \cos^{-1} \left( \frac{q^T x}{\sqrt{m/4 + \|x\|_2^{2^{m+1}}}} \right) \\ &\geq 1 - \frac{1}{\pi} \cos^{-1} \left( \frac{q^T x}{\sqrt{m/4 + U^{2^{m+1}}}} \right) \end{aligned}$$

When  $q^T x \leq cS_0$ , by noting that  $q^T x \leq \|x\|_2$ , we have

$$\begin{aligned} & Pr[h^{\text{Sign}}(Q(q)) = h^{\text{Sign}}(P(x))] \\ &= 1 - \frac{1}{\pi} \cos^{-1} \left( \frac{q^T x}{\sqrt{m/4 + \|x\|_2^{2^{m+1}}}} \right) \\ &\leq 1 - \frac{1}{\pi} \cos^{-1} \left( \frac{q^T x}{\sqrt{m/4 + (q^T x)^{2^{m+1}}}} \right) \end{aligned}$$

For this one-dimensional function  $f(z) = \frac{z}{\sqrt{a+z^b}}$ , where  $z = q^T x$ ,  $a = m/4$  and  $b = 2^{m+1} \geq 2$ , we know

$$f'(z) = \frac{a - z^b (b/2 - 1)}{(a + z^b)^{3/2}}$$

One can also check that  $f''(z) \leq 0$  for  $0 < z < 1$ , i.e.,  $f(z)$  is a concave function. The maximum of  $f(z)$  is attained at  $z^* = \left(\frac{2a}{b-2}\right)^{1/b} = \left(\frac{m/2}{2^{m+1}-2}\right)^{2^{-m-1}}$ . If  $z^* \geq cS_0$ , then we need to use  $f(cS_0)$  as the bound.  $\square$

Therefore, we have obtained, in LSH terminology,

$$p_1 = 1 - \frac{1}{\pi} \cos^{-1} \left( \frac{S_0}{\sqrt{m/4 + U^{2^{m+1}}}} \right) \quad (19)$$

$$p_2 = 1 - \frac{1}{\pi} \cos^{-1} \left( \frac{\min\{cS_0, z^*\}}{\sqrt{m/4 + (\min\{cS_0, z^*\})^{2^{m+1}}}} \right), \quad (20)$$

$$z^* = \left(\frac{m/2}{2^{m+1}-2}\right)^{2^{-m-1}} \quad (21)$$

Theorem 1 allows us to construct data structures with worst case  $O(n^\rho \log n)$  query time guarantees for  $c$ -approximate MIPS, where  $\rho = \frac{\log p_1}{\log p_2}$ . For any given  $c < 1$ , there always exist  $U < 1$  and  $m$  such that  $\rho < 1$ . This way, we obtain a sublinear query time algorithm for MIPS. Because  $\rho$  is a function of 2 parameters, the best query time chooses  $U$  and  $m$ , which minimizes the value of  $\rho$ . For convenience, we define

$$\rho^* = \min_{U, m} \frac{\log \left( 1 - \frac{1}{\pi} \cos^{-1} \left( \frac{S_0}{\sqrt{m/4 + U^{2^{m+1}}}} \right) \right)}{\log \left( 1 - \frac{1}{\pi} \cos^{-1} \left( \frac{\min\{cS_0, z^*\}}{\sqrt{m/4 + (\min\{cS_0, z^*\})^{2^{m+1}}}} \right) \right)} \quad (22)$$

See Figure 2 for the plots of  $\rho^*$ , which also compares the optimal  $\rho$  values for L2-ALSH in the prior work [23]. The results show that Sign-ALSH is noticeably better.

Figure 2: Optimal values of  $\rho^*$  (lower is better) with respect to approximation ratio  $c$  for different  $S_0$ , obtained by a grid search over parameters  $U$  and  $m$ , given  $S_0$  and  $c$ . The curves show that Sign-ALSH (solid curves) is noticeably better than L2-ALSH (dashed curves) in terms of their optimal  $\rho^*$  values. The results for L2-ALSH were from the prior work [23]. For clarity, the results are in two figures.

### 4.3 Parameter Selection

Figure 3: The solid curves are the optimal  $\rho$  values of Sign-ALSH from Figure 2. The dashed curves represent the  $\rho$  values for fixed parameters:  $m = 2$  and  $U = 0.75$  (left panel). Even with fixed parameters, the  $\rho$  does not degrade.

Figure 3 presents the  $\rho$  values for  $(m, U) = (2, 0.75)$ . We can see that even if we use fixed parameters, the per-

formance would only degrade little. This essentially frees practitioners from the burden of choosing parameters.

## 5 Removing Dependency on Norm of Query

Changing norms of the query does not affect the  $\arg \max_{x \in \mathcal{C}} q^T x$ , and hence, in practice for retrieving top- $k$ , normalizing the query should not affect the performance. But for theoretical purposes, we want the runtime guarantee to be independent of  $\|q\|_2$ . Note, both LSH and ALSH schemes solve the  $c$ -approximate instance of the problem, which requires a threshold  $S_0 = q^T x$  and an approximation ratio  $c$ . These quantities change if we change the norms. We can use the same idea used in [23] to get rid of the norm of  $q$ . Transformations  $P$  and  $Q$  were precisely meant to remove the dependency of correlation on the norms of  $x$  but at the same time keeping the inner products same. Let  $M$  be the upper bound on all the norms i.e.  $M = \max_{x \in \mathcal{C}} \|x\|_2$ . In other words  $M$  is the radius of the space.

Let  $U < 1$ , define the transformations,  $T : \mathbb{R}^D \rightarrow \mathbb{R}^D$  as

$$T(x) = \frac{Ux}{M} \quad (23)$$

and transformations  $P, Q : \mathbb{R}^D \rightarrow \mathbb{R}^{D+m}$  are the same for the Sign-ALSH scheme as defined in Eq (15) and (16).

Given the query  $q$  and any data point  $x$ , observe that the inner products between  $P(Q(T(q)))$  and  $Q(P(T(x)))$  is

$$P(Q(T(q)))^T Q(P(T(x))) = q^T x \times \left( \frac{U^2}{M^2} \right) \quad (24)$$

$P(Q(T(q)))$  appends first  $m$  zeros components to  $T(q)$  and then  $m$  components of the form  $1/2 - \|q\|_2^2$ .  $Q(P(T(x)))$  does the same thing but in a different order. Now we are working in  $D + 2m$  dimensions. It is not difficult to see that the norms of  $P(Q(T(q)))$  and  $Q(P(T(x)))$  is given by

$$\|P(Q(T(q)))\|_2 = \sqrt{\frac{m}{4} + \|T(q)\|_2^{2m+1}} \quad (25)$$

$$\|Q(P(T(x)))\|_2 = \sqrt{\frac{m}{4} + \|T(x)\|_2^{2m+1}} \quad (26)$$

The transformations are very asymmetric but we know that it is necessary.

Therefore the correlation or the cosine similarity between  $P(Q(T(q)))$  and  $Q(P(T(x)))$  is

$$Corr = \frac{q^T x \times \left( \frac{U^2}{M^2} \right)}{\sqrt{\frac{m}{4} + \|T(q)\|_2^{2m+1}} \sqrt{\frac{m}{4} + \|T(x)\|_2^{2m+1}}} \quad (27)$$

Note  $\|T(q)\|_2^{2m+1}, \|T(x)\|_2^{2m+1} \leq U < 1$ , therefore both  $\|T(q)\|_2^{2m+1}$  and  $\|T(x)\|_2^{2m+1}$  converge to zero at a tower rate and we get approximate monotonicity of correlation

with the inner products. We can apply sign random projections to hash  $P(Q(T(q)))$  and  $Q(P(T(x)))$ .

As  $0 \leq \|T(q)\|_2^{2m+1} \leq U$  and  $0 \leq \|T(x)\|_2^{2m+1} \leq U$ , it is not difficult to get  $p_1$  and  $p_2$  for Sign-ALSH, without conditions on any norms. Simplifying the expression, we get the following value of optimal  $\rho_u$  ( $u$  for unrestricted).

$$\rho_u^* = \min_{U, m} \frac{\log \left( 1 - \frac{1}{\pi} \cos^{-1} \left( \frac{S_0 \times \left( \frac{U^2}{M^2} \right)}{\frac{m}{4} + U^{2m+1}} \right) \right)}{\log \left( 1 - \frac{1}{\pi} \cos^{-1} \left( \frac{c S_0 \times \left( \frac{4U^2}{M^2} \right)}{m} \right) \right)} \quad (28)$$

$$s.t. \quad U^{2m+1} < \frac{m(1-c)}{4c}, \quad m \in \mathbb{N}^+, \quad \text{and } 0 < U < 1.$$

With this value of  $\rho_u^*$ , we can state our main theorem.

**Theorem 3** *For the problem of  $c$ -approximate MIPS in a bounded space, one can construct a data structure having  $O(n^{\rho_u^*} \log n)$  query time and space  $O(n^{1+\rho_u^*})$ , where  $\rho_u^* < 1$  is the solution to constraint optimization (28).*

Note, for all  $c < 1$ , we always have  $\rho_u^* < 1$  because the constraint  $U^{2m+1} < \frac{m(1-c)}{4c}$  is always true for big enough  $m$ . The only assumption for efficiently solving MIPS that we need is that the space is bounded, which is always satisfied for any finite dataset.  $\rho_u^*$  depends on  $M$ , the radius of the space, which is expected.

## 6 Random Space Partitioning for Inner Product

In this section, we show that due to the nature of the new transformations  $P$  and  $Q$  there is one subtle but surprising advantage of Sign-ALSH over L2-ALSH.

One popular application of LSH (Locality Sensitive Hashing) is random partitioning of the data for large scale clustering, where similar points map to the same partition (or bucket). Such partitions are very useful in many applications [12]. With classical LSH, we simply use  $h(x)$  to generate partition for  $x$ . Since  $Pr_{\mathcal{H}}(h(x) = h(y))$  is high if  $sim(x, y)$  is high, similar points are likely to go into the same partition under the usual LSH mapping. For general ALSH, this property is lost because of asymmetry.

In case of ALSH, we only know that  $Pr(h(P(x)) = h(Q(y)))$  is high if  $sim(x, y)$  is high. Therefore, given  $x$  we cannot determine whether to assign partition using  $h(P(\cdot))$  or  $h(Q(\cdot))$ . Neither  $Pr(h(P(x)) = h(P(y)))$  nor  $Pr_{\mathcal{H}}(h(Q(x)) = h(Q(y)))$  strictly indicates high value of  $sim(x, y)$  in general. Therefore, partitioning property of classical LSH does not hold anymore with general ALSHs. However for the case of inner products using Sign-ALSH, there is a subtle observation which allows us to construct the required assignment function, where pairs of points with high inner products are more likely to get mapped in

the same partition while pairs with low inner products are more likely to map into different partitions.

In case of Sign-ALSH for MIPS, we have the transformations  $P(Q(T(x)))$  and  $Q(P(T(x)))$  given by

$$P(Q(T(x))) = [x; 1/2 - \|T(x)\|_2^2; \dots; 1/2 - \|T(x)\|_2^{2m}, 0, \dots, 0]$$

$$Q(P(T(x))) = [x; 0, \dots, 0, 1/2 - \|T(x)\|_2^2; \dots; 1/2 - \|T(x)\|_2^{2m}].$$

After this transformation, we multiply the generated  $D + 2m$  dimensional vector by a random vector  $a \in \mathbb{R}^{D+2m}$  whose entries are i.i.d. Gaussian followed by taking the sign. For illustration let  $a = [w; s_1, \dots, s_m, t_1, \dots, t_m]$  where  $w \in \mathbb{R}^D$ ,  $b_i$  and  $c_i$  are numbers. All components of  $a$  are i.i.d. from  $N(0, 1)$ . With this notation, we can write the final Sign-ALSH as

$$h^{Sign}(P(Q(T(x)))) = Sign(w^T T(x) + \sum_{i=1}^m s_i (1/2 - \|T(x)\|_2^{2i}))$$

$$h^{Sign}(Q(P(T(x)))) = Sign(w^T T(x) + \sum_{i=1}^m t_i (1/2 - \|T(x)\|_2^{2i}))$$

The key observation here is that  $h^{Sign}(P(Q(T(x))))$  does not depend on  $t_i$  and  $h^{Sign}(Q(P(T(x))))$  does not depend on  $s_i$ . If we define

$$h_w(x) = Sign(w^T T(x) + \sum_{i=1}^m \alpha_i (1/2 - \|T(x)\|_2^{2i})) \quad (29)$$

where  $\alpha_i$  are sampled i.i.d. from  $N(0, 1)$  for every  $x$  independently of everything else. Then, **under the randomization of  $w$** , it is not difficult to show that

$$Pr_w(h_w(x) = h_w(y)) = Pr(h^{Sign}(P(x)) = h^{Sign}(Q(y)))$$

for any  $x, y$ . The term  $Pr(h^{Sign}(P(x)) = h^{Sign}(Q(y)))$  satisfies the LSH like property and therefore, in any partitions using  $h_w$ , points with high inner products are more likely to be together. Thus,  $h_w(x)$  is the required assignment. Note,  $h_w$  is not technically an LSH because we are randomly sampling  $\alpha_i$  for all  $x$  independently. The construction of  $h_w$  using independent randomizations could be of separate interest. To the best of our knowledge, this is the first example of LSH like partition using hash function with independent randomization for every data point.

The function  $h_w$  is little subtle here, we sample  $w$  i.i.d from Gaussian and use the same  $w$  for all  $x$ , but while computing  $h_w$  we use  $\alpha_i$  independent of everything for every  $x$ . The probability is under the randomization of  $w$  and independence of all  $\alpha_i$  ensures the asymmetry. We are not sure if such construction is possible with L2-ALSH. For LSH partitions with binary data, the idea used here can be applied on asymmetric minwise hashing [24].

## 7 Ranking Evaluations

In [23], the L2-ALSH scheme was shown to outperform other reasonable heuristics in retrieving maximum inner products. Since our proposal is an improvement over L2-ALSH, in this section we first present comparisons with L2-ALSH, in particular on ranking experiments.

### 7.1 Datasets

We use three publicly available dataset MNIST, WEBSPAM and RCV1 for evaluations. For each of the three dataset we generate two independent partitions, the query set and the train set. Each element in the query set is used for querying, while the training set serves as the collection  $\mathcal{C}$  that will be searched for MIPS. The statistics of the dataset and the partitions are summarized in Table 1

| Dataset | Dimension  | Query size | Train size |
|---------|------------|------------|------------|
| MNIST   | 784        | 10,000     | 60,000     |
| WEBSPAM | 16,609,143 | 5,000      | 100,000    |
| RCV1    | 47,236     | 5,000      | 100,000    |

Table 1: Datasets used for evaluations.

### 7.2 Evaluations

In this section, we show how the ranking of the two ALSH schemes, L2-ALSH and Sign-ALSH, correlates with inner products. Given a query vector  $q$ , we compute the top-10 gold standard elements based on the actual inner products  $q^T x$ ,  $\forall x \in \mathcal{C}$ , here our collection is the train set. We then generate  $K$  different hash codes of the query  $q$  and all the elements  $x \in \mathcal{C}$  and then compute

$$Matches_x = \sum_{t=1}^K \mathbf{1}(h_t(Q(q)) = h_t(P(x))), \quad (30)$$

where  $\mathbf{1}$  is the indicator function and the subscript  $t$  is used to distinguish independent draws of  $h$ . Based on  $Matches_x$  we rank all the elements  $x$ . Ideally, for a better hashing scheme,  $Matches_x$  should be higher for element  $x$  having higher inner products with the given query  $q$ . This procedure generates a sorted list of all the items for a given query vector  $q$  corresponding to the each of the two asymmetric hash functions under consideration.

For L2-ALSH, we used the same parameters used and recommended in [23]. For Sign-ALSH, we used the recommended choice shown in Section 4.3, which is  $U = 0.75$ ,  $m = 2$ . Note that Sign-ALSH does not have parameter  $r$ .

We compute precision and recall of the top-10 gold standard elements, obtained from the sorted list based on  $Matches_x$ . To compute this precision and recall, we start at the top of the ranked item list and walk down in order. Suppose we are at the  $k^{th}$  ranked item, we check if this element belongs to the gold standard top-10 list. If it is one of the top-10 gold standard elements, then we increment the count of *relevant seen* by 1, else we move to  $k + 1$ . By  $k^{th}$  step, we have already seen  $k$  elements, so the *total items seen* is  $k$ . The precision and recall at that point are

$$Precision = \frac{\text{relevant seen}}{k}, \quad Recall = \frac{\text{relevant seen}}{10}$$

We show performance for  $K \in \{64, 128, 256, 512\}$ . Note that it is important to balance both precision and recall. The

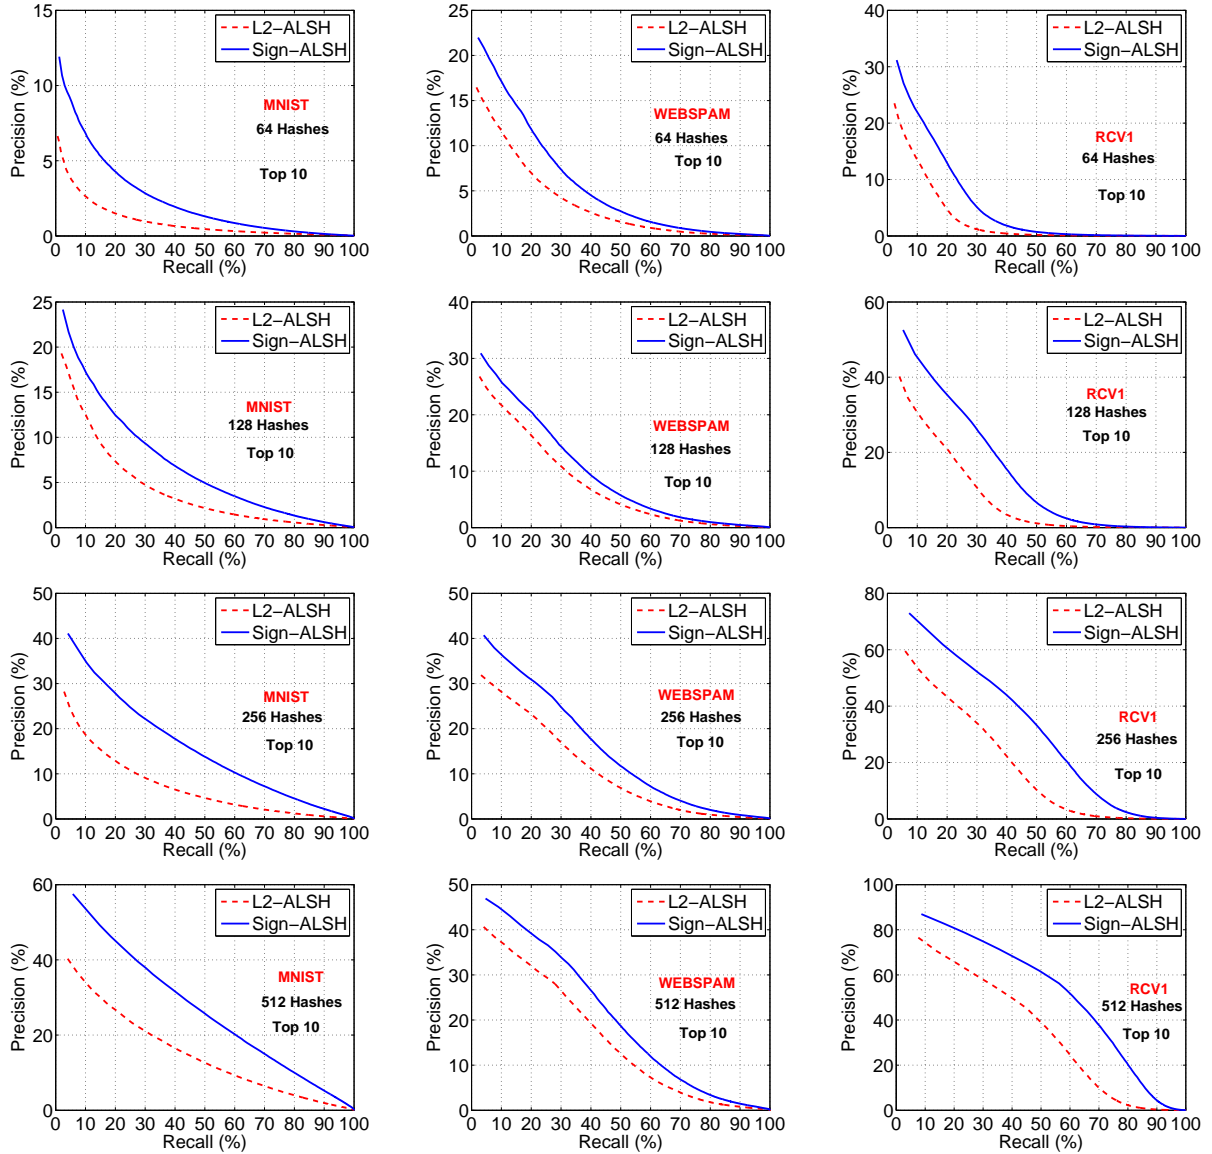

Figure 4: Precision-Recall curves (higher is better). We compare L2-ALSH (using parameters recommended in [23]) with our proposed Sign-ALSH using ( $m = 2, U = 0.75$ ) for retrieving top-10 elements. Sign-ALSH is noticeably better.

method which obtains higher precision at a given recall is superior. Higher precision indicates higher ranking of the top-10 inner products which is desirable. We report averaged precisions and recalls.

The plots for all the three datasets are shown in Figure 4. We can clearly see, that our proposed Sign-ALSH scheme gives significantly higher precision recall curves than the L2-ALSH scheme, indicating better correlation of top inner products with Sign-ALSH compared to L2-ALSH. The results are consistent across datasets.

## 8 Comparisons of Hashing Based and Tree Based Methods for MIPS

We have shown in the previous Section that Sign-ALSH outperforms L2-ALSH in ranking evaluations. In this Section, we consider the actual task of finding the maximum

inner product. Our aim is to estimate the computational saving, in finding the maximum inner product, with Sign-ALSH compared to the existing scheme L2-ALSH. In addition to L2-ALSH which is a hashing scheme, there is another tree based space partitioning method [21] for solving MIPS. Although, in theory, it is known that tree based methods perform poorly [25] due to their exponential dependence on the dimensionality, it is still important to understand the impact of such dependency in practice. Unfortunately no empirical comparison between hashing and tree based methods exists for the problem of MIPS in the literature. To provide such a comparison, we also consider tree based space partitioning method [21] for evaluations. We use the same three datasets as described in Section 7.1.

Tree based and hashing based methodologies are very different in nature. The major difference is in the stopping

criteria. Hashing based methods create buckets and stop the search once they find a good enough point, they may not succeed with some probability. On the other hand, tree based methods use branch and bound criteria to stop exploring further. So it is possible that a tree based algorithm finds the optimal point but continues to explore further requiring more computations. The usual stopping criteria thus makes tree based methods unnecessarily expensive compared to hashing based methods where the criteria is to stop after finding a good point. Therefore, to ensure fair comparisons, we allow the tree based method to stop the evaluations immediately once the algorithm finds the maximum inner product and prevent it from exploring further. Also, in case when hashing based algorithm fails to find the best inner product we resort to the full linear scan and penalize the hashing based algorithm for not succeeding. All this is required to ensure that tree based algorithm is not at any disadvantage compare to hashing methods.

We implemented the bucketing scheme with Sign-ALSH and L2-ALSH. The bucketing scheme requires creating many hash tables during the preprocessing stage. During query phase, given a query, we compute many hashes of the query and probe appropriate buckets in each table. Please refer [1] for more details on the process. We use the same fixed parameters for all the evaluations, i.e., ( $m=2$ ,  $U=0.75$ ) for Sign-ALSH and ( $m=3$ ,  $U=0.83$ ,  $r=2.5$ ) for L2-ALSH as recommended in [23]. The total number of inner products evaluated by a hashing scheme, for a given query, is the total number of hash computation for the query plus the total number of points retrieved from the hash tables. In rare cases, with very small probability, if the hash tables are unable to retrieve the gold standard maximum inner product, we resort to linear scan and also include the total number of inner products computed during the linear scan. We stop as soon as we reach the gold standard point.

We implemented Algorithm 5 from [21], which is the best performing algorithm as shown in the evaluations. For this algorithm, we need to select one parameter which is the minimum number of elements in the node required for splitting. We found that on all the three datasets the value of 100 for this parameter works the best among {500, 200, 100, 50}. Therefore, we use 100 in all our experiments. The total number of inner products evaluated by tree based algorithm is the total number of points reported plus the total number of nodes visited, where we compute the branch and bound constraint. Again we stop the search process as soon as we reach the point with gold standard maximum inner product. As argued, we need this common stopping condition to compare with hashing based methods, where we do not have any other stopping criteria [13].

For every query we compute the number of inner products evaluated by different methods for MIPS. We report the mean of the total number of inner products evaluated per query in Table 2. We can clearly see that hashing based

|          | Sign-ALSH    | L2-ALSH | Cone Trees |
|----------|--------------|---------|------------|
| MNIST    | <b>7,944</b> | 9,971   | 11,202     |
| WEBS-PAM | <b>2,866</b> | 3,813   | 22,467     |
| RCV1     | <b>9,951</b> | 11,883  | 38,162     |

Table 2: Average number of inner products evaluated per query by different MIPS algorithms. Both Sign-ALSH and L2-ALSH [23] outperform cone trees [21]. Sign-ALSH is always superior compared to L2-ALSH for MIPS.

methods are always better than the tree based algorithm. Except on MNIST dataset, hashing based methods are significantly superior, which is also not surprising because MNIST is an image dataset having low intrinsic dimensionality. Among the two hashing schemes Sign-ALSH is always better than L2-ALSH, which verifies our theoretical findings and supports our arguments in favor of Sign-ALSH over L2-ALSH for MIPS.

## 9 Conclusion

The MIPS (maximum inner product search) problem has numerous important applications in machine learning, databases, and information retrieval. [23] developed the framework of Asymmetric LSH and provided an explicit scheme (L2-ALSH) for approximate MIPS in sublinear time. L2-ALSH uses L2-LSH as a subroutine which uses suboptimal quantizations. In this study, we present another asymmetric transformation scheme (Sign-ALSH) which converts the problem of maximum inner products into the problem of maximum correlation search, which is subsequently solved by sign random projections, thereby avoiding the use of L2-LSH.

Theoretical analysis and experimental study demonstrate that **Sign-ALSH** can be noticeably more advantageous than **L2-ALSH**. The new transformations with Sign-ALSH can be adapted to generate LSH like random data partitions which is very useful for large scale clustering. Such an adaptation is not possible with existing L2-ALSH. This was a rather unexpected advantage of the proposed Sign-ALSH over L2-ALSH. We also establish by experiments that hashing based algorithms are superior to tree based space partitioning methods for MIPS.

It should be noted that for MIPS over binary data our recent work asymmetric minwise hashing [24] should be used. We showed that for binary domain asymmetric minwise hashing is both empirically and provably superior, please see [24] for more details.

## Abstract

Learning an optimal chain graph from data is an important hard computational problem. We present a new approach to solve this problem for various objective functions without making any assumption on the probability distribution at hand. Our approach is based on encoding the learning problem declaratively using the answer set programming (ASP) paradigm. Empirical results show that our approach provides at least as accurate solutions as the best solutions provided by the existing algorithms, and overall provides better accuracy than any single previous algorithm.

## 1 INTRODUCTION

Learning an optimal structure for a graphical model is a well-known and important hard computational problem. Indeed, various learning algorithms have been proposed over the years for different classes of graphical models. These algorithms can be categorized into in-exact (often local search style) approaches and exact approaches. The algorithms in the former category typically scale better, but are not in general guaranteed to produce optimal solutions without restrictive assumptions on the probability distribution at hand. The algorithms in the latter category, due to the NP-hardness of the underlying optimization problem, require more computational resources, but in turn can provide optimal solutions in much more general settings.

Two important, widely studied and applied classes of probabilistic graphical models are Bayesian networks (whose structure is represented by directed acyclic graphs), and Markov networks (represented by undirected graphs). In this paper we focus on *chain graphs* (CGs), a superclass of both Bayesian and Markov networks. CGs are hybrid graphs that can contain both directed and undirected edges, but are not allowed to contain semidirected cycles. This

makes CGs more expressive than Bayesian and Markov networks in the sense that CGs can model both symmetric (like Markov networks) and asymmetric (like Bayesian networks) relations between random variables, and hence allow for a wider range of independence models to be represented. For example, for 20 random variables, CGs can represent approximately 1000 times as many models as Bayesian networks (Sonntag et al., 2015). There exist multiple interpretations of CGs in the literature. Here we focus on the classical LWF interpretation by Frydenberg (1990); Lauritzen and Wermuth (1989).

In this work we take on the challenging task of developing exact structure learning algorithms for CGs. To our best knowledge, to date only three learning algorithms CGs have been proposed: PC (Studený, 1997), LCD (Ma et al., 2008), and CKES (Peña et al., 2014). Each of these algorithms implement forms of local search, and are guaranteed to find (inclusion) optimal solutions only under restrictive assumptions on the input. Specifically, PC and LCD assume that the probability distribution at hand is faithful to a CG. The CKES algorithm, on the other hand, assumes that the probability distribution at hand satisfies the so-called composition property. While this assumption is considerably weaker than the faithfulness assumption, it leaves room for developing CG learning algorithms that can provide optimal solutions in more general settings.

The main contribution of this paper is a versatile approach to learning CGs. Our approach improves on the earlier CG learning algorithms in that it is guaranteed to find (e.g., inclusion) optimal CGs without making assumptions on the probability distribution at hand. Moreover, our approach can easily be adapted to produce optimal CGs wrt other objective functions such as CGs that represent the largest number of independencies, or CGs with the least number of edges. Our approach is based on encoding the CG learning problem in a modular way using the answer set programming (ASP) paradigm. This enables the use of recent advances in state-of-the-art exact ASP optimization solvers that allow for a complete search in the space of CGs. Moreover, due to the expressive constraint modelling

language offered by ASP, our approach allows for integrating user knowledge into the search. This can, for example, be deployed to enforce certain substructures in the produced solutions or to adopt advanced objective functions taking non-binary information about independence constraints into account.

We also present results from an empirical comparison of our approach with the existing CG learning algorithms. As the existing algorithms make assumptions about the probability distribution at hand, the experiments involve only probability distributions that satisfy the assumptions of the existing algorithms (although unnecessary for our approach) in order to avoid biasing the results in our favour. Even in such restricted settings, the results of the evaluation indicate that our approach provides at least as accurate solutions as the best solutions provided by the existing algorithms, and overall provides better accuracy than any single previous algorithm.

This work is motivated by recent work on harnessing declarative programming (including ASP, Boolean satisfiability, maximum satisfiability, and integer programming solvers) to learn optimal Bayesian networks (Cussens and Bartlett, 2013; Berg et al., 2014; Parviainen et al., 2014), Markov networks (Corander et al., 2013) and causal structures (Hyttinen et al., 2013, 2014). However, to our best knowledge, this work is the first investigation into learning optimal CGs with declarative programming.

The rest of this paper is organized as follows. We start by reviewing CGs, their semantics, and the three existing CG learning algorithms (Section 2). We then continue by presenting and extending a set of inference rules for computing separations and non-separations in CGs (Section 3). In Section 4 we present an implementation of the CG learning approach, using the rules from the previous section. This implementation is then evaluated wrt the existing CG learning algorithms in Section 5.

## 2 CHAIN GRAPHS

In this section, we review concepts related to chain graphs as relevant to this work.

Unless otherwise stated, all the graphs in this paper are defined over a finite set of  $N$  nodes. Moreover, the graphs are *simple*, i.e., contain at most one edge between any pair of nodes. The elements of  $N$  are not distinguished from singletons. We consider graphs which may contain both undirected and directed edges. For a given graph  $G$ , we use  $x_1 - x_2$  (resp.,  $x_1 \rightarrow x_2$ ) to denote that  $G$  contains an undirected (resp., directed edge) between two nodes  $x_1$  and  $x_2$ .

The *skeleton* of  $G$  is the undirected graph that has the same adjacencies as  $G$ . A *route* between a node  $x_1$  and a node  $x_n$  in  $G$  is a sequence of (not necessarily distinct) nodes

$x_1, \dots, x_n$  such that  $x_i \rightarrow x_{i+1}$ ,  $x_i \leftarrow x_{i+1}$ , or  $x_i - x_{i+1}$  for all  $1 \leq i < n$ . A route  $x_1, \dots, x_n$  in  $G$  is a *semidirected cycle* if (i)  $x_n = x_1$ , (ii)  $x_1 \rightarrow x_2$  is in  $G$ , and (iii)  $x_i \rightarrow x_{i+1}$  or  $x_i - x_{i+1}$  is in  $G$  for all  $1 < i < n$ . A *chain graph* (CG) is a graph that contains no semidirected cycles.

A *section* of a route  $\rho$  in a CG is a *maximal* (wrt set inclusion) undirected subroute of  $\rho$ . A section  $x_2 - \dots - x_{n-1}$  of  $\rho$  is a *collider section* of  $\rho$  if  $x_1 \rightarrow x_2 - \dots - x_{n-1} \leftarrow x_n$  is a subroute of  $\rho$ . Moreover,  $\rho$  is *Z-open* with  $Z \subseteq N$  if (i) every collider section of  $\rho$  has a node in  $Z$ , and (ii) no non-collider section of  $\rho$  has a node in  $Z$ . Let  $X, Y$  and  $Z$  denote three disjoint subsets of  $N$ . If there is no  $Z$ -open route in a CG  $G$  between nodes in  $X$  and nodes in  $Y$ ,  $X$  is *separated* from  $Y$  given  $Z$  in  $G$ , denoted by  $X \perp_G Y | Z$ , meaning that  $X$  and  $Y$  are represented as conditionally independent given  $Z$  in  $G$ . Otherwise,  $X$  is *non-separated* from  $Y$  given  $Z$  in  $G$ , denoted by  $X \not\perp_G Y | Z$ . An independence model  $M$  is a set of statements of the form  $X \perp_M Y | Z$ , meaning that  $X$  is independent of  $Y$  given  $Z$ . The *independence model* represented by  $G$ , denoted by  $I(G)$ , is the set of represented independencies  $X \perp_G Y | Z$ . We denote by  $X \perp_p Y | Z$  (resp.  $X \not\perp_p Y | Z$ ) that  $X$  is independent (resp. dependent) of  $Y$  given  $Z$  under a probability distribution  $p$ . The independence model induced by  $p$ , denoted by  $I(p)$ , is the set of statements  $X \perp_p Y | Z$ . A distribution  $p$  is *faithful* to a CG  $G$  when  $X \perp_p Y | Z$  iff  $X \perp_G Y | Z$  for all pairwise disjoint subsets  $X, Y, Z$  of  $N$ . Two CGs are *Markov equivalent* if they represent the same independence model.

Let  $X, Y, Z$  and  $W$  denote four disjoint subsets of  $N$ . An independence model  $M$  is a *semi-graphoid* if it has the following properties: (i) *symmetry*:  $X \perp_M Y | Z$  implies  $Y \perp_M X | Z$ ; (ii) *decomposition*:  $X \perp_M Y \cup W | Z$  implies  $X \perp_M Y | Z$ ; (iii) *weak union*:  $X \perp_M Y \cup W | Z$  implies  $X \perp_M Y | Z \cup W$ ; and (iv) *contraction*:  $X \perp_M Y | Z \cup W$  and  $X \perp_M W | Z$  together imply  $X \perp_M Y \cup W | Z$ . A semi-graphoid  $M$  is a *graphoid* if it has the property (v) *intersection*:  $X \perp_M Y | Z \cup W$  and  $X \perp_M W | Z \cup Y$  together imply  $X \perp_M Y \cup W | Z$ . A graphoid  $M$  is *compositional* if  $X \perp_M Y | Z$  and  $X \perp_M W | Z$  together imply  $X \perp_M Y \cup W | Z$ . The independence model induced by a probability distribution is a semi-graphoid, and the independence model induced by a strictly positive probability distribution is a graphoid (Studený, 2005). While the independence model induced by a probability distribution is not a compositional graphoid in general, independence models induced by Gaussian probability distributions are compositional (Studený, 2005).

The *elementary statements* of a semi-graphoid  $M$  are those of the form  $x \perp_M y | Z$ , where  $x, y \in N$ . A semi-graphoid  $M$  is determined by its elementary statements, meaning that every statement in  $M$  follows from the elementary statements by repeatedly applying the semi-graphoid properties (Studený, 2005, Lemma 2.2). Thus one can equiv-

Figure 1: Example

alently work with the elementary statements of a semi-graphoid. We do so in the rest of the article. In other words, we restrict the independence model represented by a CG or induced by a probability distribution to its elementary statements.

A CG  $G$  is *inclusion optimal* wrt an independence model  $M$  if (i)  $I(G) \subseteq M$ , and (ii) there exists no CG  $H$  such that  $I(G) \subset I(H) \subseteq M$ . We say that an inclusion optimal  $G$  is *independence optimal* if there exists no CG  $H$  such that  $I(H) \subseteq M$  and  $|I(H)| > |I(G)|$ .

**Example 1** *Although the graph  $G$  shown in Figure 1a only contains directed and undirected edges, it is not a CG since it contains the semidirected cycle  $x \rightarrow z - y \rightarrow x$ . The graph  $H$  in Figure 1b is a CG; its independence model  $I(H)$  shown in Figure 1c. For example,  $x \perp_H y | z$  holds because the only route between  $x$  and  $y$  is  $x \rightarrow z - y$  and  $z$  is in the conditioning set. Moreover,  $I(H)$  fulfills the graphoid properties since it is symmetric and only contains one pair of independencies. Finally,  $I(H) \subset I(M)$  holds for the independence model  $M$  shown in Figure 1d. This means that  $H$  is inclusion optimal wrt  $M$ , since removing an edge from  $H$  would cause either  $x \perp_H z | \emptyset$  or  $y \perp_H z | \emptyset$  to be true, neither of which are in  $M$ . Also note that  $M$  is not faithful to any CG since there is no CG  $H'$  such that  $I(H') = I(M)$ .*

## 2.1 Algorithms for Learning CGs

We continue by a short overview of existing algorithms for CG learning. To our knowledge, only three such have been proposed earlier.

The first algorithm, proposed in (Studený, 1997), is a PC-like algorithm that first finds a skeleton, and then orients the edges according to a specific set of rules. The second algorithm, LCD, proposed by (Ma et al., 2008), uses a divide-and-conquer approach that allows for fast learning

of CGs especially in the space of sparse CGs. If the probability distribution at hand is faithful to a CG  $G$ , then both Studený's algorithm and LCD are guaranteed to find a CG  $H$  that is Markov equivalent with  $G$ .

The third algorithm for learning CGs, CKES, proposed in (Peña et al., 2014), can be viewed as an extension of the KES (Nielsen et al., 2003) Bayesian network learning algorithm. CKES works by iteratively adding (resp. removing) edges between the variables in the CG that are dependent (resp. independent) in the probability distribution at hand. The CKES algorithm guarantees to produce a CG that is inclusion optimal wrt the independence model induced by the probability distribution at hand in case the model is a compositional graphoid.

## 3 INFERENCE RULES FOR FINDING SEPARATIONS IN CHAIN GRAPHS

In this work, we rely on inference rules by Studený (1998) that allow for efficiently computing the separations and non-separations in a given CG  $G$ . We will represent these rules in our ASP encoding of CG learning, as detailed in Section 4. The rules are based on four sets of nodes  $U_x^C$ ,  $V_x^C$ ,  $W_x^C$ , and  $Z_x^C$ , that are saturated for each node  $x \in N$  wrt the conditioning set  $C \subseteq N \setminus \{x\}$ . A node  $x$  is then separated from each node  $y \in N \setminus (U_x^C \cup V_x^C)$  given the conditioning set  $C$ , i.e.,  $x \perp_G y | C$ . The rules are shown in Figure 2. For some intuition, note that

- $y \in V_x^C$  iff there exists a C-open route from  $x$  to  $y$  in  $G$  which contains the subroute  $a_i \rightarrow a_{i+1} - \dots - a_{i+k} = y$ ,  $k \geq 1$ ,
- $y \in U_x^C$  iff there exists a C-open route from  $x$  to  $y$  in  $G$  which does not contain the subroute  $a_i \rightarrow a_{i+1} - \dots - a_{i+k} = y$ ,  $k \geq 1$ ,
- $y \in W_x^C$  iff there exists a  $z \in U_x^C \cup V_x^C$  and a route  $z = a_0 \rightarrow a_1 - \dots - a_r = y$  in  $G$ ,  $r \geq 1$ , and
- $y \in Z_x^C$  iff there exists a  $z \in U_x^C \cup V_x^C$  and a route  $z = a_0 \rightarrow a_1 - \dots - a_r = y$ ,  $r \geq 1$ , with  $\{a_1, \dots, a_r\} \cap C \neq \emptyset$ .

Note that rule 7 in Figure 2 corrects a small typo in the original paper (Studený, 1998).

The correctness of these rules can be stated as follows.

### Theorem 1 (Adapted from (Studený, 1998))

*Given a CG  $G$  over a node set  $N$ , starting with  $U_x^C = V_x^C = Z_x^C = W_x^C = \emptyset$  for each node  $x \in N$  and  $C \subseteq N$ , apply the rules in Figure 2 until fixpoint. Then  $y \notin U_x^C \cup V_x^C$  iff  $x \perp_G y | C$ .*

|  |
|--|
| 0. $C \subset N, x \notin C \Rightarrow x \in U_x^C$                             |
| 1. $x \in U_a^C, x - y, y \notin C \Rightarrow y \in U_a^C$                      |
| 2. $x \in U_a^C, y \rightarrow x, y \notin C \Rightarrow y \in U_a^C$            |
| 3. $x \in U_a^C \cup V_a^C, x \rightarrow y, y \notin C \Rightarrow y \in V_a^C$ |
| 4. $x \in V_a^C, x - y, y \notin C \Rightarrow y \in V_a^C$                      |
| 5. $x \in U_a^C \cup V_a^C, x \rightarrow y \Rightarrow y \in W_a^C$             |
| 6. $x \in W_a^C, x - y \Rightarrow y \in W_a^C$                                  |
| 7. $x \in W_a^C, x \in C \Rightarrow x \in Z_a^C$                                |
| 8. $x \in Z_a^C, x - y \Rightarrow y \in Z_a^C$                                  |
| 9. $x \in Z_a^C, y \rightarrow x, y \notin C \Rightarrow y \in U_a^C$            |

Figure 2: Studený's inference rules

### 3.1 Refining Studený's Rules

It turns out that the  $W$  sets in Studený's original rules are actually redundant. In detail, the  $W$  sets can be removed by replacing the original rules 5–7 by the rules 10–11 presented in Figure 3.

|  |
|--|
| 10. $x \in U_a^C \cup V_a^C, x \rightarrow y, y \in C \Rightarrow y \in Z_a^C$ |
| 11. $x \in V_a^C, x - y, y \in C \Rightarrow y \in Z_a^C$                      |

Figure 3: Replacement for Studený's rules 5–7

**Proposition 1** *Given a CG  $G$  over a node set  $N$ , starting with  $U_x^C = V_x^C = Z_x^C = W_x^C = \emptyset$  for each node  $x \in N$  and  $C \subseteq N$ , the following computations give the same  $U_x^C$  and  $V_x^C$  sets:*

- Apply the rules 0–9 in Figure 2 until fixpoint.
- Apply rules 0–4 and rules 8–9 in Figure 2 together with rules 10–11 in Figure 3 until fixpoint.

*Proof (sketch).* Without loss of generality, perform the original and the refined computation by running the following three steps repeatedly until fixpoint. Step 1: Run rules 0–4 until fixpoint. Step 2: Run rules 5–8 (original computation) or rules 8,10–11 (refined computation) until fixpoint. Step 3: Run rule 9 until fixpoint. In order to prove the lemma, it suffices to prove that  $Z_x^C$  is the same at the end of step 2 for both computations.

Consider arbitrary  $U_x^C$  and  $V_x^C$ . Recall that by using the original rules 0–9, a node  $y \in Z_x^C$  only if there exists a

node  $z \in U_x^C \cup V_x^C$  and a route  $z = a_0 \rightarrow a_1 - \dots - a_r = y, r \geq 1$ , with  $\{a_1, \dots, a_r\} \cap C \neq \emptyset$ . Let  $a_s$  denote the first node in the subroute  $a_1 - \dots - a_r$  that is in  $C$ . Observe that  $a_{s-1} \in U_x^C \cup V_x^C$  if  $s = 1$ , and  $a_{s-1} \in V_x^C$  otherwise. One can check that we have exactly  $a_s \in Z_x^C$  both by applying rules 10–11 in the refined computation and by applying rules 5–7 in the original computation. After this,  $y \in Z_x^C$  is obtained both in the original and in the refined computation by repeatedly applying rule 8.  $\square$

### 3.2 Additional Rules

On top of the “replacement” rules 10–11, we further identify additional rules that can be applied soundly together with Studený's original rules, i.e., without affecting the resulting  $U$  and  $V$  sets. While these rules, shown in Figure 4, are redundant, encoding the rules declaratively as part of the ASP encoding presented in this work improves the overall running times of our approach in practice.

**Proposition 2** *Given a CG  $G$  over a node set  $N$ , starting with  $U_x^C = V_x^C = Z_x^C = W_x^C = \emptyset$  for each node  $x \in N$  and  $C \subseteq N$ , the following computations give the same  $U_x^C$  and  $V_x^C$  sets:*

- Apply the rules 0–9 in Figure 2 until fixpoint.
- Apply the rules 0–9 in Figure 2 together with rules 12–17 in Figure 4 until fixpoint.

*Proof (sketch).* Consider rule 12. According to the head of the rule, there exists a C-open route from  $a$  to  $x$  which does not contain the subroute  $a_i \rightarrow a_{i+1} - \dots - a_{i+k} = x$  with  $k \geq 1$ . Then, preceding this route with the edge  $b \leftarrow a$  with  $b \notin C$  results in a C-open route from  $b$  to  $x$  which does not contain the subroute  $a_i \rightarrow a_{i+1} - \dots - a_{i+k} = x$  with  $k \geq 1$ . Then, the body of the rule holds. The correctness of the rest of the rules can be proven in the same way.  $\square$

|  |
|--|
| 12. $x \in U_a^C, a \rightarrow b, b \notin C \Rightarrow x \in U_b^C$ |
| 13. $x \in V_a^C, a \rightarrow b, b \notin C \Rightarrow x \in V_b^C$ |
| 14. $x \in Z_a^C, a \rightarrow b, b \notin C \Rightarrow x \in Z_b^C$ |
| 15. $x \in U_a^C, y \in U_x^C \Rightarrow y \in U_a^C$                 |
| 16. $x \in U_a^C, y \in V_x^C \Rightarrow y \in V_a^C$                 |
| 17. $x \in U_a^C, y \in Z_x^C \Rightarrow y \in Z_a^C$                 |

## 4 LEARNING CHAIN GRAPHS VIA ASP

In this section we detail our method of learning CGs using ASP. The approach is constraint-based and allows for the objective function to take additional domain knowledge into account. We start with a short informal account of ASP.

### 4.1 Answer Set Programming

Answer set programming (ASP) is a rule-based declarative constraint satisfaction paradigm that is well-suited for representing and solving various computationally hard problems (Gelfond and Lifschitz, 1988; Niemelä, 1999; Simons et al., 2002). ASP offers an expressive declarative modelling language in terms of first-order logical rules, allowing for intuitive and compact representations of NP-hard optimization tasks. When using ASP, the first task is to model the problem in terms of ASP rules (constraints) so that the set of solutions implicitly represented by the ASP rules corresponds to the solutions of the original problem. One or multiple solutions of the original problem can then be obtained by invoking an off-the-shelf ASP solver on the constraint declaration. The algorithms underlying the ASP solver Clingo (Gebser et al., 2011) that we use in this work are based on state-of-the-art Boolean satisfiability solving techniques (Biere et al., 2009). These techniques have during the last 10-15 years emerged as robust and efficient means of solving various hard search and optimization problems and even in cases surpassed specialized algorithms while at the same time offering great flexibility as general NP-procedures for declarative problem solving. As a self-contained explanation of ASP syntax and semantics would exceed the page limit, we only aim to give an intuitive reading of our ASP encoding for learning CGs.

### 4.2 Encoding the CG structure learning problem

Our exact ASP encoding of the CG structure learning problem is modular, consisting of three parts: (1) a set of constraints representing the space of CGs with a given set of nodes, including constraints ruling out semidirected cycles (Section 4.2.1); (2) a set of rules exactly encoding the Studený inference rules and thereby the separations and non-separations of a given CG (Section 4.2.2); (3) a set of soft constraints exactly representing a well-defined objective function used for finding the optimal CG structure of a problem (Section 4.2.3). Note that parts 2 and 3 are dependent on the input data. Specifically, part 2 represents the dependencies and independencies that are determined by the data. Additional information about the dependencies and independencies can also be added to part 2, such as the confidence of their correctness. This information can then be used by the objective function in part 3 as discussed in Section 4.2.3. Essentially, by calling an ASP solver with the whole ASP encoding, consisting of parts 1–3, the solver

will perform an intelligent implicit search over the space of CGs (using part 1), and will output a CG that produces the best objective function score (based on part 3) by deriving the separations and non-separations in the CGs (using part 2). Furthermore, in Section 4.3 we discuss how additional domain knowledge can be incorporated.

#### 4.2.1 Encoding CGs

We start with part 1, i.e., by describing an ASP program encoding of the space of CGs. This base encoding is represented in Figure 5.

In the encoding, the input predicate *node* represents the fact that  $x$  is a node. We use the predicates *edge* and *arc* to represent the undirected and directed edges, respectively, of the CG  $G$ , i.e., these predicates represent the actual CG described by a solution to the ASP program. More precisely, we have that  $edge(X, Y)$  is true iff  $x - y \in G$ , and  $arc(X, Y)$  is true iff  $x \rightarrow y \in G$ . Informally, the “guess” part of the program, consisting of the two first rules, encodes a non-deterministic guess of the edges in  $G$ , which means that the ASP solver will implicitly consider all possible graphs during search. The next three rules enforce the fact that, for any pair  $x, y$  of nodes in a CG  $G$ , there can be at most one type of an edge (undirected, directed, or neither) between them. The predicate *ancestor*( $X, Y$ ) is true iff there is a semidirected route from a node  $x$  to node  $y$ , and is used to enforce that CGs cannot contain semidirected cycles. This constraint is enforced transitively by the last five rules in Figure 5.

```
%%% guess graph:
% directed edges
{ arc(X,Y) } :- node(X;Y), X!=Y,
               not edge(X,Y),
               not arc(Y,X).

% undirected edges
{ edge(X,Y) } :- node(X;Y), X!=Y,
                not arc(X,Y),
                not arc(Y,X).

%%% at most one edge between node pairs:
% symmetric undirected edge relation
edge(Y,X) :- edge(X,Y).
% disallow cases with both directed and
% undirected edges over a pair of nodes
:- edge(X,Y), arc(X,Y).
% disallow pairwise opposite arcs
:- arc(X,Y), arc(Y,X).

%%% disallow partially directed cycles
ancestor(X,X) :- node(X).
ancestor(X,Y) :- arc(X,Y).
ancestor(X,Y) :- edge(X,Y).
ancestor(X,Y) :- ancestor(X,Z),
                ancestor(Z,Y).
:- ancestor(X,Y), arc(Y,X).
```

Figure 5: ASP encoding of chain graphs

## 4.2.2 Encoding Studeny’s Rules

For inferring the separations that hold in a given CG  $G$ , we encode Studeny’s inference rules—or more precisely, the modified rule set consisting of the rules 0–4, 8–9, and 10–11 (recall Section 3)—in ASP. As shown in Figure 6, the ASP modelling language allows for very natural encoding of these rules. The predicates  $inU(X, A, C)$ ,  $inV(X, A, C)$ , and  $inZ(X, A, C)$ , respectively, are used for representing the facts that a node  $x \in U_a^C$ ,  $x \in V_a^C$ , and  $x \in Z_a^C$ , respectively. The auxiliary predicate  $in(C, X)$ , although its defining rule may seem somewhat complicated, simply represents the fact that node  $x \in C \subseteq N$ . As a technical detail, we use an index-representation for the conditioning sets and the nodes: the index of a given set  $C \subseteq N = \{1..|N|\}$  is represented as a binary vector  $b_{|N|} \dots b_2 b_1$ , where  $b_i = 1$  iff node  $i \in C$ . The sets  $C \subseteq N$  are represented by the input predicate  $set$ . Finally, the predicate  $derived\_dep(X, A, C)$  is defined to be true iff  $x \not\perp_G a | C$ , where  $G$  is the graph represented by the predi-

cates  $edge$  and  $arc$ , exactly following the conditions stated in Theorem 1.

## 4.2.3 Optimization

We proceed by detailing how different objective functions can be encoded within our approach. As noted earlier, the goal of an objective function is to assign a score to every CG  $G$ , and the set of optimal CGs is defined as those CGs which minimizes the objective function value. We consider three different objective functions that characterize different types of optimality conditions for CGs. Following Hyttinen et al. (2014)—who focused on causal structure discovery—each of the objective functions is (in some cases partially) based on how well the separations and non-separations of the given CG  $G$  corresponds to the independencies and dependencies determined from the data. In the following, we denote by  $CG(N)$  the set of CGs over the set of nodes  $N$ , and by  $I$  the (complete) set of independencies and dependencies given as input (determined before-hand from the data).

The first two objective functions follow the general idea of minimizing a sum of costs over incorrect separations and non-separations in  $G$  wrt the independencies and dependencies determined by the data. As a generalization, we associate for each (in)dependence statement determined by the data a cost (weight)  $w(x \perp y | C)$  and  $w(x \not\perp y | C)$ , which is incurred on the solution  $G$  iff the corresponding separation statement does not hold in  $G$ . This allows for formalizing a general weighted objective function

$$\min_{G \in CG(N)} \sum_{(x \not\perp y | C) \in I} w(x \not\perp y | C) \cdot T[x \perp y | C] + \sum_{(x \perp y | C) \in I} w(x \perp y | C) \cdot T[x \not\perp y | C], \quad (1)$$

where  $T[c]$  is an indicator for the condition  $c$  being true for graph  $G$ .

By setting the weights  $w$  appropriately, this gives various interesting special cases. For example, to represent independence optimal CGs as the optimal solutions, let  $w(x \not\perp y | C) = \infty$  (i.e., all dependencies have to be represented in any CG  $G$ ) and  $w(x \perp y | C) = 1$  (i.e., each independence relation not represented by  $G$  adds a unit cost to  $G$ ).

On the level of our ASP encodings of the objective functions considered, we use the input predicates  $indep(X, Y, C, W)$  and  $dep(X, Y, C, W)$ , to represent  $w(x \perp y | C)$  and  $w(x \not\perp y | C)$ , respectively. Using these predicates, the general weighted objective function is expressed as the ASP statements shown in Figure 7.

In addition to allowing for associating the same (unit) weight to all (in)dependence statements, the general weighted objective function also allows for using more elaborate weighting schemes where each (in)dependence statement have a different weight. In contrast, most

```

% in(C, X): node X in set C
in(C, X) :- set(C), node(X),
            2**(X-1) & C != 0.

% rule 0
inU(X, X, C) :- set(C), node(X),
               not in(C, X).

% rule 1
inU(Y, A, C) :- inU(X, A, C), edge(X, Y),
               not in(C, Y), not in(C, A).

% rule 2
inU(Y, A, C) :- inU(X, A, C), arc(Y, X),
               not in(C, Y), not in(C, A).

% rule 3

:~dep(X,Y,C,W), not derived_dep(X,Y,C).
                                     [W,X,Y,C]

```

Figure 7: Encoding the general weighted objective

constraint-based structure learning methods only allow for binary information about an independence statement, which means that possible additional information about the independence statements, such as the level of confidence in them, is lost. In fact, as suggested by Hyttinen et al. (2014), by developing weighting schemes, one can bring the constraint-based approaches closer to score-based methods which have traditionally used local scores as weights within the implemented objective functions. For example, a weighting scheme that was proposed and shown to produce good solutions by Hyttinen et al. (2014) uses the log of the Bayesian probability of (in)dependence statements (Margaritis and Bromberg, 2009) as weights.

As an alternative to expressing optimality in terms of weighting incorrectly represented (in)dependencies, we also consider a novel objective function that aims at minimizing the number of edges in the CG while at the same time representing all conditional dependencies in the data. The underlying idea of the objective function is to minimize the model complexity and although independence optimal solutions can no longer be guaranteed wrt the independence model of the data, any solution will still be inclusion optimal. Formally, this gives the alternative objective function

$$\begin{aligned}
\min_{G \in \text{CG}(N)} \quad & |\{(x, y) : x < y, x - y \in G\}| + \\
& |\{(x, y) : x \rightarrow y \in G\}| + \\
& \sum_{(x \perp\!\!\!\perp y | C) \in I} w(x \perp\!\!\!\perp y | C) \cdot T[x \perp\!\!\!\perp_G y | C], \quad (2)
\end{aligned}$$

where  $w(x \perp\!\!\!\perp y | C) = \infty$ . This objective function is encoded in ASP as shown in Figure 8, which in itself demonstrates the versatility of our declarative approach.

### 4.3 Imposing Additional Constraints

One of the major strengths with our CG learning approach is the possibility to incorporate further constraints to guide the search for optimal solutions, in order to e.g. speed up the search for solution or to focus the search on specific solutions of interest. In terms of domain knowledge, if we know that variable  $x$  is the direct cause of variable  $y$  in the system we are modelling, we can simply add the constraint  $\text{arc}(x, y)$  as input to the ASP solver. In terms of including redundant constraints for speeding up search, one can e.g.

```

% satisfy all dependence constraints
:- dep(X,Y,C,_), not derived_dep(X,Y,C).

% minimize undirected and directed edges
:~ edge(X,Y), X<Y. [1,X,Y]
:~ arc(X,Y). [1,X,Y]

```

Figure 8: Encoding the minimize-edges objective

encode the set of redundant rules for how the sets  $U_x^C, V_x^C$  and  $Z_x^C$  can be computed as discussed in Section 3.2. An encoding of the rules are shown in Figure 9. In fact, we observed that the solver running times decreased by approximately 50% after adding these rules to the ASP encoding.

In terms of focusing search specific solutions of interest, we now describe an ASP encoding for restricting the search to only consider so-called *largest chain graphs* (Frydenberg, 1990; Volf and Studený, 1999). Largest CGs are representatives of Markov equivalence classes of CGs. Given a Markov equivalence class, the largest CG in the class is the CG which includes a maximal number of undirected edges. More formally, largest chain graphs are defined as follows.

A *complex* in a CG  $G$  is a path  $v_1, \dots, v_k$  in  $G$  with  $k \geq 3$ , such that  $v_1 \rightarrow v_2, v_i - v_{i+1}$  for  $i = 2, \dots, k-2$ , and  $v_{k-1} \leftarrow v_k$ , and there are no other edges between the nodes  $v_1, \dots, v_k$  in  $G$ . A *complex edge* is a directed edge that belongs to a complex. A directed edge  $u \rightarrow v$  covers a directed edge  $x \rightarrow y$  in a CG  $G$  if  $u$  is an ancestor of  $x$  and  $y$  is an ancestor of  $v$  in  $G$ . A directed edge  $u \rightarrow v$  is *protected* in  $G$  if it covers a complex edge. Note that every complex edge is protected. Now, a CG  $G$  is the largest CG in a Markov equivalence class iff every directed edge of  $G$  is protected.

An ASP encoding of the largest CG constraint is presented in Figure 10. Here, the predicate  $\text{complex}(X, Y)$  indicates that  $x \rightarrow y$  is a complex edge. The auxiliary predicate  $\text{almost\_undirected\_path}(X, Y, Z)$  indicates the existence of a path  $x \rightarrow y - \dots - z$  such that there are no other edges between the nodes in the path. This predicate

```

inU(Z,Y,C) :- inU(Z,X,C), arc(X,Y),
              not in(C,X), not in(C,Y), not in(C,Z).
inV(Z,Y,C) :- inV(Z,X,C), arc(X,Y),
              not in(C,X), not in(C,Y), not in(C,Z).
inZ(Z,Y,C) :- inZ(Z,X,C), arc(X,Y),
              not in(C,X), not in(C,Y).

inU(Y,A,C) :- inU(X,A,C), inU(Y,X,C).
inV(Y,A,C) :- inU(X,A,C), inV(Y,X,C).
inZ(Y,A,C) :- inU(X,A,C), inZ(Y,X,C).

```

Figure 9: Encoding redundant domain knowledge

```

% derive complex arcs X->Y - ... <-Z
complex(X,Y) :- arc(X,Y), arc(Z,Y), X!=Z,
               not edge(X,Z),
               not arc(X,Z), not arc(Z,X).
complex(X,Y) :- almost_undirected_path(X,Y,V),
               almost_undirected_path(Z,V,Y),
               X!=Z, not edge(X,Z),
               not arc(X,Z), not arc(Z,X).
almost_undirected_path(X,Y,Z) :- arc(X,Y),
                                 edge(Y,Z), not arc(X,Z).
almost_undirected_path(X,Y,Z) :-
  almost_undirected_path(X,Y,V),
  edge(V,Z), not arc(X,Z).

% arc U->V covers arc X->Y
covers(U,V,X,Y) :- ancestor(U,X),
                   ancestor(Y,V),
                   arc(X,Y), arc(U,V).

% all arcs must be protected
1 {covers(U,V,X,Y) : complex(X,Y)} :-arc(U,V).

```

Figure 10: ASP encoding of the largest CG constraint

is used for deriving the predicate *complex*. The predicate *covers*( $U, V, X, Y$ ) encodes that  $u \rightarrow v$  covers the edge  $x \rightarrow y$ . The final cardinality constraint states that every directed edge  $u \rightarrow v$  must cover at least one complex edge  $x \rightarrow y$ , i.e.,  $u \rightarrow v$  has to be protected.

## 5 EMPIRICAL EVALUATION

We report here on an empirical evaluation comparing our declarative ASP-based approach with existing CG structure learning algorithms in terms of accuracy of the produced solutions. For solving the ASP encodings, we used the state-of-the-art ASP solver Clingo version 4.4.0. The CG learning algorithms we compare to are LCD (Ma et al., 2008) and CKES (Peña et al., 2014), for which we obtained implementations from the respective authors. We excluded the PC-like algorithm (Studený, 1997) from the comparison since Ma et al. (2008) have shown that it is outperformed by LCD.

For the ASP approach, we illustrate its diversibility by applying three different objective functions.

- (i) ASP-Indep, which implements the general weighted optimization function with  $w(x \perp\!\!\!\perp y|C) = \infty$  and  $w(x \perp\!\!\!\perp y|C) = 1$  (cf. Section 4.2.3, Equation 1);
- (ii) ASP-Weight, which implements the general weighted optimization function using a probability-based weighting scheme from (Hytinen et al., 2014, Section 4.3), following a Bayesian paradigm to assign probabilities to (in)dependence statements, using code from the authors;
- (iii) ASP-Edge, which implements the minimize edges optimization function, (cf. Section 4.2.3, Equation 2).

Since the LCD algorithm assumes faithfulness, to some CG, from the probability distribution it is trying to learn, and does not work properly otherwise, we enforced this assumption for the experiments. However, we want to emphasize that our approach works also without such assumptions. Hence, due to this strong fairness towards LCD and CKES, the empirical results may to some extent present overly positive results for LCD and CKES.

Assuming a faithful underlying probability distribution, we applied the following process. First, a set of CGs  $G$  were generated with corresponding probability distributions. These probability distributions were then sampled into datasets, each determining a set of independence and dependence statements, forming the inputs to the different algorithms. We then evaluated the learning results, i.e., the CGs output as solutions by the algorithms, by comparing them to the original CG  $G$ .

For the experiments, we generated 100 “original” CGs over  $N = 7$  nodes, with an average node-degree of 2, as well as corresponding Gaussian probability distributions. For each distribution, we obtained 500 samples. We used the simplified Wilks independence test (Wilks, 1938) for LCD, CKES, ASP-Indep and ASP-Edge. For the ASP-Weight variant, we used the more advanced, non-binary independence test following (Hytinen et al., 2014). Taking into account that CKES typically ends up in different local optima (Peña et al., 2014), we ran the CKES algorithm three times on each input, and report the best found solution—wrt independence optimality to the independence model determined by the data—as the final solution produced by CKES.

To evaluate the accuracy of the learnt CGs we compared their represented independence model with the independence model of the original CG  $G$  by calculating the true positive rate (TPR) and false positive rate (FPR) of learnt dependencies. A higher TPR means that more dependencies are correctly identified by the algorithm, while a lower FPR means that more independencies are correctly identified.

The accuracy of the results is plotted in the ROC space in Figure 11.<sup>1</sup> We observe that LCD does not achieve as high TPR as the other algorithms, but does obtain relatively low FPR. This is in line with earlier results (Ma et al., 2008; Peña et al., 2014) that show that LCD includes edges relatively cautiously. CKES, in turn, achieves relatively high TPR, but with higher FPR, which is in line with previous evidence suggesting that CKES can have problems identifying the correct independencies in a probabil-

<sup>1</sup>Note that the points are not statistical test results obtained independently of each other. Rather, they are learning results of algorithms for which the dependencies and independencies logically constrain each other. As a result, some of the algorithms are not able to produce results with low FPRs at all, making the curves non-concave.

Figure 11: Comparison of solution accuracy

ity distribution and hence is relatively generous in including edges (Peña et al., 2014). In contrast, relative to LCD and CKES, we observe that the ASP-based approach under the different objective functions perform well both in the low FPR range (similarly or better than LCD which in turn dominates CKES in the range) and the higher FPR range (similarly or better than CKES which is in turn dominates LCD in the range). Thus the overall best-performing approaches are the ASP encoding variants. Among the ASP encoding variants, we observe that the ASP-Weight variant shows best performance in the low FPR range  $< 0.01$ . The variants ASP-Weight and ASP-Indep, using instantiations of the general weighted objective function, fare better than ASP-Edge that optimally minimizes the number of edges in the output CG.

As for scalability of our approach, the average and median running times over 100 inputs in terms of the number of variables are shown in Table 1, using a single core of an Intel i5 processor running at 3.4 GHz. For a fair comparison, we note that CKES and LCD do exhibit much faster running times, e.g., 1-10 seconds per run at  $N = 7$ . Note that the median ASP running times are much lower than the average running times. We observed that relatively scarce outliers have a big negative influence on the averages. The running times include both the time it takes to reach an optimal solution as well as the additional time it takes for the solver to *prove* that the found solution is optimal. In fact,

typically proving optimality consumes the majority of the running time of the solver. Moreover, during the search, the solver actually reports increasingly good solutions, constituting an anytime learning algorithm.

## 6 CONCLUSIONS

In this article we presented a first exact approach to chain graph structure learning. In the approach the computationally hard problem is cast as a constraint optimization problem using the declarative programming of answer set programming. In contrast to previously proposed CG learning algorithms, our approach enables finding provably optimal solutions to the learning problem without making assumptions on the data. It is at the same time more general since it enables the use of various types of objective functions for optimization and specifying domain knowledge in terms of hard constraints. Via an empirical evaluation we also showed that the approach exhibits better overall accuracy than any single previously proposed CG structure learning algorithm. A topic for further work is to study ways of scaling up the approach to higher numbers of variables while still maintaining optimality guarantees. It would also be interesting to extend the approach to accommodate the alternative multivariate regression (Cox and Wermuth, 1993, 1996) and Andersson-Madigan-Perlman (Andersson et al., 2001; Levitz et al., 2001) CG interpretations.

Table 1: ASP running times under different objectives

| $N$ | Median / Average (sec) |                 |                 |
|-----|------------------------|-----------------|-----------------|
|     | ASP-Indep              | ASP-Edge        | ASP-Weight      |
| 3   | 0.02 / 0.02            | 0.02 / 0.02     | 0.02 / 0.02     |
| 4   | 0.03 / 0.03            | 0.04 / 0.04     | 0.03 / 0.03     |
| 5   | 0.11 / 0.15            | 0.33 / 0.35     | 0.24 / 0.46     |
| 6   | 0.93 / 2.06            | 7.84 / 10.10    | 5.00 / 270.35   |
| 7   | 21.35 / 243.10         | 366.86 / 489.71 | 60.70 / 2471.81 |

## Abstract

It is shown that any connected matroid having a non-trivial cluster of BN variables as its ground set induces a facet-defining inequality for the polytope(s) used in the ILP approach to globally optimal BN structure learning. The result applies to well-known  $k$ -cluster inequalities, which play a crucial role in the ILP approach.

## 1 INTRODUCTION

The motivation for this theoretical paper is learning *Bayesian network* (BN) structure. Some hidden connection of the theory of *matroids* to a recent trend in optimal BN structure learning is revealed; specifically, matroids are related to the application of *integer linear programming* (ILP) methods in this area. To explain the motivation, in this introductory section, the latest developments in the ILP approach to learning BN structure are recalled. Matroid theory is also briefly mentioned and the structure of the rest of the paper is described.

### 1.1 ILP APPROACH TO LEARNING

The usual score-based approach to BN structure learning consists in maximizing a *scoring criterion*  $G \mapsto \mathcal{Q}(G, D)$ , where  $G$  is an acyclic directed graph and  $D$  the observed database (Neapolitan, 2004). The value  $\mathcal{Q}(G, D)$  says how much the BN structure defined by the graph  $G$  fits the database  $D$ . Nevertheless, some researchers are used to identify the BN structure with the respective equivalence class of graphs and prefer to talk about learning the class.

Since the classic heuristic greedy equivalence search (GES) algorithm (Chickering, 2002) is known not to guarantee to find a globally optimal BN structure, researches started to look for alternative methods. One of them was based on the idea of *dynamic programming* (Silander, Myllymäki, 2006), which, however, was limited in the number of BN

variables (= nodes of the graph) because of the exponential growth of memory demands.

This limitation has been overcome by the ILP approach based on *family-variable vector* representation of the graphs suggested independently in (Jaakkola, Sontag, Globerson, Meila, 2010) and (Cussens, 2010). An important technical step to overcome the limitation was the idea of the reduction of the search space developed by de Campos and Ji and published in a later journal paper (2011).

Jaakkola *et al.* (2010) introduced an important class of *cluster-based* inequalities approximating the respective family-variable polytope and came with a method of gradual adding these special constraints. Cussens (2010) first applied the family-variable vector representation in the restricted context of pedigree learning. However, his next paper (Cussens, 2011), which was inspired by (Jaakkola *et al.*, 2010), dealt with general BN structure learning and came with a standard *cutting plane approach* offering a more efficient way of adding the (cluster) inequality constraints, based on solving a special simple sub-ILP problem. Moreover, his experiments with general-purpose cutting planes, the so-called Gomory cuts, lead him to the idea to introduce a wider class of *k-cluster inequalities*, where  $k$  is a natural number less than the cardinality of the cluster. Bartlett and Cussens (2013) extended later the cutting plane method to a more general *branch-and-cut* approach; they included a lot of fine improvements and achieved much better running times. One of the morals of their paper was that using additional facet-defining inequalities for the family-variable polytope can speed up the computation.

An alternative ILP approach based on *characteristic-imset* representation of BN structures appeared in (Hemmecke, Lindner, Studený, 2012); its motivational sources date back to the method of imsets from (Studený, 2005). Unlike the family-variable vectors, the characteristic imsets uniquely correspond to BN structures. However, although this ILP approach is also feasible, the computational experiments reported in (Studený, Haws, 2014) have not resulted in better running times in comparison with the 2013-year version of GOBNILP software (Cussens and Bartlett, 2015).

Our recent manuscript (Cussens, Haws, Studený, 2015) has been devoted to the comparison of the facet-defining inequalities for the family-variable polytope and for the characteristic-imset polytope. Note that the facet-defining inequalities appear to be the most useful ones in the cutting plane approach to solving ILP problems; see the reasons in §9.1-9.2 of (Wolsey, 1998). In (Cussens *et al.*, 2015), we established a one-to-one correspondence between *extreme supermodular set functions* and certain facet-defining inequalities for both polytopes. An important special case of such facet-defining inequalities are the above mentioned  $k$ -cluster constraints, which can be transformed to the characteristic-imset context.

## 1.2 MATROID THEORY

The theory of matroids had been formed in the 1930's as an abstract theory of independence and since then became one of important topics in combinatorial optimization. The reader is referred to Oxley's book (1992) for numerous examples of how matroids pervade various branches of discrete mathematics and for how they appear to be useful in computer science.

In (Cussens *et al.*, 2015) we observed an interesting relation of the above mentioned  $k$ -cluster inequalities to the so-called *connected uniform matroids*, which gives an elegant interpretation to those inequalities.

In this paper, I extend our former observation and, using an old result by Nguyen (1978) from matroid theory, show that any *connected matroid* over a cluster of BN variables involving at least two variables induces a facet-defining inequality both for the family-variable polytope and for the characteristic-imset polytope.

In my opinion, this theoretical result broadens the class of available facet-defining inequalities which can be used in the cutting plane approach to solving ILP problems arising in the optimal BN structure learning area.

## 1.3 PAPER STRUCTURE

In §2 formal definitions of basic concepts are given: from the area of BN structure learning, the theory of polytopes, and matroid theory. The next §3 then recalls a few observations on the cone of supermodular set functions and the results from (Cussens *et al.*, 2015), (Nguyen, 1978) that are needed. These allows one to formulate and prove the main result in §4. An illustrating example is given in §5. The conclusions and the discussion are in §6.

## 2 BASIC CONCEPTS

Let  $N$  be a finite set of *BN variables*; to avoid a trivial case, assume  $n := |N| \geq 2$ . In statistical context, the elements of  $N$  correspond to random variables; in graphical context,

they correspond to nodes of (acyclic directed) graphs. Its subsets  $C \subseteq N$  with  $|C| \geq 2$ , called *clusters* in this paper, will serve as ground sets of the matroids discussed here.

## 2.1 STRUCTURE LEARNING CONCEPTS

The symbol  $\text{DAGs}(N)$  will denote the collection of all acyclic directed graphs over  $N$ , which means the graphs having  $N$  as the set of nodes. Given  $G \in \text{DAGs}(N)$  and  $a \in N$ , the symbol  $\text{pa}_G(a) := \{b \in N : b \rightarrow a \text{ in } G\}$ , is the *parent set* of the node  $a$ . A well-known equivalent definition of acyclicity of a directed graph  $G$  over  $N$  is the existence of a total order  $a_1, \dots, a_n$  of nodes in  $N$  such that, for every  $i = 1, \dots, n$ ,  $\text{pa}_G(a_i) \subseteq \{a_1, \dots, a_{i-1}\}$ ; we say then the order and the graph are *consonant*.

A *BN model* is a pair  $(G, P)$ , where  $G \in \text{DAGs}(N)$  and  $P$  a probability distribution on the joint sample space  $X_N := \prod_{a \in N} X_a$ , the Cartesian product of individual non-empty finite sample spaces  $X_a$  for variables  $a \in N$ , which factorizes according to  $G$ . An equivalent characterization of the factorization property is that  $P$  is *Markovian* with respect to  $G$ , which means it satisfies the conditional independence restrictions determined by  $G$  (Lauritzen, 1996). The *BN structure* defined by  $G$  is formally the class of Markovian probability distributions with respect to  $G$ .

Different graphs over  $N$  could be *Markov equivalent*, which means they define the same BN structure. The classic graphical characterization of equivalent graphs by Verma and Pearl (1991) states that two graphs are Markov equivalent if and only if they have the same adjacencies and immoralities. Recall that an *immorality* in  $G \in \text{DAGs}(N)$  is an induced subgraph of  $G$  of the form  $a \rightarrow c \leftarrow b$ , where the nodes  $a$  and  $b$  are not adjacent in  $G$ . Markov equivalence of  $G, H \in \text{DAGs}(N)$  will be denoted by  $G \sim H$ .

The task of *learning* the BN structure is to determine it on the basis of an observed (complete) *database*  $D$ , which is a sequence  $x_1, \dots, x_m$ ,  $m \geq 1$  of elements of the joint sample space  $X_N$ . This is often done by maximizing some *quality criterion*, also called a *score* or a *scoring criterion*, which is a bivariate real function  $(G, D) \mapsto \mathcal{Q}(G, D)$ , where  $G \in \text{DAGs}(N)$  and  $D$  a database. Examples of such criteria are Schwarz's (1978) Bayesian information criterion (BIC) and Bayesian Dirichlet equivalence (BDE) score (Heckerman, Geiger, Chickering, 1995). The reader is referred to (Neapolitan, 2004) for the definition of a relevant concept of *statistical consistency*.

A crucial technical assumption from the computational point of view (Chickering, 2002) is that  $\mathcal{Q}$  should be additively *decomposable*, which means, it has the form

$$\mathcal{Q}(G, D) = \sum_{a \in N} q_D(a | \text{pa}_G(a)), \quad (1)$$

where the summands  $q_D(* | *)$  are called *local scores*. All criteria used in practice satisfy this requirement.

Given an observed database  $D$ , the goal is to maximize  $G \mapsto \mathcal{Q}(G, D)$ . Since the aim is learn the BN structure, a natural assumption is that the criterion  $\mathcal{Q}$  to be maximized is *score equivalent* (Bouckaert, 1995), which means, for every database  $D$  and  $G, H \in \text{DAGs}(N)$ ,

$$\mathcal{Q}(G, D) = \mathcal{Q}(H, D) \quad \text{whenever } G \sim H.$$

Most of the criteria used in practice satisfy that.

## 2.2 POLYTOPES FOR LEARNING

We recall a few basic concepts from polyhedral geometry; see (Barvinok, 2002) or (Ziegler, 1995) for more details.

Below we deal with the Euclidean real vector spaces  $\mathbb{R}^\Gamma$ , where  $\Gamma \neq \emptyset$  is a non-empty finite index set. Given two vectors  $v, w \in \mathbb{R}^\Gamma$ , their scalar product will be denoted by

$$\langle v, w \rangle_\Gamma := \sum_{i \in \Gamma} v_i \cdot w_i,$$

or just by  $\langle v, w \rangle$  if there is no danger of confusion.

A *polytope*  $P$  is the convex hull of finitely many vectors from  $\mathbb{R}^\Gamma$ ; we only consider non-empty  $P$ . The *dimension* of  $P$ , denoted by  $\dim(P)$ , is the dimension of its affine hull, which is nothing but a translate of a linear subspace. The maximal number of affinely independent vectors in  $P$  is then  $\dim(P) + 1$ .

Given  $o \in \mathbb{R}^\Gamma$  and  $u \in \mathbb{R}$ , a linear inequality  $\langle o, v \rangle \leq u$  for  $v \in \mathbb{R}^\Gamma$  is called *valid* for  $P$  if it holds for any  $v \in P$ . The inequality is then called *tight* for a vector  $w \in P$  if  $\langle o, w \rangle = u$ . Given such valid linear inequality for  $P$  the corresponding *face* of  $P$  is its subset  $F \subseteq P$  of the form

$$F = \{ v \in P : \langle o, v \rangle = u \}.$$

One usually deals with valid inequalities that are tight for at least one vector  $w \in P$  in which case  $F \neq \emptyset$ . Then we will name the respective inequality *face-defining*. The function  $v \in \mathbb{R}^\Gamma \mapsto \langle o, v \rangle$  is typically a linear objective to be maximized; with little abuse of terminology we will then call  $o \in \mathbb{R}^\Gamma$  an *objective*.

A *facet* of a polytope  $P$  is its face of the dimension  $\dim(P) - 1$ . The corresponding inequality will be then called *facet-defining*. Given a (non-empty) facet  $F \subseteq P$  of a full-dimensional polytope  $P$  in  $\mathbb{R}^\Gamma$ , its facet-defining inequality is unique up to a positive multiple (of both  $o \in \mathbb{R}^\Gamma$  and  $u \in \mathbb{R}$ ). A well-known fundamental result in polyhedral geometry is that every full-dimensional polytope  $P$  with non-empty facets is specified as the set of vectors  $v \in \mathbb{R}^\Gamma$  satisfying all facet-defining inequalities for  $P$ . Thus,  $P$  is a *bounded polyhedron* and the facet-defining inequalities provide its minimal description in terms of equalities.

### 2.2.1 Family-Variable Polytope

The index set for our family-variable vectors will be

$$\Upsilon := \{ (a | B) : a \in N \ \& \ \emptyset \neq B \subseteq N \setminus \{a\} \}.$$

Given  $G \in \text{DAGs}(N)$ , the symbol  $\eta_G$  will denote the *family-variable vector* encoding it:

$$\eta_G(a | B) = \begin{cases} 1 & \text{if } B = \text{pa}_G(a), \\ 0 & \text{otherwise,} \end{cases} \quad \text{for } (a | B) \in \Upsilon.$$

The *family-variable polytope* is defined as the convex hull of the collection of all such vectors:

$$F := \text{conv}(\{ \eta_G \in \mathbb{R}^\Upsilon : G \in \text{DAGs}(N) \}).$$

Clearly,  $\dim(F) = |\Upsilon| = n \cdot (2^{n-1} - 1)$ .

One can re-write (1) in terms of  $\eta_G$  in this way:

$$\mathcal{Q}(G, D) = \sum_{a \in N} \sum_{B \subseteq N \setminus \{a\}} q_D(a | B) \cdot \eta_G(a | B), \quad (2)$$

which allows one to interpret  $\mathcal{Q}$  as (the restriction of) a linear function of  $\eta_G$ . In particular, the maximization of  $\mathcal{Q}$  over  $\text{DAGs}(N)$  turns into the task to maximize a linear function with the objective  $o(a | B) = q_D(a | B)$  for  $(a | B) \in \Upsilon$  over the family-variable polytope  $F$ . In other words, the local scores become the components of the respective objective vector  $o \in \mathbb{R}^\Upsilon$ .

The assumption of score equivalence of  $\mathcal{Q}$  then implies the respective objective satisfies, for every  $G, H \in \text{DAGs}(N)$ ,

$$G \sim H \Rightarrow \langle o, \eta_G \rangle_\Upsilon = \langle o, \eta_H \rangle_\Upsilon. \quad (3)$$

Thus, if (3) holds for  $o \in \mathbb{R}^\Upsilon$  we will say that it is a *score equivalent objective*, abbreviated as *an SE objective*.

Given a cluster  $C \subseteq N$ ,  $|C| \geq 2$ , of BN variables and a natural number  $k = 1, \dots, |C| - 1$  the inequality

$$k \leq \sum_{a \in C} \sum_{B \subseteq N \setminus \{a\} : |B \cap C| < k} \eta_G(a | B)$$

is valid for any  $G \in \text{DAGs}(N)$ : as the induced subgraph  $G_C$  is acyclic, the first  $k$  nodes in a total order of nodes in  $C$  consonant with  $G_C$  have at most  $k - 1$  parents in  $C$ . In particular, the inequality is valid for any  $\eta \in F$  in place of  $\eta_G$  and one can transform it into a standardized form:

$$\sum_{a \in C} \sum_{B \subseteq N \setminus \{a\} : |B \cap C| \geq k} \eta(a | B) \leq |C| - k. \quad (4)$$

We will call (4) the *k-cluster inequality* for  $C$ ; its version for  $k = 1$  is simply the *cluster inequality* for  $C$ . Every  $k$ -cluster inequality is facet-defining for  $F$  and the objective defining (4) is SE; see (Cussens *et al.*, 2015, Corol 4).

*Example 1* Consider  $N = \{a, b, c, d\} = C$  and  $k = 2$ . Then (4) takes the following form:

$$\begin{aligned} & [\eta(a|bc) + \eta(a|bd) + \eta(a|cd) + \eta(a|bcd)] \\ & + [\eta(b|ac) + \eta(b|ad) + \eta(b|cd) + \eta(b|acd)] \quad (5) \\ & + [\eta(c|ab) + \eta(c|ad) + \eta(c|bd) + \eta(c|abd)] \\ & + [\eta(d|ab) + \eta(d|ac) + \eta(d|bc) + \eta(d|abc)] \leq 2. \end{aligned}$$

### 2.2.2 Characteristic-Imset Polytope

The *characteristic imset* of  $G \in \text{DAGs}(N)$ , introduced in (Hemmecke *et al.*, 2012) and denoted below by  $c_G$ , is an element of the vector space  $\mathbb{R}^\Lambda$  where

$$\Lambda := \{S \subseteq N : |S| \geq 2\}.$$

Recall from (Studený, Haws, 2013) that  $c_G$  is a many-to-one linear function of  $\eta_G$ , the transformation is  $\eta \mapsto c_\eta$ :

$$c_\eta(S) = \sum_{a \in S} \sum_{B: S \setminus \{a\} \subseteq B \subseteq N \setminus \{a\}} \eta(a|B) \quad (6)$$

for  $S \in \Lambda$ . Thus, given  $G \in \text{DAGs}(N)$ , (6) can serve as the definition of  $c_G$  in which one substitutes  $\eta = \eta_G$ . A fundamental observation is that, for  $G, H \in \text{DAGs}(N)$ ,  $G \sim H$  if and only if  $c_G = c_H$  (Hemmecke *et al.*, 2012). In particular, the characteristic imset is a unique representative of the corresponding BN structure.

The *characteristic-imset polytope* is defined as follows:

$$C := \text{conv}(\{c_G \in \mathbb{R}^\Lambda : G \in \text{DAGs}(N)\}).$$

One can show that  $\dim(C) = |\Lambda| = 2^n - n - 1$ . Of course,  $C$  is the image of  $F$  by the linear mapping (6).

A notable fact is that any valid inequality for  $C$  induces a valid inequality for  $F$ : if  $\langle z, c \rangle_\Lambda \leq u$ , where  $z \in \mathbb{R}^\Lambda$  and  $u \in \mathbb{R}$ , is a valid inequality for  $c \in C$ , substitute (6) into  $\langle z, c_\eta \rangle_\Lambda \leq u$  and re-arrange the terms after the components of  $\eta$ . Indeed, since the image of  $\eta_G$  by (6) is just  $c_G$ , one gets an inequality valid for any  $\eta_G$ ,  $G \in \text{DAGs}(N)$ . Moreover, the induced inequality for  $\eta \in F$  is given by an SE objective: if  $G \sim H$ , one has  $c_G = c_H$  and, therefore,  $\langle z, c_G \rangle_\Lambda = \langle z, c_H \rangle_\Lambda$ .

In fact, there is a one-to-one correspondence between the valid inequalities for  $C$  and the valid inequalities for  $F$  given by SE objectives (Cussens *et al.*, 2015). Thus, these special valid inequalities for  $F$  can also be viewed as the valid inequalities for  $C$ , that is, interpreted in the context of  $C$ . This concerns many facet-defining inequalities for  $F$ : the  $k$ -cluster inequality (4) takes the following form in the characteristic-imset context, see (Cussens *et al.*, 2015, § 9):

$$\sum_{S \subseteq C, |S| \geq k+1} z(S) \cdot c(S) \leq |C| - k,$$

where  $z(S) = (-1)^{|S|-k-1} \cdot \binom{|S|-2}{|S|-k-1}$  for any such  $S$ .

*Example 2* Consider  $N = \{a, b, c, d\}$ . Then the 2-cluster inequality for  $C = \{a, b, c, d\}$  takes the form

$$c(abc) + c(abd) + c(acd) + c(bcd) - 2 \cdot c(abcd) \leq 2.$$

Indeed, the substitution of (6) in it gives just (5).

### 2.3 CONCEPTS FROM MATROID THEORY

Let us recall some definitions and basic facts from matroid theory; see (Oxley, 1992, chapters 1,2,4) for more details.

A *matroid* is a pair  $(C, \mathcal{I})$  where  $C$  is a finite set, called its *ground set*, and  $\mathcal{I}$  a non-empty class of subsets of  $C$ , called the *independent sets* (of the matroid), which is closed under subsets:  $I \in \mathcal{I}$ ,  $J \subseteq I$  implies  $J \in \mathcal{I}$  and satisfies the *independence augmentation axiom*:

$$\begin{aligned} & \text{if } I, J \in \mathcal{I} \text{ and } |J| < |I| \\ & \text{then } a \in I \setminus J \text{ exists with } J \cup \{a\} \in \mathcal{I}. \end{aligned}$$

We will also say that the matroid is *on the set*  $C$ .

A number of equivalent descriptions of the matroid  $(C, \mathcal{I})$  exists. Any matroid can be described by the class  $\mathcal{B}$  of its *bases*, which are inclusion-maximal independent sets. The above independence augmentation axiom implies that the sets in  $\mathcal{B}$  have the same cardinality. The shared cardinality of bases of a matroid is called its *rank*. A well-known fact is that  $\mathcal{B} \subseteq \mathcal{P}(C)$  is the class of bases of a matroid on  $C$  iff it is a non-empty class of subsets of  $C$  satisfying the following *basis exchange axiom*:

$$\begin{aligned} & \text{if } I, J \in \mathcal{B} \text{ and } a \in I \setminus J \\ & \text{then } b \in J \setminus I \text{ exists with } (I \setminus \{a\}) \cup \{b\} \in \mathcal{B}. \end{aligned}$$

The class  $\mathcal{D}$  of *dependent sets* of  $(C, \mathcal{I})$  consists of those subsets of  $C$  that are not independent sets. The *circuits* of the matroid are the inclusion-minimal dependent sets. A class  $\mathcal{C} \subseteq \mathcal{P}(C)$  is the class of circuits of a matroid on  $C$  iff it is a class of non-empty inclusion-incomparable subsets of  $C$  satisfying the following *circuit elimination axiom*:

$$\begin{aligned} & \text{if } K, L \in \mathcal{C}, K \neq L \text{ and } a \in K \cap L \\ & \text{then } M \in \mathcal{C} \text{ exists with } M \subseteq (K \cup L) \setminus \{a\}. \end{aligned}$$

We will also use the description of the matroid  $(C, \mathcal{I})$  in terms of its *rank function*, which is a function  $r$  on  $\mathcal{P}(C)$  defined as follows:

$$r(J) = \max\{|I| : I \subseteq J \text{ \& } I \in \mathcal{I}\} \quad \text{for any } J \subseteq C.$$

The rank functions of matroids on  $C$  are characterized as integer-valued set functions  $r : \mathcal{P}(C) \rightarrow \mathbb{Z}$  satisfying the following three conditions:

- if  $I \subseteq C$  then  $0 \leq r(I) \leq |I|$ ,

- if  $J \subseteq I \subseteq C$  then  $r(J) \leq r(I)$ ,
- if  $I, J \subseteq C$  then  $r(I \cup J) + r(I \cap J) \leq r(I) + r(J)$ .

A set  $S \subseteq C$  is called a *separator* of a matroid  $(C, \mathcal{I})$  if

$$r(S) + r(C \setminus S) = r(C).$$

The matroid is called *connected* if it has no other separators except for the trivial ones  $S = \emptyset$  and  $S = C$ . Observe that if  $(C, \mathcal{I})$  is connected and  $|C| \geq 2$  then  $\bigcup \mathcal{B} = \bigcup \mathcal{I} = C$ , for otherwise  $\bigcup \mathcal{I}$  is a non-trivial separator or  $r \equiv 0$ . An equivalent definition of a connected matroid on  $C$  is that, for every pair  $a, b \in C$ ,  $a \neq b$ , a circuit  $D \in \mathcal{C}$  exists with  $a, b \in D$ , see (Oxley, 1992, Prop 4.1.4).

The *dual matroid* to a matroid over  $C$  having  $\mathcal{B} \subseteq \mathcal{P}(C)$  as its class of bases is the matroid on  $C$  having

$$\mathcal{B}^* := \{C \setminus B : B \in \mathcal{B}\}$$

as its class of bases. The formula for the rank function  $r^*$  of the dual matroid is as follows:

$$r^*(J) = |J| - r(C) + r(C \setminus J) \quad \text{for } J \subseteq C, \quad (7)$$

see (Oxley, 1992, Prop 2.1.9). Another well-known basic fact is that the dual matroid to a connected matroid is connected as well, see (Oxley, 1992, Corol 4.2.8).

*Example 3* Consider  $C = \{a, b, c, d\}$  and put

$$\mathcal{B} = \{ \{a, b\}, \{a, c\}, \{a, d\}, \{b, c\}, \{b, d\}, \{c, d\} \}.$$

Clearly,  $\mathcal{B}$  is the class of bases of a matroid on  $C$ . The independent sets in it are subsets of  $C$  of cardinality at most two. The circuits are subsets of  $C$  of cardinality 3. The rank function only depends on the cardinality:

$$r(J) = \min \{ |J|, 2 \} \quad \text{for } J \subseteq C.$$

The form of  $r$  implies that the only separators are  $S = \emptyset$  and  $S = C$ . In particular, the matroid is connected. The dual matroid is itself.

The above example is a special matroid in a certain sense: for any integer  $0 \leq k \leq |C|$  the *uniform matroid* on  $C$  of the rank  $k$  has the collection of subsets of  $C$  of the cardinality at most  $k$  as its class of independent sets.

In this paper, the attention is limited to matroids which have clusters of BN variables  $C \subseteq N$ ,  $|C| \geq 2$  as their ground sets. Any matroid  $(C, \mathcal{I})$  on such cluster  $C$  can be interpreted as a matroid on  $N$  because  $\mathcal{I} \subseteq \mathcal{P}(C)$  can be viewed as a class of subsets of  $N$ . This kind of *trivial extension* on  $N$  leads to the rank function  $\bar{r} : \mathcal{P}(N) \rightarrow \mathbb{Z}$  given by

$$\bar{r}(S) = r(C \cap S) \quad \text{for any } S \subseteq N.$$

### 3 SUPERMODULAR FUNCTIONS

In (Cussens *et al.*, 2015, §7) a one-to-one correspondence has been established between extreme supermodular set functions and certain important facets of  $F$ , respectively of  $C$ . The relevant concepts are recalled in this section.

A real function  $m : \mathcal{P}(N) \rightarrow \mathbb{R}$  on subsets of the set  $N$  of BN variables will be called *standardized* if  $m(S) = 0$  for  $S \subseteq N$ ,  $|S| \leq 1$ , and *supermodular* if

$$\forall U, V \subseteq N \quad m(U) + m(V) \leq m(U \cup V) + m(U \cap V).$$

Mirror images of supermodular functions are *submodular* functions, defined by the converse inequalities; recall from §2.3 that rank functions of matroids are submodular.

#### 3.1 EXTREME SUPERMODULAR FUNCTIONS

The collection of standardized supermodular functions on  $\mathcal{P}(N)$ , viewed as a set of vectors in  $\mathbb{R}^{\mathcal{P}(N)}$ , is a pointed polyhedral cone. Therefore, it has finitely many extreme rays, which makes the following definition meaningful.

A standardized supermodular function  $m : \mathcal{P}(N) \rightarrow \mathbb{R}$  will be called *extreme* if it generates an extreme ray of the standardized supermodular cone. Recall that a non-zero vector  $v$  in a cone generates its extreme ray if the only summands in (positive) convex combinations of vectors from the cone yielding  $v$  are non-negative multiples of  $v$ .

Theorems 1 and 2 from (Cussens *et al.*, 2015) together give the next observation.

**THEOREM 1** *An inequality  $\langle o, \eta \rangle_{\Upsilon} \leq u$  for  $\eta \in \mathbb{R}^{\Upsilon}$ , where  $o \in \mathbb{R}^{\Upsilon}$ ,  $u \in \mathbb{R}$ , is facet-defining for  $F$  and defined by an SE objective  $o$  iff there exists an extreme standardized supermodular function  $m$  on  $\mathcal{P}(N)$  such that  $o$  is given by*

$$o(a | B) = m(\{a\} \cup B) - m(B) \quad \text{for } (a | B) \in \Upsilon, \quad (8)$$

*and  $u$  is the shared value of  $\langle o, \eta_H \rangle_{\Upsilon}$  for full graphs  $H$  over  $N$ , that is, for such  $H \in \text{DAGs}(N)$  in which every pair of distinct nodes is adjacent.*

*Example 4* Consider  $N = \{a, b, c, d\}$  and the set function

$$m(S) = \begin{cases} 2 & \text{if } S = N, \\ 1 & \text{if } |S| = 3, \\ 0 & \text{otherwise,} \end{cases} \quad \text{for } S \subseteq N.$$

Clearly,  $m$  is a standardized supermodular function; finer arguments why  $m$  is extreme are given later (Example 5). The formula (8) leads to the inequality (5). By Theorem 1, (5) is facet-defining for the family-variable polytope  $F$ .

Moreover, Corollary 6 in (Cussens *et al.*, 2015) says what is the role of the inequalities from Theorem 1 in the characteristic-imset context; here we have in mind the correspondence of the inequalities mentioned in §2.2.2.

COROLLARY 1 *Facet-defining inequalities*  $\langle o, \eta \rangle_{\Upsilon} \leq u$  for  $\eta \in F$  with SE objectives correspond to facet-defining inequalities  $\langle z, c \rangle_{\Lambda} \leq u$  for  $c \in C$  tight for the 1-imset, which is the vector in  $\mathbb{R}^{\Lambda}$  whose all components are ones.

### 3.2 SUBMODULARITY AND RANK FUNCTIONS

Mirror images of supermodular functions are submodular ones, which play an important role in matroid theory. It follows from the facts mentioned in § 2.3 that every rank function of a matroid belongs to the cone of non-decreasing submodular functions  $r$  with  $r(\emptyset) = 0$ . This is a pointed polyhedral cone and has finitely many extreme rays.

Nguyen (1978) was interested in the question when the rank function of a matroid generates an extreme ray of that cone. The next fact follows from his Theorem 2.1.5.

THEOREM 2 *Let  $C$  be a non-empty finite set and  $(C, \mathcal{I})$  a matroid on it such that  $C = \bigcup \mathcal{I}$ . Then its rank function  $r$  generates an extreme ray of the cone of non-decreasing submodular functions on  $\mathcal{P}(C)$  satisfying  $r(\emptyset) = 0$  iff the corresponding matroid  $(C, \mathcal{I})$  is connected.*

## 4 MAIN RESULT

LEMMA 1 Given a connected matroid  $(C, \mathcal{I})$  on  $C \subseteq N$ ,  $|C| \geq 2$  with the rank function  $r : \mathcal{P}(C) \rightarrow \mathbb{Z}$ , the function

$$m(S) := |C \cap S| - r(C \cap S) \quad \text{for } S \subseteq N, \quad (9)$$

is extreme standardized supermodular function on  $\mathcal{P}(N)$ .

**Proof:** Let us denote by  $R[C]$ , for  $C \subseteq N$ , the cone of submodular functions  $r^*$  on  $\mathcal{P}(C)$  such that  $r^*(\emptyset) = 0$  and  $r^*(C) - r^*(C \setminus \{a\}) = 0$  for any  $a \in C$ . Any function  $r^*$  in  $R[C]$  is necessarily non-decreasing. The dual matroid to  $(C, \mathcal{I})$  is connected; by Theorem 2, its rank function  $r^*$  given by (7) generates an extreme ray of the non-decreasing submodular cone. Since  $(C, \mathcal{I})$  is connected,  $\bigcup \mathcal{I} = C$  says  $r(\{a\}) = 1$  for any  $a \in C$ . Moreover, the dual matroid to the dual matroid is again  $(C, \mathcal{I})$ , which gives

$$1 = r(\{a\}) = r^{**}(\{a\}) \stackrel{(7)}{=} 1 - r^*(C) + r^*(C \setminus \{a\})$$

for any  $a \in C$ ; hence,  $r^*$  belongs to the smaller cone  $R[C]$ . This easily implies that  $r^*$  generates an extreme ray of  $R[C]$ , which fact allows one to observe by a minor consideration that its trivial extension

$$\overline{r^*}(S) := r^*(C \cap S) \quad \text{for } S \subseteq N,$$

generates an extreme ray of  $R[N]$ . Finally, the formula

$$m(S) = \overline{r^*}(N) - \overline{r^*}(N \setminus S) \quad \text{for } S \subseteq N,$$

defines a one-to-one linear transformation of the cone  $R[N]$  onto the cone of standardized supermodular functions  $m$

on  $\mathcal{P}(N)$  (in fact, the transformation is self-inverse). In particular,  $\overline{r^*} \mapsto m$  maps generators of extreme rays to generators of extreme rays, implying that  $m$  is extreme in the respective cone. Thus, one can write for any  $S \subseteq N$ :

$$\begin{aligned} m(S) &= \overline{r^*}(N) - \overline{r^*}(N \setminus S) = r^*(C) - r^*(C \setminus S) \\ &\stackrel{(7)}{=} \{|C| - r(C)\} - \{|C \setminus S| - r(C) + r(C \cap S)\} \\ &= |C \cap S| - r(C \cap S), \end{aligned}$$

which gives (9).  $\square$

*Example 5* Consider  $N = \{a, b, c, d\} = C$  and take the uniform matroid on  $C$  of rank 2 from Example 3. It is a connected matroid and, by Lemma 1, it induces through (9) an extreme supermodular function  $m$  from Example 4.

THEOREM 3 *Given a connected matroid  $(C, \mathcal{I})$  on a cluster  $C \subseteq N$ ,  $|C| \geq 2$  of BN variables, the inequality*

$$\sum_{a \in C} \sum_{B \subseteq N \setminus \{a\}: \exists D \in \mathcal{C} \ a \in D \subseteq B \cup \{a\}} \eta(a|B) \leq |C| - k, \quad (10)$$

where  $k$  is the rank of  $(C, \mathcal{I})$  and  $\mathcal{C}$  the collection of its circuits, is a facet-defining inequality for  $F$ .

**Proof:** By Lemma 1, (9) gives an extreme standardized supermodular function; one can apply Theorem 1 then. The upper bound  $u$  in the respective facet-defining inequality  $\langle o, \eta \rangle_{\Upsilon} \leq u$  for  $\eta \in F$  is the shared value  $\langle o, \eta_H \rangle_{\Upsilon}$  for all graphs  $H \in \text{DAGs}(N)$ . Using (8) one gets  $u = m(N)$ , that is,  $u = m(N) \stackrel{(9)}{=} |C| - r(C) = |C| - k$ .

The formula for the objective coefficients  $o(a|B)$ , where  $a \in N$  and  $B \subseteq N \setminus \{a\}$  (possibly empty) is then

$$\begin{aligned} o(a|B) &\stackrel{(8)}{=} m(\{a\} \cup B) - m(B) \\ &\stackrel{(9)}{=} |C \cap \{a\}| - r(C \cap (\{a\} \cup B)) + r(C \cap B), \end{aligned}$$

implying  $o(a|B) = 0$  if  $a \in N \setminus C$ . In case  $a \in C$  one has

$$o(a|B) = 1 - r(C \cap (\{a\} \cup B)) + r(C \cap B) = o(a|C \cap B).$$

Therefore, in the rest of the proof, we assume  $a \in C$  and  $B \subseteq C \setminus \{a\}$ ; our goal is to verify

$$o(a|B) = \begin{cases} 1 & \exists D \in \mathcal{C} \text{ with } a \in D \ \& \ D \subseteq B \cup \{a\}, \\ 0 & \text{otherwise,} \end{cases}$$

which clearly gives (10). We come from the above formula

$$o(a|B) = 1 - r(\{a\} \cup B) + r(B). \quad (11)$$

Having fixed  $a \in C$ , the coefficient are monotone

$$E \subseteq B \subseteq C \setminus \{a\} \Rightarrow o(a|B) \geq o(a|E) \quad (12)$$

because of submodularity of  $r$ :

$$\begin{aligned} o(a|B) - o(a|E) &\stackrel{(11)}{=} r(B) + r(\{a\} \cup E) - r(E) - r(\{a\} \cup B) \geq 0. \end{aligned}$$

As  $(C, \mathcal{I})$  is connected one has  $r(\{a\}) = 1$  for any  $a \in C$ , which gives

$$o(a | \emptyset) \stackrel{(11)}{=} 1 - r(\{a\}) + r(\emptyset) = 1 - 1 + 0 = 0.$$

Since the dual matroid is also connected, one has

$$o(a | C \setminus \{a\}) \stackrel{(11)}{=} 1 - r(C) + r(C \setminus \{a\}) \stackrel{(7)}{=} r^*(\{a\}) = 1.$$

In particular, the objective coefficients are either zeros or ones. In case a circuit  $D \in \mathcal{C}$  exists with  $a \in D \subseteq B \cup \{a\}$ , it is enough to show  $o(a | D \setminus \{a\}) = 1$  and apply (12). Indeed, by the definition of a circuit,  $D \setminus \{a\} \in \mathcal{I}$  and  $r(D \setminus \{a\}) = |D| - 1$ . One cannot have  $r(D) = |D|$ , for otherwise  $D \in \mathcal{I}$  contradicts the assumption  $D \in \mathcal{C}$ . Thus,  $r(D) = |D| - 1$  and one has

$$o(a | D \setminus \{a\}) \stackrel{(11)}{=} 1 - r(D) + r(D \setminus \{a\}) = 1.$$

It remains to show that  $o(a | B) = 0$  in the complementary case that no such  $D \in \mathcal{C}$  exists for  $B$ . By the definition of the rank function  $r$ , a set  $J \subseteq B$  exists with  $J \in \mathcal{I}$  and  $|J| = r(B)$ . It is enough to show  $\{a\} \cup J \in \mathcal{I}$  because then  $r(\{a\} \cup B) = |J| + 1$  (use submodularity of  $r$ ) and

$$o(a | B) \stackrel{(11)}{=} 1 - r(\{a\} \cup B) + r(B) = 1 - (|J| + 1) + |J| = 0.$$

Thus, assume for a contradiction that  $\{a\} \cup J \in \mathcal{D}$  is a dependent set and, by the definition of circuits, find  $D \in \mathcal{C}$  with  $D \subseteq \{a\} \cup J$ . Necessarily  $a \in D$ , for otherwise a contradictory conclusion  $J \in \mathcal{D}$  is derived. This implies  $a \in D \subseteq \{a\} \cup J \subseteq \{a\} \cup B$  contradicting the assumption that no such circuit  $D \in \mathcal{C}$  exists for  $B$ .  $\square$

The observation that the  $k$ -cluster inequalities (4) are facet-defining for the family-variable polytope easily follows from Theorem 3. Indeed, any uniform matroid on  $C \subseteq N$ ,  $|C| \geq 2$  of the rank  $k$ ,  $1 \leq k \leq |C| - 1$  is connected. This fact is illustrated by the following simple example.

*Example 6* Consider  $N = \{a, b, c, d\}$ ,  $C = \{a, b, c\}$  and  $k = 1$ . The uniform matroid on  $C$  of rank 1 has the bases  $\{a\}$ ,  $\{b\}$  and  $\{c\}$ . Thus, the class of its circuits is

$$\mathcal{C} = \{ \{a, b\}, \{a, c\}, \{b, c\} \}.$$

Since every pair of BN variables in  $C$  is contained in a circuit, it is a connected matroid. To get the specific form of the inequality (10) in this case realize that  $a \in C$  is contained in two circuits  $D \in \mathcal{C}$ , namely in  $\{a, b\}$  and in  $\{a, c\}$ . Thus, one has in (10) those terms  $\eta(a | B)$  where  $B \subseteq N \setminus \{a\}$  and either  $b \in B \Leftrightarrow \{a, b\} \subseteq B \cup \{a\}$  or  $c \in B$ . Thus, (10) takes the form

$$\begin{aligned} & [\eta(a | b) + \eta(a | c) + \eta(a | bc) \\ & \quad + \eta(b | bd) + \eta(b | cd) + \eta(b | bcd)] \\ & + [\eta(b | a) + \eta(b | c) + \eta(b | ac) \\ & \quad + \eta(b | ad) + \eta(b | cd) + \eta(c | acd)] \\ & + [\eta(c | a) + \eta(c | b) + \eta(c | ab) \\ & \quad + \eta(c | ad) + \eta(c | bd) + \eta(c | abd)] \leq 2, \end{aligned}$$

which is just the cluster inequality (4) for  $C$  with  $k = 1$ . Theorem 3 claims it is a facet-defining inequality for  $F$ .

Another instance of a uniform matroid was mentioned in Example 3; in this case, the inequality (10) turns into (5) from Example 1. The next example goes beyond the scope of  $k$ -cluster inequalities and uniform matroids.

*Example 7* Consider  $C = \{a, b, c, d\} = N$  and put

$$\mathcal{B} = \{ \{a, b\}, \{a, c\}, \{a, d\}, \{b, c\}, \{b, d\} \}.$$

Clearly,  $\mathcal{B}$  is the class of bases of a matroid on  $C$  of the rank 2. The rank function has the form

$$r(J) = \begin{cases} 0 & \text{if } J = \emptyset, \\ 1 & \text{if } J = \{c, d\} \text{ or } |J| = 1, \\ 2 & \text{otherwise,} \end{cases} \quad \text{for } J \subseteq C,$$

while the class  $\mathcal{C}$  of its circuits is

$$\mathcal{C} = \{ \{a, b, c\}, \{a, b, d\}, \{c, d\} \}.$$

As every pair of elements in  $C$  is contained in a circuit, it is a connected matroid. Theorem 3 says that the inequality

$$\begin{aligned} & [\eta(a | bc) + \eta(a | bd) + \eta(a | bcd)] \\ & + [\eta(b | ac) + \eta(b | ad) + \eta(b | acd)] \\ & + [\eta(c | d) + \eta(c | ab) \\ & \quad + \eta(c | ad) + \eta(c | bd) + \eta(c | abd)] \\ & + [\eta(d | c) + \eta(d | ab) \\ & \quad + \eta(d | ac) + \eta(d | bc) + \eta(d | abc)] \leq 2. \end{aligned} \tag{13}$$

is facet-defining for  $F$ . An interesting observation is that the inequality (13) defines the so-called 4B-type facet found by Bartlett and Cussens (2013); see (13) in §6 of their paper where  $\{v_1, v_4\} = \{a, b\}$  and  $\{v_2, v_3\} = \{c, d\}$ .

**COROLLARY 2** *The inequality (10) from Theorem 3 has the following form in the characteristic-imset mode:*

$$\sum_{T \in \Lambda, T \subseteq C} z(T) \cdot c(T) \leq |C| - k \quad \text{for } c \in \mathbb{R}^\Lambda, \tag{14}$$

$$\text{where } z(T) = - \sum_{L \subseteq T} (-1)^{|T \setminus L|} \cdot r(L)$$

are determined by the rank function  $r$  of the matroid. The inequality (14) defines a facet of  $C$  containing the 1-imset.

**Proof:** This follows from Lemma 10 and the formula (20) in (Cussens *et al.*, 2015) saying that  $\langle o, \eta \rangle_\Upsilon = \langle z, c_\eta \rangle_\Lambda$  where the coefficients  $z(T)$  for  $T \in \Lambda$  are given by the Möbius transform of the corresponding standardized supermodular function  $m$ , that is, by

$$z(T) = \sum_{L \subseteq T} (-1)^{|T \setminus L|} \cdot m(L) \quad \text{for } T \in \Lambda.$$

Figure 1: Edges of the graph define a matroid.

In our case,  $m$  is given by (9), which implies  $z(T) = 0$  whenever  $T \setminus C \neq \emptyset$ . Moreover, the Möbius transform of the first term in (9) vanishes for  $T \in \Lambda$ ,  $T \subseteq C$ , which gives (14). The second claim follows from Corollary 1.  $\square$

*Example 8* Consider again the matroid from Example 7. The formula (14) applied to the rank function  $r$  gives

$$z(T) = \begin{cases} -1 & \text{if } T = C, \\ 1 & \text{if } T \in \mathcal{C}, \\ 0 & \text{otherwise,} \end{cases} \quad \text{for } T \in \Lambda, T \subseteq C.$$

In particular, the inequality (13) has the following form in the characteristic-imset mode:

$$c(abc) + c(abd) + c(cd) - c(abcd) \leq 2.$$

## 5 FIVE VARIABLES EXAMPLE

Note that in case of four BN variables there is no other matroid-based facet-defining inequality for  $F$  except the  $k$ -cluster inequalities and (13). However, there are more matroid-based inequalities in case of five BN variables.

An important class of matroids are the so-called *graphic matroids* (Oxley, 1992, § 1.1). In fact, any undirected graph  $\mathcal{G}$  defines a matroid on *the set of its edges*. Specifically, a set  $I$  of edges in  $\mathcal{G}$  is considered to be *independent* (in the graphic matroid) if the edge-subgraph of  $\mathcal{G}$  consisting of edges in  $I$  is a *forest*, that is, has no undirected cycle.

The *circuits* of this graphic matroid are then the sets  $D$  of edges in  $\mathcal{G}$  forming edge-minimal cycles in  $\mathcal{G}$ , which means the removal of any edge from  $D$  results in a forest. The idea is illustrated by an example.

*Example 9* Consider  $C = \{a, b, c, d, e\} = N$  and define a matroid on  $C$  by means of the graph in Figure 1, where the edges are identified with the elements of  $C$ . It makes no problem to observe that the matroid has three circuits:

$$\mathcal{C} = \{ \{a, b, c, d\}, \{a, c, e\}, \{b, d, e\} \},$$

while the number of bases is eight: these are all 3-element subsets of  $C$  except for  $\{a, c, e\}$  and  $\{b, d, e\}$ . Of course, these are just the sets of edges defining spanning trees for the graph from Figure 1. It is easy to see that the matroid is connected and has rank  $k = 3$ . Like in Example 6 one

can determine the terms  $\eta(* | B)$  which occur in (10). For example,  $a \in C = N$  is contained in two circuits  $D \in \mathcal{C}$ , namely in  $\{a, c, e\}$  and  $\{a, b, c, d\}$ . In particular, one has in (10) those terms  $\eta(a | B)$  where  $B \subseteq N \setminus \{a\}$  and either  $\{c, e\} \subseteq B$  or  $\{b, c, d\} \subseteq B$ . The same principle applies to  $b, c, d$  and  $e$  which results in the following abbreviated form of (10):

$$\begin{aligned} & \sum_{ce \subseteq B \vee bcd \subseteq B} \eta(a | B) + \sum_{de \subseteq B \vee acd \subseteq B} \eta(b | B) \\ & + \sum_{ae \subseteq B \vee abd \subseteq B} \eta(c | B) + \sum_{be \subseteq B \vee abc \subseteq B} \eta(d | B) \\ & + \sum_{ac \subseteq B \vee bd \subseteq B} \eta(e | B) \leq 2. \end{aligned} \quad (15)$$

Thus, by Theorem 3, the inequality (15) is facet-defining for  $F$ . We leave to the reader to derive the rank function  $r$  of the matroid and observe that its Möbius transform only has 4 non-zero values:  $-1$  for circuits in  $\mathcal{C}$  and  $+1$  for  $C = N$ . In particular, by Corollary 2, (15) has the following simple form in the characteristic-imset mode:

$$c(abcd) + c(ace) + c(bde) - c(abcde) \leq 2.$$

Example 9 indicated a way one can search for connected matroids, and, thus, for facet-defining inequalities to be used in the ILP approach to BN structure learning. Graphic matroids are common examples of matroids; but there are many matroids which are not graphic, like the uniform matroid from Example 3.

To utilize fully the matroid-based approach some computer scientists may take the following exhaustive “brute-force” approach: given a (presumably) small cluster  $C$ ,  $|C| \geq 2$  generate by means of a computer all (permutation) types of classes  $\mathcal{C}$  of inclusion-incomparable subsets of  $C$  such that  $\forall a, b \in C, a \neq b$ , a set  $D \in \mathcal{C}$  exists with  $a, b \in D$ . Then one can check (again with the help of a computer) which of them satisfy the circuit elimination axiom. In this way one gets all types of connected matroids on  $C$  and can transform them into facet-defining inequalities for the family-variable polytope or for the characteristic imset polytope.

Other people may prefer to search in the literature on matroid theory. Indeed, researcher in this area have generated various catalogues of (types of) matroids on small ground sets; see, for example (Mayhew, Royle, 2008).

## 6 CONCLUSIONS

Theorem 3 implies that every connected matroid on a non-trivial cluster of BN variables induces a facet-defining inequality for the family-variable polytope; Corollary 2 says what is the form of that inequality in the context of the characteristic-imset polytope.

This is a quite general theoretical result because the well-known  $k$ -cluster inequalities, which play the key role in contemporary ILP approaches to BN structure learning, can be derived in this way. Specifically, they correspond to the prominent (connected) uniform matroids.

The significance of the paper is mainly theoretical: the area of statistical learning is related to a seemingly remote field in discrete mathematics, namely to matroid theory. Although matroids were previously known to have many applications in *combinatorial optimization*, this particular intimate link to BN structure learning could be surprising. The advantage of the matroid-based approach to learning is that the inequalities are easy to find and the verification that they are facet-defining is immediate since testing whether a matroid is connected is easy. The result is applicable in both ILP approaches to BN structure learning, that is, both in the context of the family-variable polytope and in the context of the characteristic-imset polytope.

However, the result also has some potential for practical future use because it may lead to bettering certain currently used algorithms. Let me recall in more detail the original motivation, which was the ILP approach to BN structure learning. I have in mind the *cutting plane method* where one solves an ILP optimization problem by the method of iterative reduction of the feasible set. The solution to a *linear relaxation* problem, which is a (non-integer) linear program with a larger feasible set, specified by a small number of inequalities, is typically a fractional vector. The next step is to solve the *separation problem*, that is, to find an inequality from a reservoir of available inequalities (for example from the class of cluster inequalities) which cuts the current fractional solution from the true feasible region, which is the polytope defined as the convex hull of integer vectors in the feasible set, see (Wolsey, 1998, § 8.5)

From the point of view of computational efficiency, it is essential to find such inequality which approximates the polytope as close as possible near the current solution. This leads to the suggestion to look for the most violated inequalities by the current fractional solution; see also the heuristic justification in (Cussens, 2011, § 4.1).

The presented result broadens the reservoir of available facet-defining inequalities in the ILP approach to BN structure learning. In fact, it is claimed by Bartlett and Cussens in (2013, § 6) that the inequality (13) from Example 7 has appeared to be particularly useful in their experiments. Moreover, the other facet-defining inequalities for  $F$ , that is, those not based on matroids, have not appeared to be very useful. Their empirical observations are the basis for my hope that the matroid-based inequalities may bring some further progress in this area, perhaps even resulting in better future running times.

Nevertheless, let me emphasize that additional problems have to be solved to reach the practical applicability of

general matroid-based inequalities. More specifically, it is necessary to solve the corresponding separation problem, that is, to design a speedy algorithm for finding the (most) violated inequalities by a current (fractional) solution in the class of all general matroid-based inequalities. Thus, the next step towards the practical application of the matroid-based inequalities should be a proposal for such algorithm.

## Acknowledgements

The research on this topic has been supported by the grant GAČR n. 13-20012S. I am indebted to my colleague Fero Matúš for giving me some guidance in matroid theory.

## Abstract

The continuous time Bayesian network (CTBN) is a temporal model consisting of interdependent continuous time Markov chains (Markov processes). One common analysis performed on Markov processes is determining their long-run behavior, such as their stationary distributions. While the CTBN can be transformed into a single Markov process of all nodes' state combinations, the size is exponential in the number of nodes, making traditional long-run analysis intractable. To address this, we show how to perform "long-run" node marginalization that removes a node's conditional dependence while preserving its long-run behavior. This allows long-run analysis of CTBNs to be performed in a top-down process without dealing with the entire network all at once.

## 1 INTRODUCTION

Many problems in artificial intelligence require reasoning about complex systems. One important and challenging type of system is one that changes in time. Temporal modeling and reasoning present additional challenges in representing the system's dynamics while efficiently and accurately inferring the system's behavior through time. Continuous time Bayesian networks (CTBNs) were introduced by Nodelman et al. (2002) as a temporal model capable of representing and reasoning about finite- and discrete-state systems without uniformly discretizing time, as found with dynamic Bayesian networks (Murphy, 2002). CTBNs have since been applied in a wide variety of temporal domains, from medical prognosis (Gatti et al., 2011; Gatti, 2011) to network security (Xu & Shelton, 2008, 2010) and reliability modeling (Herbrich et al., 2007; Cao, 2011; Sturlaugson & Sheppard, 2015).

While a variety of algorithms exist for querying probabilities of nodes in a CTBN at a specific time given temporal

evidence, another useful type of query is to analyze a network's long-run behavior, i.e., the stationary distributions of a CTBN's nodes. None of the previous CTBN inference algorithms were specifically designed to solve this problem. This paper presents the first inference algorithms for efficiently computing the stationary distribution of nodes in a CTBN.

The paper is organized as follows. Section 2 provides the background for the rest of the paper. Section 3 gives the theory and algorithms for computing stationary distributions in CTBNs. In Section 4, we demonstrate the algorithms on three CTBNs. Section 5 contains the conclusion and future work.

## 2 BACKGROUND

In this section, we begin by describing Markov processes and their long-run behavior. We then introduce the CTBN and discuss how combinations of nodes can be viewed as Markov processes.

### 2.1 MARKOV PROCESSES

Although its name draws on the parallels between the conditional independence encoded by Bayesian networks, the CTBN is functionally a factored Markov process. Therefore, we start with background on Markov processes.

#### 2.1.1 Definition

There are variations and extensions of the Markov process model, but the CTBN model uses the model described in this section. We refer to a finite-state, continuous-time Markov chain as a Markov process. In a Markov process, a system comprises a discrete set of states, and the system transitions probabilistically between these states. The difference between a Markov process and a Markov chain is that each transition occurs after a real-valued, exponentially distributed sojourn time, which is the time it remains in a state before transitioning. The parameters determining the sojourn times and the transition probabilities are en-

coded in what is called an “intensity matrix.” If the intensity matrix is constant throughout the lifetime of the system, we refer to the Markov process as “homogeneous.” Formally, we define a Markov process as follows.

**Definition 2.1** (Markov Process). *A finite-state, continuous-time, homogeneous Markov process  $X$  with a state space of size  $n$  is defined by an initial probability distribution  $P_X^0$  over the  $n$  states and an  $n \times n$  transition intensity matrix*

$$\mathbf{Q}_X = \begin{pmatrix} -q_{1,1}^X & q_{1,2}^X & \cdots & q_{1,n}^X \\ q_{2,1}^X & -q_{2,2}^X & \cdots & q_{2,n}^X \\ \vdots & \vdots & \ddots & \vdots \\ q_{n,1}^X & q_{n,2}^X & \cdots & -q_{n,n}^X \end{pmatrix}$$

in which each entry  $q_{i,j}^X \geq 0$  for  $i \neq j$  gives the transition rate of the process moving from state  $i$  to state  $j$ , and each entry  $q_{i,i}^X = \sum_j q_{i,j}^X$  is the parameter for an exponential distribution, determining the sojourn times for the process to remain in state  $i$ . For notational shorthand, the size of the state-space of  $X$  will be denoted as  $|X|$ .

The value  $q_{i,i}^X$  gives the rate at which the system leaves state  $x_i$ , while the value  $q_{i,j}^X$  gives the rate at which the system transitions from state  $x_i$  to state  $x_j$ . Let  $X(t)$  denote the state of  $X$  at time  $t$ . For  $i \neq j$ , we have that

$$\lim_{h \rightarrow 0^+} \frac{P(X(t+h) = x_j | X(t) = x_i)}{h} = q_{i,j}^X,$$

while  $q_{i,i}^X = \sum_{j \neq i} q_{i,j}^X$ . With the diagonal entries constrained to be non-positive, the probability density function for the process remaining in state  $i$  is given by  $q_{i,i}^X \exp(-q_{i,i}^X t)$ , with  $t$  being the amount of time spent in state  $i$ , making the probability of remaining in a state decrease exponentially with respect to time. The expected sojourn time for state  $i$  is  $1/|q_{i,i}^X|$ . The transition probabilities from state  $i$  to state  $j$  can be calculated as  $\theta_{i,j}^X = q_{i,j}^X/q_{i,i}^X$ . Because the sojourn time uses the exponential distribution, which is “memory-less,” the Markov process model exhibits the Markov property, namely, that all future states of the process are independent of all past states of the process given its present state. In other words, for  $0 < s < t < \infty$ ,

$$P(X(t+h)|X(t), X(s)) = P(X(t+h)|X(t)).$$

Rather than looking at the Markov process as a whole, we can also consider subsets of states, which we refer to as a subsystem. Formally, a subsystem  $S$  defines the behavior of a subset of states of a full Markov process  $X$ . The intensity matrix  $\mathbf{Q}_S$  of the subsystem  $S$  is formed from the entries of  $\mathbf{Q}_X$  that correspond to the states in  $S$ .

### 2.1.2 Stationary Distributions of Markov Processes

A common analysis of Markov processes is to consider their long-run behavior. In particular, we can consider the

stationary distribution  $\pi_X = \{\pi_1^X, \dots, \pi_n^X\}$  of the process, where

$$\pi_i^X = \lim_{t \rightarrow \infty} P(X(t) = i).$$

Assuming  $\mathbf{Q}_X$  is non-singular, we can compute the stationary distribution by setting up the system of equations

$$\pi_X = \mathbf{Q}_X \pi_X \quad (1)$$

with the added constraint  $\sum_{i=1}^n \pi_i^X = 1$  (Taylor & Karlin, 1998). The complexity of solving for  $\pi_X$  is determined by  $n$ , the number of states in  $X$ .

The state convergence properties of a Markov process can be analyzed from the stationary distribution. As an application used in the paper, this could be the expected long-term availability of a system. Changes to the model could be tested to optimize the reliability of the system (e.g, what is the minimum reliability of each component to guarantee the target reliability of the entire system). Stationary distributions of Markov processes have been used to analyze long-term trends in meteorology, economics, sociology, biology, immunology—just to name a few. As a factored Markov process, the CTBN can be used wherever a Markov process is applicable, while allowing the model to become more powerful and flexible through its factored representation.

## 2.2 CONTINUOUS TIME BAYESIAN NETWORKS

The CTBN was first introduced in Nodelman et al. (2002) and then further developed in Nodelman (2007) as a continuous-time probabilistic graphical model.

### 2.2.1 Definition

The motivation behind CTBNs is to factor a Markov process in much the same way that a Bayesian network factors a joint probability distribution. Instead of conditional probabilities, the CTBN uses conditional Markov processes. The CTBN is defined formally as follows.

**Definition 2.2** (Continuous Time Bayesian Network). *Let  $\mathbf{X}$  be a set of Markov processes  $\{X_1, X_2, \dots, X_n\}$ , where each process  $X_i$  has a finite number of discrete states. Formally, a continuous time Bayesian network  $\mathcal{N} = \langle \mathcal{B}, \mathcal{G} \rangle$  over  $\mathbf{X}$  consists of two components. The first is an initial distribution denoted  $P_{\mathbf{X}}^0$  over  $\mathbf{X}$  specified as a Bayesian network  $\mathcal{B}$ . This distribution  $P_{\mathbf{X}}^0$  is only used for determining the initial state of the process. The second is a continuous-time transition model  $\mathcal{G}$ , which describes the evolution of the process from its initial distribution.  $\mathcal{G}$  is represented as a directed graph with nodes  $X_1, X_2, \dots, X_n$ . Let  $\text{Pa}(X)$  denote the set of parents of  $X$  in  $\mathcal{G}$ , and let  $\text{Ch}(X)$  denote the set of children of  $X$  in  $\mathcal{G}$ . Let  $\mathbf{pa}_X$  denote the set of all combinations of state instantiations to  $\text{Pa}(X)$ , and let  $\langle pa_X \rangle \in \mathbf{pa}_X$ . A set of*

conditional intensity matrices (CIMs), denoted  $\mathbf{Q}_{X|\mathbf{Pa}(X)}$ , is associated with each  $X \in \mathbf{X}$  and comprises matrices  $\mathbf{Q}_{X|\langle pa_X \rangle} \forall \langle pa_X \rangle \in \mathbf{pa}_X$

For example, suppose we have a two-node CTBN with dependencies as  $A \rightleftharpoons B$ . Nodes  $A$  and  $B$  each have two states, with conditional intensity matrices as follows.

$$\mathbf{Q}_{A|b_0} = \begin{matrix} & a_0 & a_1 \\ a_0 & \begin{pmatrix} -1 & 1 \\ 2 & -2 \end{pmatrix} \end{matrix}, \mathbf{Q}_{A|b_1} = \begin{matrix} & a_0 & a_1 \\ a_1 & \begin{pmatrix} -3 & 3 \\ 4 & -4 \end{pmatrix} \end{matrix}$$

$$\mathbf{Q}_{B|a_0} = \begin{matrix} & b_0 & b_1 \\ b_0 & \begin{pmatrix} -5 & 5 \\ 6 & -6 \end{pmatrix} \end{matrix}, \mathbf{Q}_{B|a_1} = \begin{matrix} & b_0 & b_1 \\ b_1 & \begin{pmatrix} -7 & 7 \\ 8 & -8 \end{pmatrix} \end{matrix}$$

Nodes  $A$  and  $B$  are two distinct but interdependent subsystems of a larger Markov process.

### 2.2.2 Amalgamation

While we have shown that the CTBN is able to represent a Markov process as a set of interdependent subsystems, it is also useful to show how the subsystems of a CTBN can be merged together into ‘‘supernodes’’ containing the dynamics of multiple subsystems (Nodelman et al., 2002).

First we introduce additional notation for specific state instantiations and sets of state instantiations. Let  $\langle pa_{X \setminus Y} \rangle$  denote the state instantiation  $\langle pa_X \rangle$  excluding any state of  $Y$  (this changes  $\langle pa_X \rangle$  only if  $Y$  is a parent of  $X$ ). Then  $\mathbf{Q}_{X|\langle pa_{X \setminus Y} \rangle, Y}$  is the set of conditional intensity matrices that are dependent on the state instantiation  $\langle pa_{X \setminus Y} \rangle$  and each state of  $Y$ ,

$$\mathbf{Q}_{X|\langle pa_{X \setminus Y} \rangle, Y} = \{\mathbf{Q}_{X|\langle pa_{X \setminus Y} \rangle, y} | y \in Y\}.$$

Let  $\mathbf{pa}_{X \setminus Y}$  denote the set of all combinations of state instantiations to  $\mathbf{Pa}(X)$  excluding any state of  $Y$  (again, this changes  $\mathbf{pa}_X$  only if  $Y$  is a parent of  $X$ ).

The process involves combining sets of conditional intensity matrices from two different nodes,  $\mathbf{Q}_{X|\langle pa_{X \setminus Y} \rangle, Y}$  and  $\mathbf{Q}_{Y|\langle pa_{Y \setminus X} \rangle, X}$ , and forming a new conditional intensity matrix  $\mathbf{Q}_{XY|\langle pa_{XY} \rangle}$ , where  $\langle pa_{XY} \rangle = \langle pa_{X \setminus Y} \rangle \cup \langle pa_{Y \setminus X} \rangle$ . That is, the state instantiations for the parents of  $X$  and  $Y$  are combined, excluding the state instantiations for  $X$  and  $Y$ . The state instantiations for  $X$  and  $Y$  are excluded from  $\langle pa_{XY} \rangle$  because  $\mathbf{Q}_{XY|\langle pa_{XY} \rangle}$  will be defined over all state combinations of  $X$  and  $Y$ .

Let  $q_{i,j}^X$  be entry  $i, j$  of  $\mathbf{Q}_{X|\langle pa_X \rangle, y_k}$ , and let  $q_{k,l}^Y$  be entry  $k, l$  of  $\mathbf{Q}_{Y|\langle pa_Y \rangle, x_i}$ . The combined CIM  $\mathbf{Q}_{XY|\langle pa_{XY} \rangle}$  is the matrix defined over the states  $(x_i, y_k)$ , with the entries populated as follows.

---

#### Algorithm 1 Amalgamate two nodes of a CTBN.

---

Amalgamate( $X, Y$ )

```

1:  $\mathbf{Q}_{XY|\mathbf{Pa}(XY)} \leftarrow \emptyset$ 
2: for  $\langle pa_{X \setminus Y} \rangle \in \mathbf{pa}_{X \setminus Y}; \langle pa_{Y \setminus X} \rangle \in \mathbf{pa}_{Y \setminus X}$ 
3:    $\mathbf{Q}_{XY} \leftarrow \mathbf{0}$ 
4:   for  $i, j = 1, \dots, |X|; l, k = 1, \dots, |Y|$ 
5:      $\mathbf{Q}_X \leftarrow \mathbf{Q}_{X|\langle pa_{X \setminus Y} \rangle, x_i}$ 
6:      $\mathbf{Q}_Y \leftarrow \mathbf{Q}_{Y|\langle pa_{Y \setminus X} \rangle, y_k}$ 
7:     if  $i = j \wedge k = l$ 
8:        $q_{(i,j),(k,l)}^{XY} \leftarrow q_{i,j}^X + q_{k,l}^Y$ 
9:     else if  $i = j \wedge k \neq l$ 
10:       $q_{(i,j),(k,l)}^{XY} \leftarrow q_{k,l}^Y$ 
11:     else if  $i \neq j \wedge k = l$ 
12:       $q_{(i,j),(k,l)}^{XY} \leftarrow q_{i,j}^X$ 
13:     end if
14:   end for
15:    $\mathbf{Q}_{XY|\langle pa_{XY} \rangle} \leftarrow \mathbf{Q}_{XY}$ 
16:    $\mathbf{Q}_{XY|\mathbf{Pa}(XY)} \leftarrow \mathbf{Q}_{XY|\mathbf{Pa}(XY)} \cup \{\mathbf{Q}_{XY|\langle pa_{XY} \rangle}\}$ 
17: end for
18: return  $\mathbf{Q}_{XY|\mathbf{Pa}(XY)}$ 

```

---

$$q_{(i,j),(k,l)}^{XY} = \begin{cases} q_{i,j}^X & \text{if } i \neq j \text{ and } k = l \\ q_{k,l}^Y & \text{if } i = j \text{ and } k \neq l \\ q_{i,j}^X + q_{k,l}^Y & \text{if } i = j \text{ and } k = l \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

The CIM  $\mathbf{Q}_{XY|\langle pa_{XY} \rangle}$  defines the simultaneous dynamics of  $X$  and  $Y$ , given that their parents are in states  $\langle pa_{XY} \rangle$ . Thus, the state-space of  $XY$  is the Cartesian product of the states of  $X$  and  $Y$ , making  $\mathbf{Q}_{XY|\langle pa_{XY} \rangle}$  an  $|X||Y| \times |X||Y|$  matrix.

**Definition 2.3** (Amalgamation). *Amalgamation takes two nodes  $X$  and  $Y$  and replaces them with node  $XY$ , having the set of conditional intensity matrices  $\mathbf{Q}_{XY|\mathbf{Pa}(XY)}$  as formed by combining  $\mathbf{Q}_{X|\langle pa_{X \setminus Y} \rangle, Y}$  and  $\mathbf{Q}_{Y|\langle pa_{Y \setminus X} \rangle, X} \forall \langle pa_{X \setminus Y} \rangle \in \mathbf{pa}_{X \setminus Y}$  and  $\forall \langle pa_{Y \setminus X} \rangle \in \mathbf{pa}_{Y \setminus X}$  according to Equation 2. Amalgamation can be viewed as a multiplication operation over sets of conditional intensity matrices and is denoted  $\mathbf{Q}_{XY|\mathbf{Pa}(XY)} = \mathbf{Q}_{X|\mathbf{Pa}(X)} \times \mathbf{Q}_{Y|\mathbf{Pa}(Y)}$ .*

Amalgamation takes two nodes and combines all of their CIMs, producing a set of CIMs that are conditioned on the combined parent states of  $X$  and  $Y$ . Thus, the set  $\mathbf{Q}_{XY|\mathbf{Pa}(XY)}$  contains  $\prod_{Z \in \mathbf{Pa}(XY)} |Z|$  conditional intensity matrices.

Algorithm 1 shows the pseudocode for amalgamating two nodes of a CTBN. Line 1 initializes the empty set of conditional intensity matrices for the amalgamated node. Lines 2-18 iterate over all combinations of parent state instantiations of  $X$  and  $Y$ , excluding the state of  $X$  and  $Y$ . Line 3 initializes the conditional intensity matrix to be populated. Lines 4-14 iterate over the state combinations of  $X$

and  $Y$ . Lines 5-6 assign the conditional intensity matrices to temporary variables for simpler notation. Lines 7-13 populate the parameters of the conditional intensity matrix initialized in line 3 per Equation 2. Lines 15-17 add the conditional intensity matrix to the set of conditional intensity matrices of the amalgamated node, which is returned in Line 19.

**Definition 2.4** (Full Joint Intensity Matrix). *The full joint intensity matrix of a CTBN is the matrix resulting from amalgamating all nodes of the CTBN,*

$$\mathbf{Q} = \prod_{X \in \mathcal{N}} \mathbf{Q}_{X|\text{Pa}(X)}.$$

The size of  $\mathbf{Q}$  is  $n \times n$ , where  $n = \prod_{X \in \mathcal{N}} |X|$ .

For example, the full joint intensity matrix from the CTBN in Section 2.2.1 is as follows.

$$\mathbf{Q}_{AB} = \begin{matrix} & (a_0, b_0) & (a_0, b_1) & (a_1, b_0) & (a_1, b_1) \\ \begin{matrix} (a_0, b_0) \\ (a_0, b_1) \\ (a_1, b_0) \\ (a_1, b_1) \end{matrix} & \begin{pmatrix} -6 & 5 & 1 & 0 \\ 6 & -9 & 0 & 3 \\ 2 & 0 & -9 & 7 \\ 0 & 4 & 8 & -12 \end{pmatrix} \end{matrix}$$

### 3 NODE MARGINALIZATION IN THE LIMIT

Now we want to address the problem of computing stationary distributions for nodes in a CTBN  $\mathcal{N}$ . Formally, we want to compute  $\pi_X$  for  $X \in \mathbf{X}$ . We can calculate the stationary distribution for a node  $X$  having no parents in  $\mathcal{N}$  by simply using the approach of Equation 1 on the single intensity matrix of  $X$  (provided that  $X$  is irreducible). For nodes with dependencies (which is the point of the CTBN model), each node's stationary distribution depends on all ancestors in the network. In the worst case, a node could have all other nodes as ancestors (one of our experiments is a case of this). But as we have shown, the number of equations is exponential in the size of the network when working with the full joint intensity matrix directly.

We need to perform node marginalization so as to remove a node's dependence on its parents. This will allow us to contain the problem to individual subnetworks and not the entire network. Marginalization methods for CTBNs have been developed in the past, most notably expectation propagation (Nodelman et al., 2005) and belief propagation (El-Hay et al., 2010). Both of these methods approximate a node's unconditional intensity matrix; however, each of the unconditional intensity matrices by these methods are computed for a specific interval of constant evidence. They are not intended to describe the dynamics of a node as  $t \rightarrow \infty$ ,

which is what we need if we are to compute stationary distributions. The remainder of this section develops a novel CTBN node marginalization method that computes a long-run unconditional intensity matrix.

#### 3.1 THEORY

The key to computing the stationary distributions of nodes in the CTBN is to compute stationary distributions of subsystems of a Markov process. This allows us to work with subsets of nodes, instead of dealing with  $\mathbf{Q}$  all at once. Let  $S$  be the starting subsystem and  $D$  be the destination subsystem. We now want to compute the rate at which  $S$  transitions to  $D$  in the limit. Formally, we want a tractable way to evaluate

$$q_{S,D}^X = \lim_{t \rightarrow \infty} \lim_{h \rightarrow 0^+} \frac{P(X(t+h) \in D | X(t) \in S)}{h}. \quad (3)$$

**Theorem 3.1.** *For a Markov process with disjoint subsystems  $S$  and  $D$  and  $q_{S,D}^X$  as defined above, then*

$$q_{S,D}^X = \frac{1}{Z} \sum_{i \in S} \pi_i^X \sum_{j \in D} q_{ij}^X$$

where  $Z = \sum_{i \in S} \pi_i^X$ .

*Proof.* Because  $S$  is a set of multiple states when conditioning on  $X(t) \in S$ , we must weight each state  $i$  in  $S$  by the probability of being in state  $i$  at time  $t$  and renormalize.

$$\begin{aligned} \lim_{t \rightarrow \infty} \lim_{h \rightarrow 0^+} \frac{P(X(t+h) \in D | X(t) \in S)}{h} &= \\ \lim_{t \rightarrow \infty} \lim_{h \rightarrow 0^+} \frac{1}{\sum_{i \in S} P(X(t) = i)} \sum_{i \in S} P(X(t) = i) &\times \\ \sum_{j \in D} \frac{P(X(t+h) = j | X(t) = i)}{h} &= \\ \lim_{t \rightarrow \infty} \frac{1}{\sum_{i \in S} P(X(t) = i)} \sum_{i \in S} P(X(t) = i) &\times \\ \sum_{j \in D} \lim_{h \rightarrow 0^+} \frac{P(X(t+h) = j | X(t) = i)}{h} &= \\ \lim_{t \rightarrow \infty} \frac{1}{\sum_{i \in S} P(X(t) = i)} \sum_{i \in S} P(X(t) = i) \sum_{j \in D} q_{ij}^X &= \\ \frac{1}{\sum_{i \in S} \pi_i^X} \sum_{i \in S} \pi_i^X \sum_{j \in D} q_{ij}^X &= \\ \frac{1}{Z} \sum_{i \in S} \pi_i^X \sum_{j \in D} q_{ij}^X & \quad \square \end{aligned}$$

**Corollary 3.2.** *Suppose that a Markov process  $X$  comprises  $n$  disjoint subsystems  $\{S_1, \dots, S_n\}$ . Then  $q_{S_i, S_i}^X = \sum_{j=1, j \neq i}^n q_{S_i, S_j}^X$ .*

---

**Algorithm 2** Compute long-run unconditional intensity matrix of a node.

---

*MarginalizeNode*( $Fam_X$ )

```

1: for  $i = 1, \dots, |X|$ 
2:   for  $j = 1, \dots, |X|$  s.t.  $j \neq i$ 
3:      $Z \leftarrow \sum_{k \in S_i} \pi_k^X$ 
4:      $q_{i,j}^X \leftarrow \frac{1}{Z} \sum_{k \in S_i} \pi_k^X \sum_{l \in D_j} q_{k,l}^{Fam_X}$ 
5:   end for
6:    $q_{i,i}^X = \sum_{j=1, j \neq i}^{|X|} q_{i,j}^X$ 
7: end for
8: return  $Q_X$ 

```

---

*Proof.* This follows from the definition of a Markov process, which constrains  $q_{i,i}^X = \sum_{j \neq i} q_{i,j}^X$ . In other words, if we know the rate at which the process leaves one subsystem and enters every other subsystem, we also know the rate with which the process leaves the subsystem.  $\square$

### 3.2 ALGORITHMS

Now we apply this idea of computing long-run transition rates for Markov process subsystems to amalgamated nodes in a CTBN. In this case, we take the subsystems to be the states of a child node in an amalgamation of the child and its parents. After computing the long-run transition rates for the subsystems, we can construct an unconditional intensity matrix for the child node.

Algorithm 2 computes a long-run unconditional intensity matrix for node  $X$  from a set of amalgamated nodes  $Fam_X$  that includes  $X$  and all parents of  $X$ . The variables  $i$  and  $j$  iterate over the rows and columns, respectively, for the unconditional intensity matrix of  $X$ . Line 3 computes the normalization constant. The sets  $S_i$  and  $D_j$  are the states in  $Fam_X$  that include state  $i$  and state  $j$  of  $X$ , respectively. Line 4 computes the long-run transition rate of node  $X$  from state  $i$  to state  $j$ , according to Theorem 3.1. Line 6 computes the long-run sojourn rate of state  $i$  of node  $X$ , according to Corollary 3.2. Line 8 returns the long-run unconditional intensity matrix of  $X$  that are populated by entries  $q_{i,j}^X$ . The complexity of Algorithm 2 is dominated by the computation of the stationary distribution. Assuming  $Q_X$  is non-singular, its stationary distribution can be computed in  $O(n^3)$ .

Now that we can compute a long-run unconditional intensity matrix for a node, we can break the dependence of the child on its parents. The unconditional intensity matrix computed for the child will already incorporate the stationary distribution of the parents. We can repeat the process in a top-down fashion through the network, computing the stationary distributions of every node in the network without having to deal with the entire network all at once. Algorithm 3 calculates the long-run unconditional intensity matrices for all of the nodes in a CTBN.

---

**Algorithm 3** Compute long-run unconditional intensity matrices of a CTBN.

---

*MarginalizeCTBN*( $\mathcal{G}$ )

```

1:  $\mathcal{G}' \leftarrow \text{CollapseCycles}(\mathcal{G})$ 
2: repeat until termination
3:    $L_1 \leftarrow \bigcup_{X \in \mathcal{G}'} X$  s.t.  $\text{Pa}(X) = \text{null}$ 
4:    $L_2 \leftarrow \bigcup_{X \in L_1} \text{Ch}(X)$  s.t.  $\text{Pa}(\text{Ch}(X)) \subseteq L_1$ 
5:   if  $L_2 = \text{null}$  then terminate
6:   for  $X \in L_2$ 
7:      $Fam_X \leftarrow X$ 
8:     for  $Y \in \text{Pa}(X)$ 
9:        $Fam_X \leftarrow \text{Amalgamate}(Fam_X, Y)$ 
10:    end for
11:     $Q_{X'} \leftarrow \text{MarginalizeNode}(Fam_X)$ 
12:    for  $Y \in \text{Pa}(X)$ 
13:      remove edge  $(Y, X)$  from  $\mathcal{G}'$ 
14:    end for
15:     $Q_X \leftarrow Q_{X'}$ 
16:  end for
17: end repeat

```

---

We need to turn  $\mathcal{G}$  into a directed acyclic graph (DAG) from which we can divide the graph into top-to-bottom levels. The behavior of a node depends on all of its ancestors, thus to create a DAG we need to amalgamate all the nodes of each cycle. In the next section we will show an approximation step that avoids collapsing cycles when the cycles themselves are too large for their amalgamation to be tractable.

In Algorithm 3, line 1 collapses the cycles in the  $\mathcal{G}$  by amalgamating all of the nodes in each cycle. Lines 2-17 iterate over the levels of the DAG. Lines 3-4 find all of the 2nd-level nodes, i.e., nodes with no other ancestors than their immediate parents. If there are no more 2nd-level nodes, then all of the nodes have been marginalized (no nodes have parents), and line 5 terminates the loop. Lines 6-16 iterate over all of the 2nd-level nodes. Lines 7-10 amalgamate each 2nd-level node with all of its parents. Line 11 computes the long-run unconditional intensity matrix for each 2nd-level node. Lines 12-14 remove the dependency of the node on its parents, and line 15 updates the node's set of intensity matrices with the single intensity matrix from line 11. At the conclusion of the algorithm, the nodes of  $\mathcal{N}$  are individual unconditional Markov processes. Note that the stationary distributions are computed along the way by Algorithm 2. The complexity of the algorithm is dominated by the maximum number of parents of any node (analogous to tree-width in Bayesian network inference).

### 3.3 APPROXIMATION FOR CYCLES

One difficulty of node marginalization is that the dynamics of a node depend on all of its ancestors. If the network is a directed acyclic graph (DAG), then we can marginalize each level in succession, and the complexity of isolation depends on the number of immediate parents to each node. However, cycles are allowed in CTBNs. When a cycle is introduced, every node in the cycle must be included to marginalize any node in the cycle, because every node in the cycle is an ancestor of every other node in the cycle.

We can address this complication by adding an iterative step to our long-run node marginalization algorithm that avoids dealing with the entire cycle all at once. First, we identify the cycles and all of the nodes they comprise. Let  $\mathbf{X}_C$  denote the set of arbitrarily chosen nodes that cover all of the cycles (it is possible that a single node could cover multiple cycles). The set  $\mathbf{X}_C$  covers a cycle when at least one node in  $\mathbf{X}_C$  is part of the cycle.

For each  $X \in \mathbf{X}_C$ , we temporarily remove all incoming arcs. Previously, the node had a set of conditional intensity matrices, whereas now we need to replace it with one unconditional intensity matrix. While this unconditional intensity matrix depends on the dynamics of the parents that were just removed, we simply use an unconditional intensity matrix that is the average of the node’s conditional intensity matrices. Formally, for each  $X \in \mathbf{X}_C$ , we remove the incoming arcs to  $X$  and estimate an initial unconditional intensity matrix for  $X$  as

$$\hat{\mathbf{Q}}_X \leftarrow \frac{1}{|\mathbf{Q}_{X|\mathbf{Pa}(X)}|} \sum_{\mathbf{Q}_{X|\langle pa_X \rangle} \in \mathbf{Q}_{X|\mathbf{Pa}(X)}} \mathbf{Q}_{X|\langle pa_X \rangle}.$$

Once we have done this for every cycle, the graph becomes a DAG, and we run the *MarginalizeCTBN* algorithm as before.

Depending on the actual parameters, the resulting unconditional intensity matrices could be a poor approximation, because of how we estimated the unconditional intensity matrix of the nodes in  $\mathbf{X}_C$ . Now we can improve on our estimates for  $\hat{\mathbf{Q}}_X$  because, after the first iteration, we have an unconditional intensity matrix for every immediate parent of  $X$ . So we add back all of the incoming nodes of each  $X \in \mathbf{X}_C$  and call *MarginalizeNode* on each of these nodes. This results in updated estimates for each  $\hat{\mathbf{Q}}_X$  which now take into account an estimate of the dynamics of the parents of each  $X$ . Now we have the original DAG with updated unconditional intensity matrices for each  $X \in \mathbf{X}_C$ . We can call *MarginalizeCTBN* again.

This process continues to loop around the cycles until convergence. This process is analogous to loopy belief propagation in cyclic graphs, such as in Markov random fields

Figure 1: Drug effect network.

and in Bayesian networks in which the acyclic constraint has been relaxed (Koller & Friedman, 2009). The long-run unconditional intensity matrices are approximations in this case, because we have never viewed the cycle as a whole. On the other hand, if the cycles have too many nodes, we have kept the problem tractable.

## 4 EXPERIMENTS

We demonstrate the long-run marginalization methods on three networks—two synthetic networks and one real-world network. The two synthetic networks are small enough that we can compute the stationary distributions from the full joint intensity matrix. For the real-world network, we can approximate the stationary distributions by forward sampling the CTBN long enough into the future such that the samples will have converged to the stationary distribution.

### 4.1 DRUG EFFECT NETWORK

First, we used the drug effect network from Nodelman et al. (2002) as shown in Figure 1. The network is a toy model that shows the interaction of several variables on a patient’s pain and drowsiness.

We collapse the *Hungry*  $\rightarrow$  *Eating*  $\rightarrow$  *Full Stomach* cycle and marginalize *Concentration*. The unconditional intensity matrix of *Concentration* is

$$\mathbf{Q}_{Concentration} \approx \begin{pmatrix} -0.02 & 0.01 & 0.01 \\ 0.25 & -0.26 & 0.01 \\ 0.01 & 0.50 & -0.51 \end{pmatrix}.$$

We then marginalize *Pain* and *Drowsy*, which yields,

$$\mathbf{Q}_{Pain} \approx \begin{pmatrix} -0.56 & 0.56 \\ 0.28 & -0.28 \end{pmatrix}$$

and

$$\mathbf{Q}_{Drowsy} \approx \begin{pmatrix} -0.18 & 0.18 \\ 0.46 & -0.46 \end{pmatrix}.$$

The calculated stationary distributions from both the marginalized nodes and the full joint intensity matrix are

$$\begin{aligned}\pi_{\text{pain}} &\approx 0.336 \\ \pi_{\text{pain-free}} &\approx 0.664 \\ \pi_{\text{drowsy}} &\approx 0.713 \\ \pi_{\text{non-drowsy}} &\approx 0.287.\end{aligned}$$

However, using the full joint intensity matrix (brute-force method) required solving a system of 864 equations. Through our long-run node marginalization method, we needed to solve systems of 72, 12, and 4 equations. In other words, the complexity has been reduced by approximately a factor of 10.

## 4.2 RING NETWORK

This second experiment tests our long-run marginalization method on cyclic networks of varying length. For a ring network of size  $n$ , we construct the network by adding  $n$  three-state ( $s_0, s_1, s_2$ ) nodes and connecting them as follows:

$$X_1 \rightarrow X_2 \rightarrow \dots \rightarrow X_n \rightarrow X_1.$$

Let each  $q_{i,j}^k$  be an independent sample from a uniform distribution over the interval  $(0, 1)$ . The conditional intensity matrices for the nodes are defined as follows (for ease of definition,  $X_0$  and  $X_n$  denote the same node):

$$\begin{aligned}\mathbf{Q}_{X_k|X_{k-1}=s_0} &= \begin{pmatrix} -q_{1,1}^k & q_{1,1}^k & 0 \\ 0 & -q_{1,2}^k & q_{1,2}^k \\ q_{1,3}^k & 0 & -q_{1,3}^k \end{pmatrix}, \\ \mathbf{Q}_{X_k|X_{k-1}=s_1} &= \begin{pmatrix} -q_{2,1}^k & \frac{q_{2,1}^k}{2} & \frac{q_{2,1}^k}{2} \\ \frac{q_{2,2}^k}{2} & -q_{2,2}^k & \frac{q_{2,2}^k}{2} \\ \frac{q_{2,3}^k}{2} & \frac{q_{2,3}^k}{2} & -q_{2,3}^k \end{pmatrix}, \\ \mathbf{Q}_{X_k|X_{k-1}=s_2} &= \begin{pmatrix} -q_{3,1}^k & 0 & q_{3,1}^k \\ q_{3,2}^k & -q_{3,2}^k & 0 \\ 0 & q_{3,3}^k & -q_{3,3}^k \end{pmatrix}.\end{aligned}$$

We vary the length of the cycle from 3 nodes to 8 nodes and, for each cycle length, apply the approximate node marginalization method described in Section 3.3 and compare the accuracy to the results from the brute-force method. (Note that in this case the brute-force and exact node marginalization methods are identical, because the whole network is a cycle.) Because each network is generated with random parameters, we run a total of 100 trials for each cycle length and average the results. We keep track of the average number of iterations for the stationary distribution estimates to converge, and we compute the average KL-divergence of the stationary distributions results using the full joint intensity matrix from the results using the iterative node marginalization method. These results are shown in Table 1.

Table 1: Results for the ring networks.

| Cycle Length | Avg. Iterations to Converge | Average KL-Divergence |
|--------------|-----------------------------|-----------------------|
| 3            | 12.1                        | 3.1E-4                |
| 4            | 10.1                        | 5.5E-5                |
| 5            | 8.2                         | 2.1E-5                |
| 6            | 7.6                         | 1.7E-5                |
| 7            | 6.8                         | 1.9E-5                |
| 8            | 6.0                         | 1.4E-5                |

At least for these randomly generated networks, the iterative node marginalization method maintained accurate estimates of the stationary distributions, and the number of iterations to converge tended to decrease as the cycle grew. Notice that the error decreases as the cycle length increases. For these networks, at least, the dynamics of a node are most influenced by the immediate parent. The second-most influential node is the parent’s parent, and so on. As the length of the cycle increases, the influence of the “arc that completes the cycle” (whichever arc one chooses this to be) exerts less influence on the dynamics of the cycle as a whole. Therefore, temporarily removing an arc has a decreasing impact as the cycle becomes larger.

For a 3-node cycle, amalgamating the whole cycle will most likely still be a tractable approach. For longer cycle lengths, on the other hand, the applicability of the iterative node marginalization method becomes more critical. In our setup, every node added to the cycle triples the size of the full joint intensity matrices and hence the system of equations to solve.

## 4.3 CARDIAC ASSIST SYSTEM

Third, we compared the inference methods on a larger, real-world network. We used the model for a cardiac assist system (CAS), presented by Cao (2011), which is broadly used in the literature and based on a real-world system (Boudali et al., 2007; Portinale et al., 2010). Cao (2011) shows how the CTBN is able to encode Dynamic Fault Trees (DFTs), which are reliability models that use Boolean logic to combine series of lower-level failure events while preserving failure sequence information (Dugan et al., 1992). The intensity matrices of the CTBN are used to represent the gates available in the DFT, including AND, OR, warm spare (WSP), sequence enforcing (SEQ), probabilistic dependency (PDEP), and priority AND (PAND). Our model for this experiment is the DFT for the CAS system represented as a CTBN. Of the various repair policies evaluated by Cao (2011), we use the repair rate of  $\mu = 0.1$  (10 hours) for all components.

Figure 2 shows the network, while Table 2 gives the node names. In this model, we are interested in the stationary

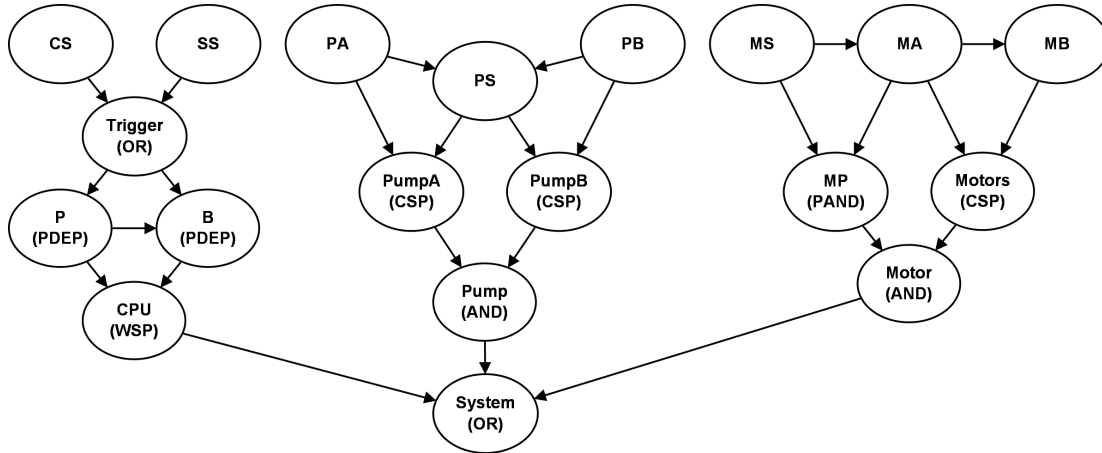

Figure 2: Cardiac assist system model.

distribution of the *System* node, i.e., in the long run, what proportion of the time will the *System* be operational? This corresponds to the operational availability of the subsystem.

Notice that the node in which we are most interested is a descendant of every other node in the network. Using our node marginalization method, we can compute the stationary distribution of the *System* node as

$$\begin{aligned}\pi_{\text{system-up}} &\approx 0.942 \\ \pi_{\text{system-down}} &\approx 0.058.\end{aligned}$$

If we had attempted to work with the full joint intensity matrix directly, we would be faced with solving a system of over 6.6 million equations. In other words, the brute-force method is intractable for this real-world network. Instead, our node marginalization method divided the network into a total of 14 subnetworks, with the two largest representing systems of only 20 equations.

Instead of trying to solve the system of equations for this large network, we can approximate the stationary distribution by forward sampling the CTBN and observing the convergence of the state probabilities. Because this is an approximation method, we ran multiple trials to quantify the average behavior of the approximation. We ran 100 trials and averaged the results. For each trial, we sampled the network so that we had 10K transitions for the *System* node. Because the dynamics of *System* depend on every other node, we had to sample transitions from all other nodes as well. By the time we had generated 10K transitions for *System*, we had generated more than 100K transitions on average for the other nodes. Our approximation of the stationary distribution of *System* from 10K transitions still resulted in a KL-divergence of  $7.2E-3$  on average. On the other hand, our node marginalization method computed the exact answer over 3 times faster on average.

Note that our node marginalization method produces an

Table 2: CAS component names.

| Abbreviation | Name                | Subsystem |
|--------------|---------------------|-----------|
| P            | primary CPU         | CPU       |
| B            | warm spare CPU      | CPU       |
| CS           | cross switch        | CPU       |
| SS           | system supervision  | CPU       |
| MA           | primary motor       | Motor     |
| MB           | cold spare motor    | Motor     |
| MS           | switching component | Motor     |
| PA           | pump A              | Pump      |
| PB           | pump B              | Pump      |
| PS           | cold shared pump    | Pump      |

Table 3: Expected sojourn times for CAS subsystems.

| Subsystem | MTBF (hrs) | MTTR (hrs) |
|-----------|------------|------------|
| CPU       | 154        | 9.38       |
| Pump      | 60K        | 5.00       |
| Motor     | 410M       | 6.50       |

other useful output. Because the method computes unconditional intensity matrices along the way, we can observe not only the stationary distributions of different nodes but their long-run expected sojourn times as well. For example, looking at the diagonal entries of the unconditional intensity matrices of *System*, we see that, in the long-run, the mean time between failures (MTBF) for the system is about 153 hours and the mean time to repair (MTTR) is about 9.37 hours. Which of the three subsystems contributes the most to these values? Because of the top-down marginalization process, we have already calculated the same values for each of three subsystems, summarized in Table 3.

We have identified that the *CPU* subsystem contributes the most to *System* failure, while the *Motor* subsystem, due to

its high reliability rates and its redundancy, very rarely contributes to *System* failures. The *Pump* subsystem is identified as the fastest to be repaired. From long-run analysis on both the stationary distributions and the expected sojourn times, we have efficiently identified and quantified the unreliability of the *CPU* subsystem for efforts to make the CAS more robust and reliable.

## 5 DISCUSSION

The experiments demonstrate the capability of the exact and approximate node marginalization methods developed in this paper. We started with two synthetic networks that were small enough to compute the stationary distributions using the traditional approach when viewing a CTBN as a Markov process via its full joint intensity matrix. With the drug effect network, we showed that the exact method computes the same values with a fraction of the computational complexity. With the cyclic network, the brute-force and exact methods become indistinguishable. We showed how an iterative variation of the exact node marginalization method can effectively approximate the stationary distributions of nodes in cycles without handling the entire cycle all at once. Lastly, we applied the node approximation method to a non-trivial real-world network. In this case, working with the full joint intensity matrix (the tradition, brute-force approach) is intractable. We compare our exact node marginalization method to an approximate method based on forward sampling. For this experiment, our node marginalization method is both more efficient and yields the exact answer instead of an approximation.

Our methods assume that the stationary distributions of individual subnetworks can be computed efficiently. Specifically, solving Equation 1 requires the matrix to be non-singular (i.e., that the Markov process be irreducible). For some CTBNs, this may not be the case, and some sub-systems of the process may not be irreducible. Our exact method breaks down in this case. However, note that the traditional approach also breaks down, because it is also based on Equation 1. As long as there exists a method to compute  $\pi$  for a subnetwork (or at least approximate  $\pi$ ), this vector can be used in our top-down and/or iterative node marginalization methods.

## 6 CONCLUSION

We have shown how to compute stationary distributions and long-run expected sojourn times for CTBNs tractably without working directly with the full joint intensity matrix. For CTBNs with long cycles, we have shown an iterative marginalization method that can be used to approximate the long-run behavior. To demonstrate the methods, we tested on three networks of varying complexity and showed the advantage of using our marginalization methods. Fu-

ture work involves analyzing the behavior of the iterative marginalization method, including research into network topologies and parameters that could make the approximation poor, as well as analyzing convergence properties such as proof of convergence.

## Abstract

We establish a connection between optimizing the Bellman Residual and worst case long-term predictive error. In the online learning framework, learning takes place over a sequence of trials with the goal of predicting a future discounted sum of rewards. Our analysis shows that, together with a stability assumption, *any* no-regret online learning algorithm that minimizes Bellman error ensures small prediction error. No statistical assumptions are made on the sequence of observations, which could be non-Markovian or even adversarial. Moreover, the analysis is independent of the particular form of function approximation and the particular (stable) no-regret approach taken. Our approach thus establishes a broad new family of provably sound algorithms for Bellman Residual-based learning and provides a generalization of previous worst-case result for minimizing predictive error. We investigate the potential advantages of some of this family both theoretically and empirically on benchmark problems.

## 1 INTRODUCTION

*Reinforcement learning* (RL) is an online paradigm for optimal sequential decision making where an agent interacts with an environment, takes actions, receives rewards and tries to maximize its *long-term reward*, a discounted sum of all the rewards that will be received from now on. An important part of RL is policy evaluation, the problem of evaluating the expected long-term rewards of a fixed policy. *Temporal Difference* (TD) is a famous family of algorithms for policy evaluation. In practice, we are typically interested in complex problem domains (e.g., continuous state space RL) and function approximations (e.g., linear functions) are used for policy evaluation. However, it has been observed that when combined with function approxi-

mation, TD may diverge and lead to poor prediction. The *Residual Gradient* (RG) was proposed (Baird, 1995) to address these concerns. RG attempts to minimize the *Bellman Error* (BE) (see definition in Sec. 2), typically with linear function approximation, using stochastic gradient descent. Since then comparison between the family of TD algorithms and RG has received tremendous attention, although most of the analyses heavily rely on certain stochastic assumptions of the environment such as that the sequence of observations are Markovian or from a static Markov Decision Process (MDP). For instance Schoknecht and Merke (2003) showed that TD converges provably faster than RG if the value functions are presented by tabular form. Scherrer (2010) shows that Bellman Residual minimization enjoys a guaranteed performance while TD does not in general when states are sampled from arbitrary distributions that may not correspond to trajectories taken by the system. Experimentally, they also show that TD converges faster but may generate poor prediction when it is close to divergence.

Schapire and Warmuth (1996) and Li (2008) provided worst-case analysis of long-term predictive error for variants of the linear TD and RG under a non-probabilistic online learning setting. Their results rely on an elegant spectral analysis of a matrix that is related to **specific** update rules of the TD and RG algorithms under linear function approximation. Unfortunately, this approach makes it more difficult to extend their worst-case (assumption free) analysis to broader families of algorithms and representations that target the Bellman and Temporal Difference errors.

Following Schapire and Warmuth (1996) and Li (2008)'s online learning framework, we present a simple, general connection between long-term predictive error and no-regret online learning that attempts to minimize BE. The central idea is that methods such as RG should be fundamentally understood as online algorithms as opposed to standard gradient methods, and that one cannot simultaneously make consistent predictions in the sense of BE while doing a poor job in terms of long-run predictions. Similar to Schapire and Warmuth (1996) and Li (2008), our analysis does not rely on any statistical assumptions about the

underlying system. This allows us to analyze more difficult scenarios such as Markov Decision Process with transition probabilities changing over time or even with each transition chosen entirely adversarial. Our analysis generalizes to a broader class of functions to approximate the value function. Previous work from Robards et al. (2011) and Engel et al. (2005) explored the possibility of using non-linear function approximation, but to our knowledge no further analysis on the soundness with respect to prediction error are known.

Our analysis of the connection between online long-term reward prediction and no-regret online learning provides a unifying view of the relationship between prediction errors and BE and consequently suggests a broad new family of algorithms. Specifically, we present and analyze concrete examples of how to apply several well-known no-regret online algorithms such as *Online Gradient Descent* (OGD) from Zinkevich (2003), *Online Newton Step* (ONS) from Hazan et al. (2006) and *Online Frank Wolf* (OFW) from Hazan and Kale (2012) to online prediction of long-term rewards. Particularly, our analysis generalizes the RG algorithm from Baird (1995) in the following three aspects: (1) RG is a specific example of our family of algorithms that runs OGD on a sequence of BE loss functions, (2) RG can be naturally combined with more general function approximation such as functions in *Reproducing Kernel Hilbert Space* (RKHS), and (3) applying our analysis to RG provides asymptotically tighter bounds on the average prediction error of long-term rewards than that provided in Li (2008). We also find that ONS, which has no-regret rate of  $O(\log T/T)$ , has a faster convergence of the average prediction error of long-term rewards. With OFW, we are able to achieve sparse predictors under some conditions. We analyze these algorithms in detail in Sec. 4.

We emphasize that stability of online algorithms is essential for our results—the no-regret property can be shown by example to be insufficient to achieve low predictive error. We hence introduce the definition of *Online Stability* condition in Sec. 2, which intuitively measures the difference between two successive predictors. Our online stability condition is general enough such that most popular no-regret online algorithms naturally satisfy this condition and hence this condition does not severely limit the scope of no-regret online algorithms. Our analysis shows that the combination of the no-regret property and online stability is sufficient to promise small predictive error on the long-term rewards.

## 2 PRELIMINARIES

### 2.1 PROBLEM SETTING

We consider the sequential online learning model presented in Schapire and Warmuth (1996); Li (2008) where no sta-

tistical assumptions about the sequence of observations are made. The sequence of the observations forms a connected stream of states which can either be Markovian as typically assumed in RL problem settings or even adversarial. We define the observation at time step  $t$  as  $\mathbf{x}_t \in \mathbb{R}^n$ , which usually represents the features of the environment at  $t$ . Throughout the paper, we assume that feature vector  $\mathbf{x}$  is bounded as  $\|\mathbf{x}\|_2 \leq X, X \in \mathbb{R}^+$ . The corresponding reward at step  $t$  is defined as  $r_t \in \mathbb{R}$ , where we assume that reward is always bounded  $|r| \leq R \in \mathbb{R}^+$ . Given a sequence of observations  $\{\mathbf{x}_t\}$  and a sequence of rewards  $\{r_t\}$ , the long-term reward at  $t$  is defined as  $v_t = \sum_{k=t}^{\infty} \gamma^{k-t} r_s$ , where  $\gamma \in [0, 1)$  is a discount factor. Given a function space  $\mathcal{F}$  the learner chooses a predictor  $f$  at each time step from  $\mathcal{F}$  for predicting long-term rewards. Throughout this paper, we assume that any prediction made by a predictor  $f$  at a state  $\mathbf{x}$  is upper bounded as  $|f(\mathbf{x})| \leq P \in \mathbb{R}^+$ , for any  $f \in \mathcal{F}$  and  $\mathbf{x}$ .

At time step  $t = 0$ , the learner receives  $\mathbf{x}_0$ , initializes a predictor  $f_0 \in \mathcal{F}$  and makes prediction of  $v_0$  as  $f_0(\mathbf{x}_0)$ . Rounds of learning then proceeds as follows: the learner makes a prediction of  $v_t$  at step  $t$  as  $f_t(\mathbf{x}_t)$ ; the learner then observes a reward  $r_t$  and the next state  $\mathbf{x}_{t+1}$ ; the learner updates its predictor to  $f_{t+1}$ . This interaction repeats and is terminated after  $T$  steps. Throughout this paper, we call this problem setting as *online prediction of long-term reward*.

We define the *signed Bellman Error* at step  $t$  for predictor  $f_t$  as  $b_t = f_t(\mathbf{x}_t) - r_t - \gamma f_t(\mathbf{x}_{t+1})$ , which measures effectively how self consistent  $f_t$  is in its predictions between time step  $t$  and  $t + 1$ . For any  $f^* \in \mathcal{F}$ , we define the corresponding signed Bellman Error as  $b_t^* = f^*(\mathbf{x}_t) - r_t - \gamma f^*(\mathbf{x}_{t+1})$ . We denote the *Bellman Error* (BE) as the square of the signed Bellman error  $b_t^2$ .

The *Signed Prediction Error* of long-term reward at  $t$  for  $f_t$  is defined as  $e_t = f_t(\mathbf{x}_t) - v_t$  and  $e_t^* = f^*(\mathbf{x}_t) - v_t$  for  $f^*$  accordingly. We will typically be interested in bounding the *Prediction Error* (PE)  $e_t^2$  of a given algorithm in terms of the best possible PE. To lighten notation in the following sections, all sums over time indices implicitly run from 0 to  $T - 1$  unless explicitly noted otherwise.

### 2.2 NO-REGRET ONLINE LEARNING

Under our online setting, we will define loss functional  $l_t$  at step  $t$  as the traditional Bellman Error (BE):

$$l_t(f) = (f(\mathbf{x}_t) - r_t - \gamma f(\mathbf{x}_{t+1}))^2. \quad (1)$$

Note that  $l_t(f_t) = b_t^2$ .

Following the setting of online prediction of long-term reward, the learner computes predictor  $f_t$  at time step  $t$  and then receives the loss function  $l_t$  and the loss  $l_t(f_t)$  (after the learner receives  $r_t$  and  $\mathbf{x}_{t+1}$ ). We say that the online

algorithm is no-regret with respect to BE if:

$$\lim_{T \rightarrow \infty} \frac{1}{T} \sum l_t(f_t) - \frac{1}{T} \sum l_t(f^*) \leq 0, \quad (2)$$

for any predictor  $f^* \in \mathcal{F}$ , including the best predictor that minimizes  $\sum l_t(f)$  in hindsight.

The sequence of predictors  $f_t$  being no-regret intuitively means that the predictors are giving nearly as consistent predictions over time as is possible in that function class. One might wish that the sequence of predictors being no-regret is a sufficient condition for small prediction error. More formally, one might expect that if Eq. 2 holds for the sequence of predictors  $\{f_t\}$ ,  $\sum e_t^2$  can be upper bounded:

$$\lim_{T \rightarrow \infty} \frac{1}{T} \sum e_t^2 \leq C \frac{1}{T} \sum e_t^{*2}, \quad \forall f^* \in \mathcal{F}, \quad (3)$$

where  $C \in \mathbb{R}^+$  is a constant. Schapire and Warmuth (1996) showed such a conclusion (Eq. 3) for TD and later on Li (2008) proved such a conclusion for RG, both under the assumption that  $f(\mathbf{x})$  is linear.

Unfortunately, however, simply being no-regret (Eq. 2) is **not** a sufficient condition for upper bounding prediction error ( $\sum e_t^2$ ) as in the form of Eq. 3 for general function approximation form:

**Theorem 2.1** *There exists a sequence of  $\{f_t\}$  that is no-regret with respect to the loss functions  $\{l_t(f)\}$ , but no  $C \in \mathbb{R}^+$  exists that makes Eq. 3 hold.*

We prove Theorem 2.1 by providing an example in Appendix (see *Supplementary Material*) which is no-regret on  $\{l_t(f_t)\}$  (Eq. 2 holds) but Eq. 3 does not hold.

### 2.3 ONLINE STABILITY

The counter example that supports Theorem 2.1 presents a sequence of unstable predictors  $\{f_t\}$  where two successive predictors  $f_t$  and  $f_{t+1}$  vary wildly when predicting the long-term reward of  $\mathbf{x}_{t+1}$ . Such behavior is rather unusual for typical no-regret online learning algorithms. This suggests introducing a notion of *Online Stability* which we defined as:

**Definition Online Stability:** For the generated sequence of predictors  $f_t$ , we say the algorithm is online stable if:

$$\lim_{T \rightarrow \infty} \frac{1}{T} \sum (f_t(\mathbf{x}_{t+1}) - f_{t+1}(\mathbf{x}_{t+1}))^2 = 0. \quad (4)$$

Intuitively, the online stability means that on average the difference between successive predictors is eventually small. That is, the difference between  $f_t(\mathbf{x}_{t+1})$  and  $f_{t+1}(\mathbf{x}_{t+1})$  is small on average. Online stability is a general condition and does not severely limit the scope of the online learning algorithms. For instance, when  $f$  is linear,

the definition of stability of online learning in (Saha et al., 2012) (see Eq. 3 in Saha et al. (2012)) and (Ross and Bagnell, 2011) implies our form of online stability. We also show in the following section that many popular no-regret online learning algorithms including OGD, ONS and OWF, satisfy our online stability condition.

We show in next section that the sequence of predictors  $\{f_t\}$  being no-regret with respect to the loss functions  $\{l_t(f_t)\}$  **and satisfying the online stability condition** is sufficient for deriving an upper bound for prediction error as shown in Eq. 3.

## 3 ONLINE LEARNING FOR LONG-TERM REWARD PREDICTION

In this section, we combine the no-regret condition on loss functions  $\{l_t(f)\}$  and the online stability condition together to provide a worst-case analysis of sum of PE  $\sum e_t^2$ , which builds a connection between the PE of long-term rewards, regret and online stability.

More formally, our worst-case analysis shows that if the online algorithm running on the sequence of loss  $\{l_t(f)\}$  is no-regret and the generated sequence of predictors  $\{f_t\}$  satisfies the online stability condition, predictor error can be upper bounded in the form of Eq. 3. The analysis does not place any probabilistic assumption on the sequence of observations  $\{\mathbf{x}_t\}$  or any assumption on the form of predictors  $f \in \mathcal{F}$  (e.g.,  $f(\mathbf{x})$  does not have to be linear).

We start by first providing two important lemmas below:

**Lemma 3.1** *Let us define  $d_t = f_t(\mathbf{x}_t) - r_t - \gamma f_{t+1}(\mathbf{x}_{t+1})$ . We have:*

$$\sum d_t^2 \geq (1 - \gamma)^2 \sum e_t^2 + (\gamma^2 - \gamma)(e_T^2 - e_0^2). \quad (5)$$

Note that the difference between  $d_t$  and  $b_t$  is that  $d_t$  uses  $f_{t+1}(\mathbf{x}_{t+1})$  to estimate the long-term reward at step  $t + 1$  while  $b_t$  uses  $f_t(\mathbf{x}_{t+1})$ .

**Proof** Schapire and Warmuth (1996) implicitly showed that  $d_t = (f_t(\mathbf{x}) - v_t + v_t - (r_t + \gamma f_{t+1}(\mathbf{x}_{t+1}))) = (e_t - \gamma e_{t+1})$ . Squaring both sides and summing over from  $t = 0$  to  $t = T - 1$ , we get:

$$\begin{aligned} \sum d_t^2 &= \sum (e_t - \gamma e_{t+1})^2 \\ &= \sum e_t^2 + \gamma^2 \sum e_{t+1}^2 - 2\gamma \sum e_t e_{t+1} \\ &\geq \sum e_t^2 + \gamma^2 \sum e_{t+1}^2 - \gamma \sum e_t^2 - \gamma \sum e_{t+1}^2 \\ &= (1 - \gamma)^2 \sum e_t^2 + (\gamma^2 - \gamma)(e_T^2 - e_0^2). \end{aligned} \quad (6)$$

The first inequality is obtained by applying Young's inequality to  $2e_t e_{t+1}$  to get  $2e_t e_{t+1} \leq e_t^2 + e_{t+1}^2$ . ■

**Lemma 3.2** For any  $f^* \in \mathcal{F}$ , the prediction error  $\sum e_t^{*2}$  upper bounds the BE  $\sum b_t^{*2}$  as follows:

$$\sum b_t^{*2} \leq (1 + \gamma)^2 \sum e_t^{*2} + (\gamma + \gamma^2)(e_0^{*2} - e_T^{*2}). \quad (7)$$

The proof of Lemma 3.2 is similar to the one for Lemma 3.1. We present the proof in Appendix.

Now let us define a measure of the change in predictors between the steps of the online algorithm as  $\epsilon_t = f_t(\mathbf{x}_{t+1}) - f_{t+1}(\mathbf{x}_{t+1})$ , which is closely related to the online stability condition. The  $b_t$  and  $d_t$  are then closely related with each other by  $\epsilon_t$ :

$$\begin{aligned} d_t &= f_t(\mathbf{x}_t) - r_t - \gamma f_{t+1}(\mathbf{x}_{t+1}) - \gamma f_t(\mathbf{x}_{t+1}) + \gamma f_t(\mathbf{x}_{t+1}) \\ &= b_t + \gamma \epsilon_t. \end{aligned}$$

Squaring both sides, we get:

$$\begin{aligned} d_t^2 &= b_t^2 + 2b_t\gamma\epsilon_t + \gamma^2\epsilon_t^2 \leq b_t^2 + b_t^2 + \gamma^2\epsilon_t^2 + \gamma^2\epsilon_t^2 \\ &= 2b_t^2 + 2\gamma^2\epsilon_t^2, \end{aligned} \quad (8)$$

where the first inequality is coming from applying Young's inequality to  $2b_t\gamma\epsilon_t$  to get  $2b_t\gamma\epsilon_t \leq b_t^2 + \gamma^2\epsilon_t^2$ . We are now ready to state the following main theorem of this paper:

**Theorem 3.3** Assume a sequence of predictors  $\{f_t\}$  is generated by running some online algorithm on the sequence of loss functions  $\{l_t\}$ . For any predictor  $f^* \in \mathcal{F}$ , the sum of prediction errors  $\sum e_t^{*2}$  can be upper bounded as:

$$\begin{aligned} (1 - \gamma)^2 \sum e_t^{*2} &\leq 2 \sum (b_t^2 - b_t^{*2}) + 2\gamma^2 \sum \epsilon_t^2 \\ &\quad + 2(1 + \gamma)^2 \sum e_t^{*2} + M, \end{aligned} \quad (9)$$

where

$$M = 2(\gamma + \gamma^2)(e_0^{*2} - e_T^{*2}) - (\gamma^2 - \gamma)(e_T^2 - e_0^2).$$

By running a no-regret and online stable algorithm on the loss functions  $\{l_t(f)\}$ , as  $T \rightarrow \infty$ , the average prediction error is then asymptotically upper bounded by a constant factor of the best possible prediction error in the function class:

$$\lim_{T \rightarrow \infty} \frac{\sum e_t^{*2}}{T} \leq \frac{2(1 + \gamma)^2 \sum e_t^{*2}}{(1 - \gamma)^2 T}. \quad (10)$$

**Proof** Combining Lemma. 3.1 and Lemma. 3.2, we have:

$$\begin{aligned} &\sum d_t^2 - 2 \sum b_t^{*2} \\ &\geq (1 - \gamma)^2 \sum e_t^{*2} + (\gamma^2 - \gamma)(e_T^2 - e_0^2) \\ &\quad - 2(1 + \gamma)^2 \sum e_t^{*2} \\ &\quad - 2(\gamma + \gamma^2)(e_0^{*2} - e_T^{*2}). \end{aligned} \quad (11)$$

Subtracting  $2b_t^{*2}$  on both sides of Eq. 8, and then summing over from  $t = 1$  to  $T - 1$ , we have:

$$\sum d_t^2 - \sum 2b_t^{*2} \leq 2 \sum (b_t^2 - b_t^{*2}) + 2\gamma^2 \sum \epsilon_t^2.$$

Combining the above two inequalities together, we have:

$$\begin{aligned} &2 \sum (b_t^2 - b_t^{*2}) + 2\gamma^2 \sum \epsilon_t^2 \\ &\geq (1 - \gamma)^2 \sum e_t^{*2} + (\gamma^2 - \gamma)(e_T^2 - e_0^2) \\ &\quad - 2(1 + \gamma)^2 \sum e_t^{*2} - 2(\gamma + \gamma^2)(e_0^{*2} - e_T^{*2}). \end{aligned} \quad (12)$$

Rearrange inequality (12) and define  $M = 2(\gamma + \gamma^2)(e_0^{*2} - e_T^{*2}) - (\gamma^2 - \gamma)(e_T^2 - e_0^2)$ , we obtain inequality (9).

Assume that the  $\bar{f} = \arg \min_{f \in \mathcal{F}} \sum l_t(f)$ , then if the online algorithm is no-regret, we have

$$\begin{aligned} \frac{1}{T} \sum b_t^2 - b_t^{*2} &= \frac{1}{T} \sum l_t(f_t) - l_t(f^*) \\ &\leq \frac{1}{T} \sum l_t(f_t) - l_t(\bar{f}) \\ &= \frac{1}{T} \text{Regret} \leq 0, \quad T \rightarrow \infty. \end{aligned} \quad (13)$$

If the online algorithm satisfies the stability condition (Eq. 4), we have:  $\frac{1}{T} \sum \epsilon_t^2 = 0$  when  $T \rightarrow \infty$ .

Also, since we assume  $|f(\mathbf{x})| \leq P$  and  $|r| \leq R$ , we can see  $M$  must be upper bounded by some constant. Hence, we must have  $\frac{M}{T} = 0$ , as  $T \rightarrow \infty$ .

Under the conditions that the online algorithm is no-regret and satisfies online stability, we get Eq. 10 by dividing both sides of Eq. 9 by  $T$  and taking  $T$  to infinity. ■

Note that in Theorem 3.3, Eq. 9 holds for any  $f^* \in \mathcal{F}$ , including the  $f^*$  that minimizes the prediction error. But note that the one that minimizes prediction error, PE, does not necessarily optimize the BE, which may lead to an improvement of the bound in Eq. 10 in practice. To see this, note that we showed in the proof that for a no-regret algorithm:

$$\frac{1}{T} \sum b_t^2 - b_t^{*2} \leq \frac{1}{T} \text{Regret} \leq 0, \quad \text{as } T \rightarrow \infty. \quad (14)$$

Hence the limit of  $(1/T) \sum (b_t^2 - b_t^{*2})$  may be negative for some  $f^* \in \mathcal{F}$ , which could lead to a potential decrease in the upper bound of  $(1/T) \sum e_t^{*2}$  in Eq. 10 and give us a tighter bound in practice.

When  $e_t^* = 0, \forall t$ , from Theorem 3.3, it is easy to see that no-regret rate of  $(1/T) \sum (b_t^2 - b_t^{*2})$  and the online stability rate of  $(1/T) \sum \epsilon_t^2$  together determine the rate of the convergence of  $(1/T) \sum e_t^{*2}$ .

When  $T \rightarrow \infty$  and  $\gamma \rightarrow 1$  (specifically when  $\gamma \geq (1/\sqrt{2})$ ), our upper bound analysis in Eq. 10 is asymptotically tighter than the upper bound in Li (2008) (Eq. 12)

provided for  $\text{RG}$ , which is a special case of our approach as we demonstrate in the following section. As we will additionally show, a large number of popular no-regret online algorithms also satisfy the online stability condition, broadening the family of algorithms that can be used to learn predictors of long-term rewards.

## 4 ALGORITHMS

Our analysis in Sec. 3 provides a reduction from the online prediction of long-term reward to the no-regret online learning setting on a sequence of loss functions  $\{l_t(f)\}$  defined in Sec. 2.1, which enables us to develop a new set of algorithms. In this section, we give concrete examples of new Bellman Residual algorithms based on well-known no-regret online learning procedures such as Online Gradient Descent (OGD), Online Newton Step (ONS) and the Online variant of Frank Wolfe (OFW). The choice of algorithm depends on the size and sparsity level of features and the available computational budget. For instance, OGD generalizes  $\text{RG}$  and has  $O(n)$  computational complexity at every update step which makes it suitable for applications where sampling observations is cheap (e.g., RL for video games). ONS provides a logarithmic no-regret rate and could lead to faster convergence in practice, making it potentially suitable for applications where obtaining samples of observations is expensive (e.g., RL for a physical robot). Finally, OFW introduces sparsity and can be applied to problems where the feature dimension is larger than the number of samples.

Although the analysis in Sec. 3 does not place any assumption on predictors  $f \in \mathcal{F}$ , in practice to achieve the no-regret property on the loss functions  $\{l_t(f)\}$ , additional assumptions of loss functions (e.g., convexity) are needed. Since we discuss concrete no-regret online algorithms in this section, for  $\mathcal{F}$  we focus on vector spaces equipped with inner product. Specifically, we focus on two vector spaces: (1) *Reproducing Kernel Hilbert Spaces* (RKHS) where  $f = \sum \alpha_i K(\mathbf{x}_i, \cdot) \in \mathcal{F}$ , for some kernel  $K(\mathbf{x}, \cdot)$  and (2) spaces consisting of linear functions  $f(\mathbf{x}) = \mathbf{w}^T \mathbf{x}$ ,  $\mathbf{w} \in \mathcal{W}^1$ . We now summarize the assumptions that we will use in section:

1. We assume  $\mathcal{F}$  (or  $\mathcal{W}$ ) is convex and bounded in a sense that the diameter of  $\mathcal{F}$  (or  $\mathcal{W}$ ) is upper bounded as  $\max_{f_1, f_2 \in \mathcal{F}} \|f_1 - f_2\| \leq D \in \mathbb{R}^+$ , where the norm  $\|f\|$  is defined by the inner product associated with the function space:  $\|f\|^2 = \langle f, f \rangle$ ;
2. We assume that  $\|\mathbf{x}_t\|_2 \leq X$ ,  $\forall t$ ,  $|K(\mathbf{x}_1, \mathbf{x}_2)| \leq K$ ,  $\forall \mathbf{x}_1, \mathbf{x}_2$ ,  $\|f\| \leq F$ ,  $\forall f \in \mathcal{F}$ , and  $\|\mathbf{w}\|_2 \leq W$ ,  $\forall \mathbf{w} \in \mathcal{W}$ , where  $K \in \mathbb{R}^+$ ,  $F \in \mathbb{R}^+$ ,  $W \in \mathbb{R}^+$ .

<sup>1</sup>Linear function space is a special case of RKHS. We discuss linear function separately since some online algorithms discussed here only work for linear functions

Any prediction  $f(\mathbf{x})$  is always bounded, since for RKHS,  $f(\mathbf{x})$  is bounded as  $|f(\mathbf{x})| \leq \|f\| \|K(\mathbf{x}, \cdot)\| \leq F\sqrt{K}$ , and for  $f(\mathbf{x}) = \mathbf{w}^T \mathbf{x}$ , we also have  $|f(\mathbf{x})| \leq \|\mathbf{w}\|_2 \|\mathbf{x}\|_2 \leq WX$ . For notation simplicity, we then simply assume that  $f(\mathbf{x})$  is always bounded as  $|f(\mathbf{x})| \leq P$ ,  $P \in \mathbb{R}^+$ .

**Lemma 4.1** *With the above assumptions, for any pair of  $\mathbf{x}_t$  and  $\mathbf{x}_{t+1}$ , for RKHS, the loss functional  $l_t(f)$  is convex and Lipschitz continuous with respect to the norm defined by the inner product  $\langle \cdot, \cdot \rangle_K$ ; for  $f(\mathbf{x}) = \mathbf{w}^T \mathbf{x}$ , the loss function  $l_t(\mathbf{w})$  is convex and Lipschitz continuous with respect to either  $L_1$  norm  $\|\cdot\|_1$  or  $L_2$  norm  $\|\cdot\|_2$ .*

We present the proof of the above lemma in Appendix.

### 4.1 GRADIENT-BASED APPROACHES

Before diving into the detailed examples of mirror descent and gradient based approaches, we first introduce an important lemma about the stability of one particular online algorithm: *Follow the Regularized Leader* (FTRL). It is well known that gradient-based and mirror descent approaches can be understood in the framework of FTRL. In particular, we only focus on the case where the loss functions are convex and  $L$ -Lipschitz continuous with a regularization that is strongly-convex. We refer reader to Shalev-Shwartz (2011) for detailed definitions of convex functions, Lipschitz continuous, and strong convexity.

The update rule of FTRL at step  $t$  can be summarized as:

$$f_{t+1} = \arg \min_{f \in \mathcal{F}} \sum_{i=0}^t l_i(f) + \frac{1}{\mu} R(f). \quad (15)$$

**Lemma 4.2** *For FTRL with convex and  $L$ -Lipschitz continuous loss functions  $l_t(f)$  and strongly convex regularization function  $R(f)$  (with respect to  $\|f\|$ ), we have:*

$$\sum \|f_t - f_{t+1}\| \leq LT\mu. \quad (16)$$

Setting  $\mu = \frac{1}{\sqrt{T}}$  to achieve no-regret property, then we have:

$$\lim_{T \rightarrow \infty} \frac{1}{T} \sum \|f_t - f_{t+1}\| = 0. \quad (17)$$

Similar proofs has been shown in (Ross and Bagnell, 2011) and (Saha et al., 2012). For completeness, we present the proof of the above lemma in Appendix following our notation and problem setting.

#### 4.1.1 Gradient Descent on BE

Gradient descent approaches can be understood in the FTRL framework where the convex loss functions in FTRL are replaced by a linear approximation:

$$f_{t+1} = \arg \min_{f \in \mathcal{F}} \sum_{i=0}^t \langle g_i, f \rangle + \frac{1}{\mu_t} R(f), \quad (18)$$

where  $g_t \in \partial l_t(f_t)$  is a sub-gradient of  $l_t$  at  $f_t$  and  $R(f)$  is a strongly convex regularizer.

We first consider the special case where  $f(\mathbf{x}) = \mathbf{w}^T \mathbf{x}$  is linear. Note that our loss function is  $l_t(\mathbf{w}) = (\mathbf{w}^T \mathbf{x}_t - r_t - \gamma \mathbf{w}^T \mathbf{x}_{t+1})^2$  and its gradient  $g_t$  at  $\mathbf{w}_t$  is  $g_t = (\mathbf{w}_t^T \mathbf{x}_t - r_t - \gamma \mathbf{w}_t^T \mathbf{x}_{t+1})(\mathbf{x}_t - \gamma \mathbf{x}_{t+1})$ . Setting the regularization  $R(\mathbf{w}) = \frac{1}{2} \|\mathbf{w}\|_2^2$ , which is 1-strongly convex, we obtain the RG algorithm in Baird (1995), where the update step at  $t$  is:

$$\mathbf{w}_{t+1} := \mathbf{w}_t - \mu_t (\mathbf{w}_t^T (\mathbf{x}_t - \gamma \mathbf{x}_{t+1}) - r_t) (\mathbf{x}_t - \gamma \mathbf{x}_{t+1}),$$

Note that the linear loss function is convex and Lipschitz continuous ( $\|g_t\|_2$  is bounded based on our assumptions that  $\|\mathbf{x}\|_2$ ,  $|r|$  and  $\|\mathbf{w}\|_2$  are all bounded). Online Gradient Descent (OGD) is no-regret (Zinkevich, 2003) with  $\mu_t = 1/\sqrt{T}$  and from Lemma 4.2, we have:

$$\begin{aligned} & \frac{1}{T} \sum (\mathbf{w}_t^T \mathbf{x}_{t+1} - \mathbf{w}_{t+1}^T \mathbf{x}_{t+1})^2 \\ & \leq \frac{1}{T} \sum \|\mathbf{x}_{t+1}\|_2^2 \|\mathbf{w}_t - \mathbf{w}_{t+1}\|_2^2 \\ & \leq X^2 \frac{1}{T} \sum \|\mathbf{w}_t - \mathbf{w}_{t+1}\|_2^2 = 0, \quad T \rightarrow \infty, \end{aligned} \quad (19)$$

which exactly satisfies the online stability condition. Hence, RG enjoys the guarantee of our main theorem 3.3.

#### 4.1.2 Exponentiated Gradient Descent on BE

When we set the regularization  $R(\mathbf{w}) = \sum_i \mathbf{w}^i (\log(\mathbf{w}^i) - 1)$ , where for vector  $\mathbf{w}$ ,  $\mathbf{w}^i$  is the  $i$ -th component of  $\mathbf{w}$ , we generalize RG to *Exponentiated Gradient* (EG) descent as Precup and Sutton (1997) did for TD.

Since we assumed that  $\|\mathbf{w}\|_2 \leq W$ , then  $\|\mathbf{w}\|_1 \leq W'$  for  $W' \in \mathbb{R}^+$ . Then the regularization  $R(\mathbf{w})$  becomes  $(1/W')$ -strongly-convex and the loss function  $l_t(\mathbf{w})$  is Lipschitz continuous with respect to  $L_1$  norm  $\|\cdot\|_1$ . Solving Eq.18, we obtain the update step at  $t$  as:

$$\mathbf{w}_{t+1}^i = \mathbf{w}_t^i \exp(-\mu_t (\mathbf{w}_t^T (\mathbf{x}_t - \gamma \mathbf{x}_{t+1}) - r_t) (\mathbf{x}_t^i - \gamma \mathbf{x}_{t+1}^i)).$$

Similar to RG, using Lemma 4.2 (the norm in Lemma 4.2 becomes  $L_1$  norm) we can show that EG satisfies our online stability condition:

$$\begin{aligned} & \frac{1}{T} \sum (\mathbf{w}_t^T \mathbf{x}_{t+1} - \mathbf{w}_{t+1}^T \mathbf{x}_{t+1})^2 \\ & \leq \frac{1}{T} X^2 \sum \|\mathbf{w}_t - \mathbf{w}_{t+1}\|_1^2 \\ & \leq \frac{1}{T} X^2 \sum \|\mathbf{w}_t - \mathbf{w}_{t+1}\|_1^2 = 0, \quad T \rightarrow \infty, \end{aligned} \quad (20)$$

and is also no-regret on  $\{l_t(\mathbf{w})\}$  when  $\mu_t = 1/\sqrt{T}$ . Hence, EG descent approach enjoys our main theorem 3.3.

#### 4.1.3 Gradient Descent in RKHS

Now we consider functions  $f(\mathbf{x})$  that belongs to RKHS  $\mathcal{H}_{\mathcal{K}}$ . For the special case where  $R(f) = \frac{1}{2} \langle f, f \rangle_{\mathcal{K}}$ , we obtain an RG-style update based on functional gradient descent (Scholkopf and Smola, 2001):

$$\begin{aligned} f_{t+1} := & f_t - \mu_t \left( (f_t(\mathbf{x}_t) - r_t - \gamma f_t(\mathbf{x}_{t+1})) \right. \\ & \left. \times (K(\mathbf{x}_t, \cdot) - \gamma K(\mathbf{x}_{t+1}, \cdot)) \right). \end{aligned} \quad (21)$$

Similarly, it is straightforward to show that gradient descent in RKHS satisfies our stability condition and no-regret condition when  $\mu_t = 1/\sqrt{T}$ . Hence, gradient descent in RKHS also enjoys the predictive error guarantees derived in Theorem 3.3.

### 4.2 IMPLICIT ONLINE LEARNING

Recently Tamar et al. (2014) has demonstrated implicit online learning for temporal difference method. We consider the same approach for Bellman Residual minimization by applying implicit online learning from Kulis et al. (2010) to the loss functions  $\{l_t(f)\}$  and thus provide worst-case guarantees. Specifically at iteration  $t$ ,  $f_{t+1}$  is computed implicitly as:

$$\begin{aligned} f_{t+1} = & \arg \min_{f \in \mathcal{F}} \mathcal{D}_R(f, f_t) + \mu_t l_t(f) \\ = & \arg \min_{f \in \mathcal{F}} \mathcal{D}_R(f, f_t) + \mu_t (f(x_t) - \gamma f(x_{t+1}) - r_t)^2, \end{aligned} \quad (22)$$

where  $\mathcal{D}_R$  is a Bregman divergence. Saha et al. (2012) show that when  $\mu_t = 1/\sqrt{t}$ , the generating function  $R(f)$  is positive and strongly-convex, and the loss function  $l_t(f)$  is convex and Lipschitz continuous, implicit online learning is shown to be no-regret and also satisfies Eq. 17.

#### 4.2.1 Implicit Online Gradient Descent

Particularly, we first consider  $f = \sum \alpha_i K(\mathbf{x}_i, \cdot)$  in RKHS. Setting  $R(f) = \frac{1}{2} \langle f, f \rangle_{\mathcal{K}}$ , we have  $\mathcal{D}_R(f, f_t) = \frac{1}{2} \|f - f_t\|_{\mathcal{K}}^2$ . Then solving Eq. 22, we obtain the following update rule:

$$\begin{aligned} f_{t+1} := & f_t - \frac{\mu_t}{1 + \mu_t \|K(\mathbf{x}_t, \cdot) - \gamma K(\mathbf{x}_{t+1}, \cdot)\|_{\mathcal{K}}^2} \\ & \times (f_t(\mathbf{x}_t) - \gamma f_t(\mathbf{x}_{t+1}) - r_t) \\ & \times (K(\mathbf{x}_t, \cdot) - \gamma K(\mathbf{x}_{t+1}, \cdot)). \end{aligned}$$

When considering linear function  $f(x) = \mathbf{w}^T \mathbf{x}$  and  $R(\mathbf{w}) = \frac{1}{2} \|\mathbf{w}\|_2^2$ , we obtain a similar update step:

$$\begin{aligned} \mathbf{w}_{t+1} = & \mathbf{w}_t - \frac{\mu_t}{1 + \mu_t \|\mathbf{x}_t - \gamma \mathbf{x}_{t+1}\|_2^2} \\ & \times (\mathbf{w}_t^T (\mathbf{x}_t - \gamma \mathbf{x}_{t+1}) - r_t) (\mathbf{x}_t - \gamma \mathbf{x}_{t+1}). \end{aligned}$$

As we will show in the experiments, compared to RG (OGD on BE), implicit OGD on BE is less sensitive to the

choice of step-size, which enables us to set large step-size to achieve faster convergence for  $(1/T) \sum e_t^2$ . This phenomenon is also observed by Tamar et al. (2014) when they compare implicit temporal difference to the original TD algorithm (Sutton and Barto, 1998).

### 4.3 ONLINE NEWTON STEP

We also analyze an online second-order method: the Online Newton Step (ONS) (Hazan et al., 2006) for online prediction of long-term reward. For ONS, we only focus on linear function approximation  $f(\mathbf{x}) = \mathbf{w}^T \mathbf{x}$ . We slightly adapt the ONS for our loss function  $l_t(\mathbf{w})$ . We first present the following lemma:

**Lemma 4.3** *For loss function  $l_t(\mathbf{w}) = (\mathbf{w}^T \mathbf{x}_t - r_t - \gamma \mathbf{w}^T \mathbf{x}_{t+1})^2$ , there exists a  $\lambda \in \mathbb{R}^+$ , such that for all  $\mathbf{w}$  and  $\mathbf{w}'$ :*

$$l_t(\mathbf{w}) \geq l_t(\mathbf{w}') + \nabla l_t(\mathbf{w}')^T (\mathbf{w} - \mathbf{w}') + \frac{\lambda}{2} (\mathbf{w} - \mathbf{w}')^T \nabla l_t(\mathbf{w}') \nabla l_t(\mathbf{w}')^T (\mathbf{w} - \mathbf{w}').$$

We present the proof of the above lemma in appendix.

With  $\lambda$ , then the iterative update rule for ONS is:

$$\mathbf{w}_t = \Pi_{\mathcal{W}}^{A_t} \left( \mathbf{w}_{t-1} - \frac{1}{\lambda} A_{t-1}^{-1} \nabla l_{t-1}(\mathbf{w}_{t-1}) \right), \quad (23)$$

where  $A_t = \sum_{i=0}^t \nabla l_t(\mathbf{w}_t) \nabla l_t(\mathbf{w}_t)^T + \epsilon I_n$ ,  $\epsilon \in \mathbb{R}^+$ , and  $\Pi_{\mathcal{W}}^{A_t}$  is a projection to  $\mathcal{W}$  with the norm induced by  $A_t$ :  $\Pi_{\mathcal{W}}^{A_t}(\mathbf{y}) = \arg \min_{\mathbf{w} \in \mathcal{W}} (\mathbf{w} - \mathbf{y})^T A_t (\mathbf{w} - \mathbf{y})$ , which makes this projection operator  $\Pi_{\mathcal{W}}^{A_t}$  not trivial and equal to solving a convex program usually.

Since  $\|\mathbf{x}\|_2 \leq X$ ,  $\|\mathbf{w}\|_2 \leq W$  and  $|r| \leq R$ , we have  $\|\nabla l_t(\mathbf{w})\|_2 \leq G$ , for  $G \in \mathbb{R}^+$ . The following lemma shows that ONS satisfies the our online stability condition:

**Lemma 4.4** *The sequence  $\{\mathbf{w}_t\}$  generated by ONS satisfies the online stability condition:*

$$\begin{aligned} & \frac{1}{T} \sum (\mathbf{w}_t^T \mathbf{x}_{t+1} - \mathbf{w}_{t+1}^T \mathbf{x}_{t+1})^2 \\ & \leq \frac{1}{T} \frac{X^2}{G^2 \lambda^2} n \log(T+1) = 0, \quad T \rightarrow \infty. \end{aligned} \quad (24)$$

The proof borrows ideas from Hazan et al. (2006) and is presented in the Appendix. Note that the convergence rate of  $\frac{1}{T} \sum (f_t(\mathbf{x}_{t+1}) - f_{t+1}(\mathbf{x}_{t+1}))^2$  is  $O(\log T/T)$ , which is the same as the no-regret rate of ONS.

### 4.4 PROJECTION-FREE ONLINE LEARNING

We analyze the Online Frank Wolfe (OFW) (Hazan and Kale, 2012) for online prediction of long-term reward. Previously introduced methods, including OGD, EG, OGD in

RKHS, Implicit OGD, and implicit OGD in RKHS, usually need a projection operation in each update step if the newly updated predictor is out of its pre-defined convex set  $\mathcal{F}$ , although in many cases, projection operations are simple<sup>2</sup>. OFW is a projection-free online method and every step involves solving a (typically very simple) linear programming problem. Again, we restrict our analysis to linear functions  $f = \mathbf{w}^T \mathbf{x}$  for OFW. Without loss of generality, we assume  $l_t(\mathbf{w})$  is  $L$ -Lipschitz continuous with some  $L \in \mathbb{R}^+$  (Lemma 4.1).

Applying the adversarial variant of OFW to the sequence of loss functions  $\{l_t(f)\}$ , we have the following iterative update step:

$$\begin{aligned} \mathbf{v}_t &= \arg \min_{\mathbf{w} \in \mathcal{W}} \nabla F_t(\mathbf{w}_t)^T \mathbf{w}, \\ \mathbf{w}_{t+1} &= (1 - t^{-\alpha}) \mathbf{w}_t + t^{-\alpha} \mathbf{v}_t, \end{aligned} \quad (25)$$

where  $\alpha = \frac{1}{4}$  and  $F_t(\mathbf{w})$  is computed as:

$$\begin{aligned} F_t(\mathbf{w}) &= \frac{1}{t+1} \sum_{i=0}^t \hat{l}_i(\mathbf{w}) \\ &= \frac{1}{t+1} \sum_{i=0}^t (\nabla l_i(\mathbf{w}_i)^T \mathbf{w} + \sigma_i \|\mathbf{w} - \mathbf{w}_0\|_2^2) \\ &= \frac{1}{t+1} \sum_{i=0}^t \left( (\mathbf{w}_i^T \mathbf{x}_i - r_i - \gamma \mathbf{w}_i^T \mathbf{x}_{i+1}) (\mathbf{x}_i - \gamma \mathbf{x}_{i+1})^T \mathbf{w} + \sigma_i \|\mathbf{w} - \mathbf{w}_0\|_2^2 \right), \end{aligned}$$

where  $\sigma_t = (L/D)t^{-1/4}$ ,  $\mathbf{w}_0$  is the initialization.

The online stability of OFW can be shown easily:

$$\begin{aligned} & \frac{1}{T} \sum (\mathbf{w}_t^T \mathbf{x}_{t+1} - \mathbf{w}_{t+1}^T \mathbf{x}_{t+1})^2 \\ & \leq \frac{1}{T} X^2 \sum \|\mathbf{w}_t - \mathbf{w}_{t+1}\|_2^2 \\ & \leq \frac{1}{T} X^2 \sum t^{-2\alpha} \|\mathbf{w}_t - \mathbf{v}_t\|_2^2 \\ & \leq \frac{1}{T} X^2 D^2 \sum t^{-2\alpha} = 0, \quad T \rightarrow \infty. \end{aligned}$$

The first inequality comes from Cauchy-Schwartz inequality and the assumption that  $\|\mathbf{x}\|_2 \leq X$ . The last equality follows from the fact that  $2\alpha > 0$ , and  $\frac{1}{T} \sum_{t=1}^T t^{-\xi} = 0$ , when  $\xi > 0$  and  $T \rightarrow \infty$ .

Note that the output of the OFW  $\mathbf{w}_t$  is sparse when  $\mathcal{W}$  is defined as  $\mathcal{W} = \{\mathbf{w} : \|\mathbf{w}\|_1 \leq W'\}$  for some  $W' \in \mathbb{R}^+$  and  $\mathbf{w}_0$  is initialized to the origin or any corner point of  $\mathcal{W}$ . This is because the output  $\mathbf{v}_t$  of Eq. 25 will be always one of the corner points of  $\mathcal{W}$  and  $\mathbf{w}_t$  hence is a linear combination of corner points  $\{\mathbf{w}_0, \mathbf{v}_0, \dots, \mathbf{v}_{t-1}\}$ , leading to the

<sup>2</sup>Usually, when  $\mathcal{W}$  is defined as  $\{\mathbf{w} : \|\mathbf{w}\|_2 \leq W\}$ , an  $L_2$  projection to such  $\mathcal{W}$  is easy and can be implemented in  $O(n)$ . The same for  $L_2$  projection in RKHS when  $\mathcal{F} = \{f : \|f\| \leq F\}$ .

Figure 3: Convergence of prediction error for Helicopter Hover with linear function approximation

**Helicopter Hover** The helicopter simulator has a continuous 21-dimensional state space and a continuous 4-dimensional control. The reward is equal to the negative of the quadratic deviation to the targeted hover state. To generate sequence of states, we apply an LQR controller using linearized dynamics around the target hover state. We additionally corrupt the dynamics simulation with noise sampled from a Gaussian distribution. We used a degree-two polynomial feature that maps an original 21-dimensional state to a feature vector  $\mathbf{x} \in \mathbb{R}^{253}$  (Fig. 3(a)) and attempt to predict the long-term cost-to-go.

**Analysis of results** We fixed TD(0)’s step-size but a wide range of step-sizes were tried, and the best choice in terms of prediction error was used for TD(0). For RG, implicit OGD, and EG, we set the step-size to  $c/\sqrt{t}$ , where  $c$  is a constant. We also tried a range of  $c$  and chose the one that leads to the best performance. For all algorithms, we provided the same random initialization. All the results are computed by averaging over 100 random trials. As we can see from Fig. 3, ONS and implicit OGD give good convergence speed in general. Implicit OGD performed well with both RKHS and linear function approximation. Throughout the experiments, we found that implicit OGD was able to use a larger  $c$  to speed up convergence while still maintaining good stability. Surprisingly, our experimental results clearly show that our approaches have the possibility to achieve smaller prediction error than TD(0) (e.g., Fig. 2(b), bottom). This runs counter to the fact that the upper bound of prediction error provided by our analysis in Sec. 3 is looser than the upper bound of prediction error of TD(0) from both Li (2008) and Schapire and Warmuth (1996). Though our analysis is more general, further investigation is needed to tighten the worst-case bounds on our approach.

## 6 CONCLUSION

We established a general connection between the worst-case prediction of long term reward and Bellman errors for

stable prediction algorithms. We showed that together with this online stability condition, **any** no-regret online learning algorithm optimizing Bellman errors ensures small prediction errors. The stability condition is weak enough such that most popular no-regret online algorithms satisfy it. Our approach then suggests and provides soundness guarantees for online prediction of long-term reward using a broad new family of algorithms, including Online BE Newton Step, Online BE Frank Wolf, Implicit BE online learning (implicit gradient descent). The analysis itself can be applied to more general function space of hypotheses including Reproducing Kernel Hilbert Space representations and even to discrete hypothesis classes (i.e. trees). However we also want to point out that while our setting is very general, one might expect that in strongly non-Markovian situations there may fail to be a good predictor—e.g., no linear predictor using only the features of  $x_t$  can do a good job. In that sense our theorem in this paper is relative—essentially temporally coherent predictions (in the sense of small Bellman error) imply doing nearly as well as can be done at long term prediction: whether that is actually good performance depends on the quality of both features and hypothesis class, but not on any probabilistic assumptions.

## 7 DISCUSSION

Although our analysis provides broad and sound generalizations of RG, it does not provide guarantees on what we believe are the natural generalization of TD(0) or its variants as online algorithms on a sequence of temporal difference loss functions (TD-loss) which is defined as:

$$\tilde{l}_t(f) = (f(\mathbf{x}_t) - r_t - \gamma f_t(\mathbf{x}_{t+1}))^2. \quad (26)$$

Note that the difference between  $\tilde{l}_t$  and  $l_t$  is the subscript on the second predictor. The reason that we call it TD-loss is that when  $f(\mathbf{x}) = \mathbf{w}^T \mathbf{x}$  is linear, applying OGD to  $\tilde{l}_t(\mathbf{w})$  with respect  $\mathbf{w}$  exactly reveals the update step of TD(0). By properly choosing step-size ( $\mu = O(1/\sqrt{T})$ ), OGD is no-regret on the TD-loss functions  $\{\tilde{l}_t(f)\}$ . Similar to our analysis of Bellman error algorithms, we believe that it is possible that no-regret property on TD-loss functions and stability condition of online algorithms together could lead us to similar predictive guarantees as shown in Theorem 3.3. In fact our empirical results (included in Appendix) suggested that such approaches are both sound and may outperform Bellman Residual methods. We leave it as future work to establish regret bounds for temporal difference minimizing online algorithms.

## 8 ACKNOWLEDGEMENTS

This work is supported by the ONR MURI grant N00014-09-1-1052, Reasoning in Reduced Information Spaces. We gratefully thank Arun Venkatraman for valuable discussions.

## Abstract

Kernel methods give powerful, flexible, and theoretically grounded approaches to solving many problems in machine learning. The standard approach, however, requires pairwise evaluations of a kernel function, which can lead to scalability issues for very large datasets. Rahimi and Recht (2007) suggested a popular approach to handling this problem, known as random Fourier features. The quality of this approximation, however, is not well understood. We improve the uniform error bound of that paper, as well as giving novel understandings of the embedding’s variance, approximation error, and use in some machine learning methods. We also point out that surprisingly, of the two main variants of those features, the more widely used is strictly higher-variance for the Gaussian kernel and has worse bounds.

## 1 INTRODUCTION

Kernel methods provide an elegant, theoretically well-founded, and powerful approach to solving many learning problems. Since traditional algorithms require the computation of a full  $N \times N$  pairwise kernel matrix to solve learning problems on  $N$  input instances, however, scaling these methods to large-scale datasets containing more than thousands of data points has proved challenging. Rahimi and Recht (2007) spurred interest in one very attractive approach: approximating a continuous shift-invariant kernel  $k : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$  by

$$k(x, y) \approx z(x)^\top z(y) =: s(x, y),$$

where  $z : \mathcal{X} \rightarrow \mathbb{R}^D$ . Then primal methods in  $\mathbb{R}^D$  can be used, allowing most learning problems to be solved in  $O(N)$  time (e.g. Joachims 2006). Recent work has also exploited these embeddings in some of the most-scalable kernel methods to date (Dai et al. 2014).

Rahimi and Recht (2007) give two such embeddings, based on the Fourier transform  $P(\omega)$  of the kernel  $k$ : one of the form

$$\tilde{z}(x) := \sqrt{\frac{2}{D}} \begin{bmatrix} \sin(\omega_1^\top x) \\ \cos(\omega_1^\top x) \\ \vdots \\ \sin(\omega_{D/2}^\top x) \\ \cos(\omega_{D/2}^\top x) \end{bmatrix}, \quad \omega_i \stackrel{iid}{\sim} P(\omega) \quad (1)$$

and another of the form

$$\check{z}(x) := \sqrt{\frac{2}{D}} \begin{bmatrix} \cos(\omega_1^\top x + b_1) \\ \vdots \\ \cos(\omega_{D/2}^\top x + b_{D/2}) \end{bmatrix}, \quad \begin{matrix} \omega_i \stackrel{iid}{\sim} P(\omega) \\ b_i \stackrel{iid}{\sim} \text{Unif}_{[0, 2\pi]} \end{matrix} \quad (2)$$

Bochner’s theorem (1959) guarantees that for any continuous positive-definite function  $k(x - y)$ , its Fourier transform will be a nonnegative measure; if  $k(0) = 1$ , it will be properly normalized. Letting  $\tilde{s}$  be the reconstruction based on  $\tilde{z}$  and  $\check{s}$  that for  $\check{z}$ , we have that:

$$\begin{aligned} \tilde{s}(x, y) &= \frac{1}{D/2} \sum_{i=1}^{D/2} \cos(\omega_i^\top (x - y)) \\ \check{s}(x, y) &= \frac{1}{D} \sum_{i=1}^{D/2} \cos(\omega_i^\top (x - y)) + \cos(\omega_i^\top (x + y) + 2b_i). \end{aligned}$$

Letting  $\Delta := x - y$ , we have:

$$\mathbb{E} \cos(\omega^\top \Delta) = \Re \int e^{\omega^\top \Delta \sqrt{-1}} dP(\omega) = \Re k(\Delta) \quad (3)$$

$$\mathbb{E}_\omega \mathbb{E}_b \cos(\omega^\top (x + y) + 2b) = 0. \quad (4)$$

Thus each  $s(x, y)$  is a mean of bounded terms with expectation  $k(x, y)$ . For a given embedding dimension  $D$ , it is not immediately obvious which approximation is preferable:  $\check{z}$  gives twice as many samples for  $\omega$ , but adds additional (non-shift-invariant) noise. The academic literature seems split on the issue: of the first 100 papers citing Rahimi and Recht (2007) in a Google Scholar search, 15 used either  $\check{z}$  or the equivalent complex formulation, 14

used  $\tilde{z}$ , 28 did not specify, and the remainder didn't use the embedding. (None discussed that there was a choice.) Not included in the count are Rahimi and Recht's later work (2008a; 2008b), which used  $\tilde{z}$ ; indeed, post-publication revisions of the original paper only discuss  $\tilde{z}$ . Practically, we are aware of three implementations in machine learning libraries, each of which use  $\tilde{z}$  at the time of writing: scikit-learn (Pedregosa et al. 2011), Shogun (Sonnenburg et al. 2010), and JSAT (Raff 2011-15).

We show that  $\tilde{z}$  is superior for the popular Gaussian kernel, as well as how to decide which to use for other kernels.

The primary previous analyses of these embeddings, outside the one in the original paper, have been by Rahimi and Recht (2008a), who bound the increase in error of empirical risk estimates when learning models in the induced RKHS, and by Yang et al. (2012), who compare the ability of the Nyström and Fourier embeddings to exploit eigengaps in the learning problem. We instead study the approximation directly, providing a complementary view of the quality of these embeddings.

Section 2.1 studies the variance of each embedding, showing that which is preferable depends on the kernel as well as the particular value of  $\Delta$ , but for the popular Gaussian kernel  $\tilde{s}$  is uniformly lower-variance. Section 2.2 studies uniform convergence bounds, tightening constants in the original  $\tilde{z}$  bound and proving a comparable one (with worse constants) for  $\tilde{z}$ , bounding the expectation of the maximal error, and providing exponential concentration about the mean. Section 2.3 studies the  $L_2$  convergence of each approximation;  $\tilde{z}$  is again superior for the Gaussian kernel. Section 3 discusses the effect of this approximation error when used in various machine learning methods. Section 4 evaluates the two embeddings and the bounds empirically.

## 2 APPROXIMATION ERROR

We will give various analyses of the error due to each approximation.

### 2.1 VARIANCE

(3) and (4) establish that  $\mathbb{E}s(\Delta) = k(\Delta)$ . What about the variance? We have that

$$\begin{aligned} & \text{Cov}(\tilde{s}(\Delta), \tilde{s}(\Delta')) \\ &= \text{Cov}\left(\frac{2}{D} \sum_{i=1}^{D/2} \cos(\omega_i^\top \Delta), \frac{2}{D} \sum_{i=1}^{D/2} \cos(\omega_i^\top \Delta')\right) \\ &= \frac{2}{D} \text{Cov}(\cos(\omega^\top \Delta), \cos(\omega^\top \Delta')) \\ &= \frac{2}{D} \left[\frac{1}{2}k(\Delta - \Delta') + \frac{1}{2}k(\Delta + \Delta') - k(\Delta)k(\Delta')\right] \end{aligned}$$

Figure 1: The variance per dimension of  $\tilde{s}$  (blue) and  $\check{s}$  (orange) for the Gaussian RBF kernel (green).

using  $\cos(\alpha)\cos(\beta) = \frac{1}{2}\cos(\alpha + \beta) + \frac{1}{2}\cos(\alpha - \beta)$  and also  $\mathbb{E}\cos(\omega^\top \Delta) = k(\Delta)$ . Thus

$$\text{Var} \tilde{s}(\Delta) = \frac{1}{D} [1 + k(2\Delta) - 2k(\Delta)^2]. \quad (5)$$

Similarly, denoting  $x + y$  by  $t$ ,

$$\begin{aligned} & \text{Cov}(\check{s}(x, y), \check{s}(x', y')) \\ &= \frac{1}{D} \text{Cov}(\cos(\omega^\top \Delta) + \cos(\omega^\top t + 2b), \\ & \quad \cos(\omega^\top \Delta') + \cos(\omega^\top t' + 2b)) \\ &= \frac{1}{D} \left[\frac{1}{2}k(\Delta - \Delta') + \frac{1}{2}k(\Delta + \Delta') - k(\Delta)k(\Delta') \right. \\ & \quad \left. + \frac{1}{2}k(t - t')\right] \end{aligned}$$

which gives

$$\text{Var} \check{s}(x, y) = \frac{1}{D} \left[1 + \frac{1}{2}k(2\Delta) - k(\Delta)^2\right]. \quad (6)$$

Thus  $\tilde{s}$  has lower variance than  $\check{s}$  if

$$\text{Var} \cos(\omega^\top \Delta) = \frac{1}{2} + \frac{1}{2}k(2\Delta) - k(\Delta)^2 \leq \frac{1}{2}. \quad (7)$$

The Gaussian kernel  $k(\Delta) = \exp\left(-\frac{\|\Delta\|^2}{2\sigma^2}\right)$  has

$$\text{Var} \cos(\omega^\top \Delta) = \frac{1}{2} \left(1 - \exp\left(-\frac{\|\Delta\|^2}{\sigma^2}\right)\right)^2 \leq \frac{1}{2},$$

so that  $\tilde{z}$  is always lower-variance than  $\check{z}$ , and the difference in variance is greatest when  $k(\Delta)$  is largest. This is illustrated in Figure 1.

### 2.2 UNIFORM ERROR BOUND

Let  $f(x, y) := s(x, y) - k(x, y)$  denote the error of the approximation. We will investigate  $\|f\|_\infty$ , i.e. the maximal approximation error across the domain of  $k$ . We first consider the bound given by Rahimi and Recht (2007), and then provide a new bound on  $\mathbb{E}\|f\|_\infty$  and its concentration around that mean.

### 2.2.1 Original High-Probability Bound

Claim 1 of Rahimi and Recht (2007) is that if  $\mathcal{X} \subset \mathbb{R}^d$  is compact with diameter  $\ell$ ,<sup>1</sup>

$$\Pr(\|f\|_\infty \geq \varepsilon) \leq 256 \left(\frac{\sigma_p \ell}{\varepsilon}\right)^2 \exp\left(-\frac{D\varepsilon^2}{8(d+2)}\right),$$

where  $\sigma_p^2 = \mathbb{E}[\omega^\top \omega] = \text{tr} \nabla^2 k(0)$  depends on the kernel.

It is not necessarily clear in that paper that this bound applies only to the  $\tilde{z}$  embedding; we can also tighten some constants. We first state the tightened bound for  $\tilde{z}$ .

**Proposition 1.** *Let  $k$  be a continuous shift-invariant positive-definite function  $k(x, y) = k(\Delta)$  defined on  $\mathcal{X} \subset \mathbb{R}^d$ , with  $k(0) = 1$  and such that  $\nabla^2 k(0)$  exists. Suppose  $\mathcal{X}$  is compact, with diameter  $\ell$ . Denote  $k$ 's Fourier transform as  $P(\omega)$ , which will be a probability distribution; let  $\sigma_p^2 = \mathbb{E}_p \|\omega\|^2$ . Let  $\tilde{z}$  be as in (1), and define  $\tilde{f}(x, y) := \tilde{z}(x)^\top \tilde{z}(y) - k(x, y)$ . For any  $\varepsilon > 0$ , let*

$$\alpha_\varepsilon := \min\left(1, \sup_{x, y \in \mathcal{X}} \frac{1}{2} + \frac{1}{2}k(2x, 2y) - k(x, y)^2 + \frac{1}{3}\varepsilon\right),$$

$$\beta_d := \left(\left(\frac{d}{2}\right)^{\frac{-d}{d+2}} + \left(\frac{d}{2}\right)^{\frac{2}{d+2}}\right) 2^{\frac{6d+2}{d+2}}.$$

Then, assuming only for the second statement that  $\varepsilon \leq \sigma_p \ell$ ,

$$\Pr(\|\tilde{f}\|_\infty \geq \varepsilon) \leq \beta_d \left(\frac{\sigma_p \ell}{\varepsilon}\right)^{\frac{2}{1+\frac{2}{d}}} \exp\left(-\frac{D\varepsilon^2}{8(d+2)\alpha_\varepsilon}\right)$$

$$\leq 66 \left(\frac{\sigma_p \ell}{\varepsilon}\right)^2 \exp\left(-\frac{D\varepsilon^2}{8(d+2)}\right).$$

Thus, we can achieve an embedding with pointwise error no more than  $\varepsilon$  with probability at least  $1 - \delta$  as long as

$$D \geq \frac{8(d+2)\alpha_\varepsilon}{\varepsilon^2} \left[\frac{2}{1+\frac{2}{d}} \log \frac{\sigma_p \ell}{\varepsilon} + \log \frac{\beta_d}{\delta}\right].$$

The proof strategy is very similar to that of Rahimi and Recht (2007): place an  $\varepsilon$ -net with radius  $r$  over  $\mathcal{X}_\Delta := \{x - y : x, y \in \mathcal{X}\}$ , bound the error  $\tilde{f}$  by  $\varepsilon/2$  at the centers of the net by Hoeffding's inequality (1963), and bound the Lipschitz constant of  $f$ , which is at most that of  $\tilde{s}$ , by  $\varepsilon/(2r)$  with Markov's inequality. The introduction of  $\alpha_\varepsilon$  is by replacing Hoeffding's inequality with that of Bernstein (1924) when it is tighter, using the variance from (5). The constant  $\beta_d$  is obtained by exactly optimizing the value of  $r$ , rather than the algebraically simpler value originally used;  $\beta_{64} = 66$  is its maximum, and  $\lim_{d \rightarrow \infty} \beta_d = 64$ , though it is lower for small  $d$ , as shown in Figure 2. The additional hypothesis, that  $\nabla^2 k(0)$  exists, is equivalent to the existence of the first two moments of  $P(\omega)$ ; a finite first moment is used in the proof, and of course without a finite second moment the bound is vacuous. The full proof is given in Appendix A.1.

<sup>1</sup>Note that our  $D$  is half of the  $D$  in Rahimi and Recht (2007), since we want to compare embeddings of the same dimension.

Figure 2: The coefficient  $\beta_d$  of Proposition 1 (blue, for  $\tilde{z}$ ) and  $\beta'_d$  of Proposition 2 (orange, for  $\check{z}$ ). Rahimi and Recht (2007) used a constant of 256 for  $\tilde{z}$ .

For the Gaussian kernel,  $\alpha_\varepsilon \leq \frac{1}{2} + \frac{1}{3}\varepsilon$  and  $\sigma_p^2 = d/\sigma^2$ ; the Bernstein bound is tighter when  $\varepsilon < \frac{3}{2}$ .

For  $\check{z}$ , since the embedding  $\check{s}$  is not shift-invariant, we must instead place the  $\varepsilon$ -net on  $\mathcal{X}^2$ . The additional noise in  $\check{s}$  also increases the expected Lipschitz constant and gives looser bounds on each term in the sum, though there are twice as many such terms. The corresponding bound is as follows:

**Proposition 2.** *Let  $k, \mathcal{X}, \ell, P(\omega)$ , and  $\sigma_p$  be as in Proposition 1. Define  $\check{z}$  by (2), and  $\check{f}(x, y) := \check{z}(x)^\top \check{z}(y) - k(x, y)$ . For any  $\varepsilon > 0$ , define*

$$\alpha'_\varepsilon := \min\left(1, \sup_{x, y \in \mathcal{X}} \frac{1}{4} + \frac{1}{8}k(2x, 2y) - \frac{1}{4}k(x, y)^2 + \frac{1}{6}\varepsilon\right),$$

$$\beta'_d := \left(d^{\frac{-d}{d+1}} + d^{\frac{1}{d+1}}\right) 2^{\frac{5d+1}{d+1}} 3^{\frac{d}{d+1}}.$$

Then, assuming only for the second statement that  $\varepsilon \leq \sigma_p \ell$ ,

$$\Pr(\|\check{f}\|_\infty \geq \varepsilon) \leq \beta'_d \left(\frac{\sigma_p \ell}{\varepsilon}\right)^{\frac{2}{1+\frac{1}{d}}} \exp\left(-\frac{D\varepsilon^2}{32(d+1)\alpha'_\varepsilon}\right)$$

$$\leq 98 \left(\frac{\sigma_p \ell}{\varepsilon}\right)^2 \exp\left(-\frac{D\varepsilon^2}{32(d+1)}\right).$$

Thus, we can achieve an embedding with pointwise error no more than  $\varepsilon$  with probability at least  $1 - \delta$  as long as

$$D \geq \frac{32(d+1)\alpha'_\varepsilon}{\varepsilon^2} \left[\frac{2}{1+\frac{1}{d}} \log \frac{\sigma_p \ell}{\varepsilon} + \log \frac{\beta'_d}{\delta}\right].$$

$\beta'_{48} = 98$ , and  $\lim_{d \rightarrow \infty} \beta'_d = 96$ , also shown in Figure 2. The full proof is given in Appendix A.2.

For the Gaussian kernel,  $\alpha'_\varepsilon \leq \frac{1}{4} + \frac{1}{6}\varepsilon$ , so that the Bernstein bound is essentially always superior.

### 2.2.2 Expected Max Error

Noting that  $\mathbb{E}\|f\|_\infty = \int_0^\infty \Pr(\|f\|_\infty \geq \varepsilon) d\varepsilon$ , one could consider bounding  $\mathbb{E}\|f\|_\infty$  via Propositions 1 and 2. Unfortunately, that integral diverges on  $(0, \gamma)$  for any  $\gamma > 0$ .

If we instead integrate the minimum of that bound and 1, the result depends on a solution to a transcendental equation, so analytical manipulation is difficult.

We can, however, use a slight generalization of Dudley’s entropy integral (1967) to obtain the following bound:

**Proposition 3.** *Let  $k$ ,  $\mathcal{X}$ ,  $\ell$ , and  $P(\omega)$  be as in Proposition 1. Define  $\tilde{z}$  by (1), and  $\tilde{f}(x, y) := \tilde{z}(x)^\top \tilde{z}(y) - k(x, y)$ . Let  $\mathcal{X}_\Delta := \{x - y \mid x, y \in \mathcal{X}\}$ ; suppose  $k$  is  $L$ -Lipschitz on  $\mathcal{X}_\Delta$ . Let  $R := \mathbb{E} \max_{i=1, \dots, \frac{D}{2}} \|\omega_i\|$ . Then*

$$\mathbb{E} \left[ \|\tilde{f}\|_\infty \right] \leq \frac{24\gamma\sqrt{d}\ell}{\sqrt{D}}(R + L)$$

where  $\gamma \approx 0.964$ .

The proof is given in Appendix A.3. In order to apply the method of Dudley (1967), we must work around  $\|\omega_i\|$  (which appears in the covariance of the error process) being potentially unbounded. To do so, we bound a process with truncated  $\|\omega_i\|$ , and then relate that bound to  $f$ .

For the Gaussian kernel,  $L = 1/(\sigma\sqrt{e})$  and<sup>2</sup>

$$\begin{aligned} R &\leq \left( \sqrt{2} \frac{\Gamma((d+1)/2)}{\Gamma(d/2)} + \sqrt{2 \log(D/2)} \right) / \sigma \\ &\leq \left( \sqrt{d} + \sqrt{2 \log(D/2)} \right) / \sigma. \end{aligned}$$

Thus  $\mathbb{E}\|\tilde{f}\|_\infty$  is less than

$$\frac{24\gamma\sqrt{d}\ell}{\sqrt{D}\sigma} \left( e^{-1/2} + \sqrt{d} + \sqrt{2 \log(D/2)} \right). \quad (8)$$

We can also prove an analogous bound for the  $\tilde{z}$  features:

**Proposition 4.** *Let  $k$ ,  $\mathcal{X}$ ,  $\ell$ , and  $P(\omega)$  be as in Proposition 1. Define  $\check{z}$  by (2), and  $\check{f}(x, y) := \check{z}(x)^\top \check{z}(y) - k(x, y)$ . Suppose  $k(\Delta)$  is  $L$ -Lipschitz. Let  $R := \mathbb{E} \max_{i=1, \dots, D} \|\omega_i\|$ . Then, for  $\mathcal{X}$  and  $D$  not extremely small,*

$$\mathbb{E} \left[ \|\check{f}\|_\infty \right] \leq \frac{48\gamma'_\mathcal{X}\ell\sqrt{d}}{\sqrt{D}}(R + L)$$

where  $0.803 < \gamma'_\mathcal{X} < 1.542$ . See Appendix A.4 for details on  $\gamma'_\mathcal{X}$  and the “not extremely small” assumption.

The proof is given in Appendix A.4. It is similar to that for Proposition 3, but the lack of shift invariance increases some constants and otherwise slightly complicates matters. Note also that the  $R$  of Proposition 4 is somewhat larger than that of Proposition 3.

<sup>2</sup>By the Gaussian concentration inequality (Boucheron et al. 2013, Theorem 5.6), each  $\|\omega\| - \mathbb{E}\|\omega\|$  is sub-Gaussian with variance factor  $\sigma^{-2}$ ; the claim follows from their Section 2.5.

### 2.2.3 Concentration About Mean

Bousquet’s inequality (2002) can be used to show exponential concentration of  $\sup f$  about its mean.

We consider  $\tilde{f}$  first. Let

$$\tilde{f}_\omega(\Delta) := \frac{2}{D} (\cos(\omega^\top \Delta) - k(\Delta)),$$

so  $f(\Delta) = \sum_{i=1}^{D/2} \tilde{f}_{\omega_i}(\Delta)$ . Define the “wimpy variance” of  $\tilde{f}/2$  (which we use so that  $|\tilde{f}/2| \leq 1$ ) as

$$\begin{aligned} \sigma_{\tilde{f}/2}^2 &:= \sup_{\Delta \in \mathcal{X}_\Delta} \sum_{i=1}^{D/2} \text{Var} \left[ \frac{1}{2} \tilde{f}_{\omega_i}(\Delta) \right] \\ &= \frac{1}{D} \sup_{\Delta \in \mathcal{X}_\Delta} [1 + k(2\Delta) - 2k(\Delta)^2] \\ &=: \frac{1}{D} \sigma_w^2, \end{aligned}$$

using (7). Clearly  $1 \leq \sigma_w^2 \leq 2$ ; for the Gaussian kernel, it is 1.

**Proposition 5.** *Let  $k$ ,  $\mathcal{X}$ , and  $P(\omega)$  be as in Proposition 1, and  $\tilde{z}$  be defined by (1). Let  $\tilde{f}(\Delta) = \tilde{z}(x)^\top \tilde{z}(y) - k(\Delta)$  for  $\Delta = x - y$ , and  $\sigma_w^2 := \sup_{\Delta \in \mathcal{X}_\Delta} 1 + k(2\Delta) - 2k(\Delta)^2$ . Then*

$$\begin{aligned} \Pr \left( \|\tilde{f}\|_\infty - \mathbb{E}\|\tilde{f}\|_\infty \geq \varepsilon \right) \\ \leq 2 \exp \left( - \frac{D\varepsilon^2}{D\mathbb{E}\|\tilde{f}\|_\infty + \frac{1}{2}\sigma_w^2 + \frac{D\varepsilon}{6}} \right). \end{aligned}$$

*Proof.* We use the Bernstein-style form of Theorem 12.5 of Boucheron et al. (2013) on  $\tilde{f}(\Delta)/2$  to obtain that  $\Pr \left( \sup \tilde{f} - \mathbb{E} \sup \tilde{f} \geq \varepsilon \right)$  is at most

$$\exp \left( - \frac{\varepsilon^2}{\mathbb{E} \sup \tilde{f} + \frac{1}{2}\sigma_{\tilde{f}/2}^2 + \frac{\varepsilon}{6}} \right).$$

The same holds for  $-\tilde{f}$ , and  $\mathbb{E} \sup \tilde{f} \leq \mathbb{E} \sup \|f\|_\infty$ ,  $\mathbb{E} \sup(-\tilde{f}) \leq \mathbb{E} \sup \|f\|_\infty$ . The claim follows by a union bound.  $\square$

A bound on the lower tail, unfortunately, is not available in the same form.

For  $\check{f}$ , note  $|\check{f}| \leq 3$ , so we use  $\check{f}/3$ . Letting  $\check{f}_\omega := \frac{1}{D} (\cos(\omega^\top \Delta) - k(\Delta))$ , we have  $\sigma_{\check{f}/3}^2 = \frac{1}{18D} (\sigma_w^2 + 1)$ . Thus the same argument gives us:

**Proposition 6.** *Let  $k$  and  $\mathcal{X}$  be as in Proposition 1, with  $P(\omega)$  defined as there. Let  $\check{z}$  be as in (2),  $\check{f}(x, y) = \check{z}(x)^\top \check{z}(y) - k(x, y)$ , and define  $\sigma_w$  as above. Then*

$$\begin{aligned} \Pr \left( \|\check{f}\|_\infty - \mathbb{E}\|\check{f}\|_\infty \geq \varepsilon \right) \\ \leq 2 \exp \left( - \frac{D\varepsilon^2}{\frac{4}{9}D\mathbb{E}\|\check{f}\|_\infty + \frac{1}{81}(\sigma_w^2 + 1) + \frac{2}{27}D\varepsilon} \right). \end{aligned}$$

Note that Proposition 6 actually gives a somewhat tighter concentration than Proposition 5. This is most likely because, between the space of possible errors being larger and the higher base variance illustrated in Figure 1, the  $\check{f}$  error function has more “opportunities” to achieve its maximal error. The experimental results (Figure 5) show that, at least in one case,  $\|\check{f}\|_\infty$  does concentrate about its mean more tightly, but that mean is enough higher than that of  $\|\tilde{f}\|_\infty$  that  $\|\check{f}\|_\infty$  stochastically dominates  $\|\tilde{f}\|_\infty$ .

### 2.3 $L_2$ ERROR BOUND

$L_\infty$  bounds provide useful guarantees, but are very strict. It can also be useful to consider a less stringent error measure. Let  $\mu$  be a  $\sigma$ -finite measure on  $\mathcal{X} \times \mathcal{X}$ ; define

$$\|f\|_\mu^2 := \int_{\mathcal{X}^2} f(x, y)^2 d\mu(x, y). \quad (9)$$

First, we have that

$$\begin{aligned} \mathbb{E}\|\tilde{f}\|_\mu^2 &= \mathbb{E} \int_{\mathcal{X}^2} \tilde{f}(x, y)^2 d\mu(x, y) \\ &= \int_{\mathcal{X}^2} \mathbb{E} \tilde{f}(x, y)^2 d\mu(x, y) \\ &= \int_{\mathcal{X}^2} \frac{1}{D} [1 + k(2x, 2y) - 2k(x, y)^2] d\mu(x, y) \\ &= \frac{1}{D} \left[ \mu(\mathcal{X}^2) + \int_{\mathcal{X}^2} k(2x, 2y) d\mu(x, y) - 2\|k\|_\mu^2 \right] \\ \mathbb{E}\|\check{f}\|_\mu^2 &= \frac{1}{D} \left[ \mu(\mathcal{X}^2) + \frac{1}{2} \int_{\mathcal{X}^2} k(2x, 2y) d\mu(x, y) - \|k\|_\mu^2 \right] \end{aligned} \quad (10)$$

where (10) is justified by Tonelli’s theorem.

If  $\mu = P_X \times P_Y$  is a joint distribution of independent variables, then  $\int_{\mathcal{X}^2} k(2x, 2y) d\mu(x, y) = \text{MMK}(P_{2X}, P_{2Y})$ , where MMK is the mean map kernel (see Section 3.3). Likewise,  $\|k\|_\mu^2 = \text{MMK}(P_X, P_Y)$  using the kernel  $k^2$ .<sup>3</sup>

Viewing  $\|\tilde{f}\|_\mu$  as a function of  $\omega_1, \dots, \omega_{D/2}$ , changing  $\omega_i$  to a different  $\hat{\omega}_i$  changes the value of  $\|\tilde{f}\|_\mu$  by at most  $4\frac{D+1}{D^2}\mu(\mathcal{X}^2)$ ; this can be seen by simple algebra and is shown in Appendix B.1. Thus McDiarmid (1989) gives us an exponential concentration bound:

**Proposition 7.** *Let  $k$  be a continuous shift-invariant positive-definite function  $k(x, y) = k(\Delta)$  defined on  $\mathcal{X} \subseteq \mathbb{R}^d$ , with  $k(0) = 1$ . Let  $\mu$  be a  $\sigma$ -finite measure on  $\mathcal{X}^2$ , and define  $\|\cdot\|_\mu^2$  as in (9). Define  $\tilde{z}$  as in (1) and let  $\tilde{f}(x, y) = \tilde{z}(x)^\top \tilde{z}(y) - k(x, y)$ . Let  $\mathcal{M} := \mu(\mathcal{X}^2)$ . Then*

$$\begin{aligned} \Pr \left( \left| \|\tilde{f}\|_\mu^2 - \mathbb{E}\|\tilde{f}\|_\mu^2 \right| \geq \varepsilon \right) &\leq 2 \exp \left( \frac{-D^3 \varepsilon^2}{8(4D+1)^2 \mathcal{M}^2} \right) \\ &\leq 2 \exp \left( \frac{-D \varepsilon^2}{200 \mathcal{M}^2} \right). \end{aligned}$$

<sup>3</sup> $k^2$  is also a PSD kernel, by the Schur product theorem.

The second version of the bound is simpler, but somewhat looser for  $D \gg 1$ ; asymptotically, the coefficient of the denominator becomes 128.

Similarly, the variation of  $\|\check{f}\|_\mu$  is bounded by at most  $32\frac{D+1}{D^2}\mu(\mathcal{X}^2)$  (shown in Appendix B.2). Thus:

**Proposition 8.** *Let  $k$ ,  $\mu$ ,  $\|\cdot\|_\mu$ , and  $\mathcal{M}$  be as in Proposition 7. Define  $\check{z}$  as in (2) and let  $\check{f}(x, y) = \check{z}(x)^\top \check{z}(y) - k(x, y)$ . Then*

$$\begin{aligned} \Pr \left( \left| \|\check{f}\|_\mu^2 - \mathbb{E}\|\check{f}\|_\mu^2 \right| \geq \varepsilon \right) &\leq 2 \exp \left( \frac{-D^3 \varepsilon^2}{512(D+1)^2 \mathcal{M}^2} \right) \\ &\leq 2 \exp \left( \frac{-D \varepsilon^2}{2048 \mathcal{M}^2} \right). \end{aligned}$$

The cost of a simpler dependence on  $D$  is higher here; the asymptotic coefficient of the denominator is 512.

## 3 DOWNSTREAM ERROR

Rahimi and Recht (2008a; 2008b) give a bound on the  $L_2$  distance between any given function in the reproducing kernel Hilbert space (RKHS) induced by  $k$  and the closest function in the RKHS of  $s$ : results invaluable for the study of learning rates. In some situations, however, it is useful to consider not the learning-theoretic convergence of hypotheses to the assumed “true” function, but rather directly consider the difference in predictions due to using the  $z$  embedding instead of the exact kernel  $k$ .

### 3.1 KERNEL RIDGE REGRESSION

We first consider kernel ridge regression (KRR; Saunders et al. 1998). Suppose we are given  $n$  training pairs  $(x_i, y_i) \in \mathbb{R}^d \times \mathbb{R}$  as well as a regularization parameter  $\lambda = n\lambda_0 > 0$ . We construct the training Gram matrix  $K$  by  $K_{ij} = k(x_i, x_j)$ . KRR gives predictions  $h(x) = \alpha^\top k_x$ , where  $\alpha = (K + \lambda I)^{-1} y$  and  $k_x$  is the vector with  $i$ th component  $k(x_i, x)$ .<sup>4</sup> When using Fourier features, one would not use  $\alpha$ , but instead a primal weight vector  $w$ ; still, it will be useful for us to analyze the situation in the dual.

Proposition 1 of Cortes et al. (2010) bounds the change in KRR predictions from approximating the kernel matrix  $K$  by  $\hat{K}$ , in terms of  $\|\hat{K} - K\|_2$ . They assume, however, that the kernel evaluations at test time  $k_x$  are unapproximated, which is certainly not the case when using Fourier features. We therefore extend their result to Proposition 9 before using it to analyze the performance of Fourier features.

<sup>4</sup>If a bias term is desired, we can use  $k'(x, x') = k(x, x') + 1$  by appending a constant feature 1 to the embedding  $z$ . Because this change is accounted for exactly, it affects the error analysis here only in that we must use  $\sup |k(x, y)| \leq 2$ , in which case the first factor of (11) becomes  $(\lambda_0 + 2)/\lambda_0^2$ .

**Proposition 9.** Given a training set  $\{(x_i, y_i)\}_{i=1}^n$ , with  $x_i \in \mathbb{R}^d$  and  $y_i \in \mathbb{R}$ , let  $h(x)$  denote the result of kernel ridge regression using the PSD training kernel matrix  $K$  and test kernel values  $k_x$ . Let  $\hat{h}(x)$  be the same using a PSD approximation to the training kernel matrix  $\hat{K}$  and test kernel values  $\hat{k}_x$ . Further assume that the training labels are centered,  $\sum_{i=1}^n y_i = 0$ , and let  $\sigma_y^2 := \frac{1}{n} \sum_{i=1}^n y_i^2$ . Also suppose  $\|k_x\|_\infty \leq \kappa$ . Then:

$$|h'(x) - h(x)| \leq \frac{\sigma_y}{\sqrt{n}\lambda_0} \|\hat{k}_x - k_x\| + \frac{\kappa\sigma_y}{n\lambda_0^2} \|\hat{K} - K\|_2.$$

*Proof.* Let  $\alpha = (K + \lambda I)^{-1}y$ ,  $\hat{\alpha} = (\hat{K} + \lambda I)^{-1}y$ . Thus, using  $\hat{M}^{-1} - M^{-1} = -\hat{M}^{-1}(\hat{M} - M)M^{-1}$ , we have

$$\begin{aligned} \hat{\alpha} - \alpha &= -(\hat{K} + \lambda I)^{-1}(\hat{K} - K)(K + \lambda I)^{-1}y \\ \|\hat{\alpha} - \alpha\| &\leq \|(\hat{K} + \lambda I)^{-1}\|_2 \|\hat{K} - K\|_2 \|(K + \lambda I)^{-1}\|_2 \|y\| \\ &\leq \frac{1}{\lambda^2} \|\hat{K} - K\|_2 \|y\| \end{aligned}$$

since the smallest eigenvalues of  $K + \lambda I$  and  $\hat{K} + \lambda I$  are at least  $\lambda$ . Since  $\|k_x\| \leq \sqrt{n}\kappa$  and  $\|\hat{\alpha}\| \leq \|y\|/\lambda$ :

$$\begin{aligned} |\hat{h}(x) - h(x)| &= |\hat{\alpha}^\top \hat{k}_x - \alpha^\top k_x| \\ &= |\hat{\alpha}^\top (\hat{k}_x - k_x) + (\hat{\alpha} - \alpha)^\top k_x| \\ &\leq \|\hat{\alpha}\| \|\hat{k}_x - k_x\| + \|\hat{\alpha} - \alpha\| \|k_x\| \\ &\leq \frac{\|y\|}{\lambda} \|\hat{k}_x - k_x\| + \frac{\sqrt{n}\kappa\|y\|}{\lambda^2} \|\hat{K} - K\|_2. \end{aligned}$$

The claim follows from  $\lambda = n\lambda_0$ ,  $\|y\| = \sqrt{n}\sigma_y$ .  $\square$

Suppose that, per the uniform error bounds of Section 2.2,  $\sup |k(x, y) - s(x, y)| \leq \varepsilon$ . Then  $\|\hat{k}_x - k_x\| \leq \sqrt{n}\varepsilon$  and  $\|\hat{K} - K\|_2 \leq \|\hat{K} - K\|_F \leq n\varepsilon$ , and Proposition 9 gives

$$\begin{aligned} |\hat{h}(x) - h(x)| &\leq \frac{\sigma_y}{\sqrt{n}\lambda_0} \sqrt{n}\varepsilon + \frac{\sigma_y}{n\lambda_0^2} n\varepsilon \\ &\leq \frac{\lambda_0 + 1}{\lambda_0^2} \sigma_y \varepsilon. \end{aligned} \quad (11)$$

Thus

$$\Pr(|h'(x) - h(x)| \geq \varepsilon) \leq \Pr\left(\|f\|_\infty \geq \frac{\lambda_0^2 \varepsilon}{(\lambda_0 + 1)\sigma_y}\right).$$

which we can bound with Proposition 1 or 2. We can therefore guarantee  $|h(x) - h'(x)| \leq \varepsilon$  with probability at least  $\delta$  if

$$D = \Omega\left(d \left(\frac{(\lambda_0 + 1)\sigma_y}{\lambda_0^2 \varepsilon}\right)^2 \left[\log \delta + \log \frac{\lambda_0^2 \varepsilon}{(\lambda_0 + 1)\sigma_y} - \log \sigma_p \ell\right]\right).$$

Note that this rate does not depend on  $n$ . If we want  $h'(x) \rightarrow h(x)$  at least as fast as  $h(x)$ 's convergence rate of  $O(1/\sqrt{n})$  (Bousquet and Elisseeff 2001), ignoring the logarithmic terms, we thus need  $D$  to be linear in  $n$ , matching the conclusion of Rahimi and Recht (2008a).

## 3.2 SUPPORT VECTOR MACHINES

Consider a Support Vector Machine (SVM) classifier with no offset, such that  $h(x) = w^\top \Phi(x)$  for a kernel embedding  $\Phi(x) : \mathcal{X} \rightarrow \mathcal{H}$  and  $w$  is found by

$$\operatorname{argmin}_{w \in \mathcal{H}} \frac{1}{2} \|w\|^2 + \frac{C_0}{n} \sum_{i=1}^n \max(0, 1 - y_i \langle w, \Phi(x_i) \rangle)$$

where  $\{(x_i, y_i)\}_{i=1}^n$  is our training set with  $y_i \in \{-1, 1\}$ , and the decision function is  $h(x) = \langle w, \Phi(x) \rangle$ .<sup>5</sup> For a given  $x$ , Cortes et al. (2010) consider an embedding in  $\mathcal{H} = \mathbb{R}^{n+1}$  which is equivalent on the given set of points. They bound  $|\hat{h}(x) - h(x)|$  in terms of  $\|\hat{K} - K\|_2$  in their Proposition 2, but again assume that the test-time kernel values  $k_x$  are exact. We will again extend their result in Proposition 10:

**Proposition 10.** Given a training set  $\{(x_i, y_i)\}_{i=1}^n$ , with  $x_i \in \mathbb{R}^d$  and  $y_i \in \{-1, 1\}$ , let  $h(x)$  denote the decision function of an SVM classifier using the PSD training matrix  $K$  and test kernel values  $k_x$ . Let  $\hat{h}(x)$  be the same using a PSD approximation to the training kernel matrix  $\hat{K}$  and test kernel values  $\hat{k}_x$ . Suppose  $\sup k(x, x) \leq \kappa$ . Then:

$$\begin{aligned} |\hat{h}(x) - h(x)| &\leq \sqrt{2}\kappa^{\frac{3}{4}} C_0 \left(\|\hat{K} - K\|_2 + \|\hat{k}_x - k_x\| + |f_x|\right)^{1/4} \\ &\quad + \sqrt{\kappa} C_0 \left(\|\hat{K} - K\|_2 + \|\hat{k}_x - k_x\| + |f_x|\right)^{1/2}, \end{aligned}$$

where  $f_x = \hat{k}(x, x) - k(x, x)$ .

*Proof.* Use the setup of Section 2.2 of Cortes et al. (2010). In particular, we will use  $\|w\| \leq \sqrt{\kappa} C_0$  and their (16-17):

$$\begin{aligned} \Phi(x_i) &= K_x^{1/2} e_i \\ \|\hat{w} - w\|^2 &\leq 2C_0^2 \sqrt{\kappa} \|\hat{K}_x^{1/2} - K_x^{1/2}\|, \end{aligned}$$

where  $K_x = \begin{bmatrix} K & k_x \\ k_x^\top & k(x, x) \end{bmatrix}$  and  $e_i$  the  $i$ th standard basis.

Further, Lemma 1 of Cortes et al. (2010) says that  $\|\hat{K}_x^{1/2} - K_x^{1/2}\|_2 \leq \|\hat{K}_x - K_x\|_2^{1/2}$ . Let  $f_x := \hat{k}(x, x) - k(x, x)$ ; Then, by Weyl's inequality for singular values,

$$\left\| \begin{bmatrix} \hat{K} - K & \hat{k}_x - k_x \\ \hat{k}_x^\top - k_x^\top & f_x \end{bmatrix} \right\|_2 \leq \|\hat{K} - K\|_2 + \|\hat{k}_x - k_x\| + |f_x|.$$

<sup>5</sup>We again assume there is no bias term for simplicity; adding a constant feature again changes the analysis only in that it makes the  $\kappa$  of Proposition 10 2 instead of 1.

Thus

$$\begin{aligned}
& |\hat{h}(x) - h(x)| \\
&= \left| (\hat{w} - w)^\top \hat{\Phi}(x) + w^\top (\hat{\Phi}(x) - \Phi(x)) \right| \\
&\leq \|\hat{w} - w\| \|\hat{\Phi}(x)\| + \|w\| \|\hat{\Phi}(x) - \Phi(x)\| \\
&\leq \sqrt{2}\kappa^{\frac{1}{4}} C_0 \|\hat{K}_x^{1/2} - K_x^{1/2}\|_2^{1/2} \sqrt{\kappa} \\
&\quad + \sqrt{\kappa} C_0 \|(\hat{K}_x^{1/2} - K_x^{1/2})e_{n+1}\| \\
&\leq \sqrt{2}\kappa^{\frac{3}{4}} C_0 \|\hat{K}_x - K_x\|_2^{1/4} \\
&\quad + \sqrt{\kappa} C_0 \|\hat{K}_x - K_x\|_2^{1/2} \\
&\leq \sqrt{2}\kappa^{\frac{3}{4}} C_0 \left( \|\hat{K} - K\|_2 + \|\hat{k}_x - k_x\| + |f_x| \right)^{1/4} \\
&\quad + \sqrt{\kappa} C_0 \left( \|\hat{K} - K\|_2 + \|\hat{k}_x - k_x\| + |f_x| \right)^{1/2}
\end{aligned}$$

as claimed.  $\square$

Suppose that  $\sup|k(x, y) - s(x, y)| \leq \varepsilon$ . Then, as in the last section,  $\|\hat{k}_x - k_x\| \leq \sqrt{n}\varepsilon$  and  $\|\hat{K} - K\|_2 \leq n\varepsilon$ . Then, letting  $\gamma$  be 0 for  $\tilde{z}$  and 1 for  $\check{z}$ , Proposition 10 gives

$$\begin{aligned}
|\hat{h}(x) - h(x)| &\leq \sqrt{2}C_0 (n + \sqrt{n} + \gamma)^{1/4} \varepsilon^{1/4} \\
&\quad + C_0 (n + \sqrt{n} + \gamma)^{1/2} \varepsilon^{1/2}.
\end{aligned}$$

Then  $|\hat{h}(x) - h(x)| \geq u$  only if

$$\varepsilon \leq \frac{2C_0^2 + 4C_0u + u^2 - 2(C_0 + u)\sqrt{C_0(C_0 + 2u)}}{C_0^2(n + \sqrt{n} + \gamma)}.$$

This bound has the unfortunate property of requiring the approximation to be *more* accurate as the training set size increases, and thus can prove only a very loose upper bound on the number of features needed to achieve a given approximation accuracy, due to the looseness of Proposition 10. Analyses of generalization error in the induced RKHS, such as Rahimi and Recht (2008a) and Yang et al. (2012), are more useful in this case.

### 3.3 MAXIMUM MEAN DISCREPANCY

Another area of application for random Fourier embeddings is to the mean embedding of distributions, which uses some kernel  $k$  to represent a probability distribution  $P$  in the RKHS induced by  $k$  as  $\varphi(P) = \mathbb{E}_{x \sim P} [k(x, \cdot)]$ . For samples  $\{X_i\}_{i=1}^n \sim P$  and  $\{Y_j\}_{j=1}^m \sim Q$ , we can estimate the inner product in the embedding space, the *mean map kernel* (MMK), by

$$\text{MMK}(X, Y) := \frac{1}{nm} \sum_{i=1}^n \sum_{j=1}^m k(X_i, Y_j) \approx \langle \varphi(P), \varphi(Q) \rangle.$$

The distance  $\|\varphi(P) - \varphi(Q)\|$  is known as the *maximum mean discrepancy* (MMD), which can be estimated with:

$$\begin{aligned}
& \|\varphi(P) - \varphi(Q)\|^2 \\
&= \langle \varphi(P), \varphi(P) \rangle + \langle \varphi(Q), \varphi(Q) \rangle - 2 \langle \varphi(P), \varphi(Q) \rangle.
\end{aligned}$$

MMK( $X, X$ ) is a biased estimator, because of the  $k(X_i, X_i)$  and  $k(Y_i, Y_i)$  terms; removing them gives an unbiased estimator (Gretton et al. 2012). The MMK can be used in standard kernel methods to perform learning on probability distributions, such as when images are treated as sets of local patch descriptors (Muandet et al. 2012) or documents as sets of word descriptors (Yoshikawa et al. 2014). The MMD has strong applications to two-sample testing, where it serves as the statistic for testing the hypothesis that  $X$  and  $Y$  are sampled from the same distribution (Gretton et al. 2012); this has applications in, for example, comparing microarray data from different experimental situations or in matching attributes when merging databases.

The MMK estimate can clearly be approximated with an explicit embedding: if  $k(x, y) \approx z(x)^\top z(y)$ ,

$$\begin{aligned}
\text{MMK}_z(X, Y) &= \frac{1}{nm} \sum_{i=1}^n \sum_{j=1}^m z(X_i)^\top z(Y_j) \\
&= \left( \frac{1}{n} \sum_{i=1}^n z(X_i) \right)^\top \left( \frac{1}{m} \sum_{j=1}^m z(Y_j) \right) \\
&= \bar{z}(X)^\top \bar{z}(Y).
\end{aligned}$$

Thus the biased estimator of MMK( $X, X$ ) is just  $\|\bar{z}(X)\|^2$ ; the unbiased estimator is

$$\frac{n^2}{n^2 - n} \left( \|\bar{z}(X)\|^2 - \frac{1}{n^2} \sum_{i=1}^n \|z(X_i)\|^2 \right)$$

When  $z(x)^\top z(x) = 1$ , as with  $\tilde{z}$ , this simplifies to  $\frac{n}{n-1} \|\bar{z}(X)\|^2 - \frac{1}{n-1}$ . When that is not necessarily true, as with  $\check{z}$ , that simplification holds only in expectation.

This has been noticed a few times in the literature, e.g. by Li and Tsang (2011). Gretton et al. (2012) gives different linear-time test statistics based on subsampling the sum over pairs; this version avoids reducing the amount of data used in favor of approximating the kernel. Additionally, when using the MMK in a kernel method this approximation allows the use of linear solvers, whereas the other linear approximations must still perform some pairwise computation. Zhao and Meng (2014) compare the empirical performance of an approximation equivalent to  $\check{z}$  against other linear-time approximations for two-sample testing. They find it is slower than the MMD-linear approximation but far more accurate, while being more accurate and comparable in speed to a block-based  $B$ -test (Zaremba et al. 2013).

Zhao and Meng (2014) also state a simple uniform error bound on the quality of this approximation. Specifically, since we can write  $|\text{MMK}_z(X, Y) - \text{MMK}(X, Y)|$  as the mean of  $|f(X_i, Y_j)|$ , uniform error bounds on  $f$  apply directly to  $\text{MMK}_z$ , including to the unbiased version of  $\text{MMK}_z(X, X)$ . Moreover, since  $\text{MMD}^2(X, Y) = \text{MMK}(X, X) + \text{MMK}(Y, Y) - 2\text{MMK}(X, Y)$ , its error is at most 4 times  $\|f\|_\infty$ . The advantage of this bound is that it applies uniformly to all sample sets on the input space  $\mathcal{X}$ , which is useful when we use  $\text{MMK}$  for a kernel method.

For a single two-sample test, however, we can get a tighter bound. Consider  $X$  and  $Y$  fixed for now. Note that  $\mathbb{E}\text{MMK}_z(X, Y) = \text{MMK}(X, Y)$ , by linearity of expectation. The variance of  $\text{MMK}_z(X, Y)$  is exactly

$$\frac{1}{n^2 m^2} \sum_{i,j} \sum_{i',j'} \text{Cov}(s(X_i, Y_j), s(X_{i'}, Y_{j'})), \quad (12)$$

which can be evaluated using the formulas of Section 2.1 and so, viewed only as a function of  $D$ , is  $O(1/D)$ . Alternatively, we can use a bounded difference approach: viewing  $\text{MMK}_z(X, Y)$  as a function of the  $\omega_i$ s, changing  $\omega_i$  to  $\hat{\omega}_i$  changes the  $\text{MMK}$  estimate by

$$\left| \frac{1}{nm} \sum_{i=1}^n \sum_{j=1}^m \frac{2}{D} (\cos(\hat{\omega}_i^\top (X_i - Y_j)) - \cos(\omega_i^\top (X_i - Y_j))) \right|,$$

which is at most  $4/D$ . The bound for  $\check{z}$  is in fact the same here. Thus McDiarmid’s inequality tells us that for fixed sets  $X$  and  $Y$  and either  $z$ ,

$$\Pr(|\text{MMK}_z(X, Y) - \text{MMK}(X, Y)| \leq 2 \exp(-\frac{1}{8} D \varepsilon^2)).$$

Thus  $\mathbb{E}|\text{MMK}_z(X, Y) - \text{MMK}(X, Y)| \leq 2\sqrt{2\pi/D}$ . Similarly,  $\text{MMD}_z$  can be changed by at most  $16/D$ , giving

$$\Pr(|\text{MMD}_z(X, Y) - \text{MMD}(X, Y)| \leq 2 \exp(-\frac{1}{128} D \varepsilon^2))$$

and expected absolute error of at most  $8\sqrt{2\pi/D}$ .

Now, if we consider the distributions  $P$  and  $Q$  to be fixed but the sample sets random, Theorems 7 and 10 of Gretton et al. (2012) give exponential convergence bounds for the biased and unbiased population estimators of  $\text{MMD}$ , which can easily be combined with the above bounds. Note that this approach allows the domain  $\mathcal{X}$  to be unbounded, unlike the other bound. One could extend this to a bound uniform over some smoothness class of distributions using the techniques of Section 2.2, though we do not do so here.

## 4 NUMERICAL EVALUATION

### 4.1 APPROXIMATION ON AN INTERVAL

We first conduct a detailed study of the approximations on the interval  $\mathcal{X} = [-b, b]$ . Specifically, we

evenly spaced 1000 points on  $[-5, 5]$  and approximated the kernel matrix using both embeddings at  $D \in \{50, 100, 200, \dots, 900, 1\,000, 2\,000, \dots, 9\,000, 10\,000\}$ , repeating each trial 1000 times, estimating  $\|f\|_\infty$  and  $\|f\|_\mu$  at those points. We do not consider  $d > 1$  here, because obtaining a reliable estimate of  $\sup|f|$  becomes very computationally expensive even for  $d = 2$ .

Figure 3 shows the behavior of  $\mathbb{E}\|f\|_\infty$  as  $b$  increases for various values of  $D$ . As expected, the  $\check{z}$  embeddings have almost no error near 0. The error increases out to one or two bandwidths, after which the curve appears approximately linear in  $\ell/\sigma$ , as predicted by Proposition 3.

Figure 3: The maximum error within a given radius in  $\mathbb{R}$ , averaged over 1000 evaluations. Solid lines represent  $\check{z}$  and dashed lines  $\check{z}$ ; black is  $D = 50$ , blue is  $D = 100$ , red  $D = 500$ , and cyan  $D = 1000$ .

Figure 4 fixes  $b = 3$  and shows the expected maximal error as a function of  $D$ . It also plots the expected error obtained by numerically integrating the bounds of Propositions 1 and 2 (using the minimum of 1 and the bound). We can see that all of the bounds are fairly loose, but that the first version of the bound in the propositions (with  $\beta_d$ , the exponent depending on  $d$ , and  $\alpha_\varepsilon$ ) is substantially tighter than the second version when  $d = 1$ .

The bounds on  $\mathbb{E}\|f\|_\infty$  of Propositions 3 and 4 are unfortunately too loose to show on the same plot. However, one important property does hold. For a fixed  $\mathcal{X}$ , (8) predicts that  $\mathbb{E}\|f\|_\infty = O(1/\sqrt{D})$ . This holds empirically: performing linear regression of  $\log \mathbb{E}\|\tilde{f}\|_\infty$  against  $\log D$  yields a model of  $\mathbb{E}\|\tilde{f}\|_\infty = e^c D^m$ , with a 95% confidence interval for  $m$  of  $[-0.502, -0.496]$ ;  $\|\check{f}\|_\infty$  gives  $[-0.503, -0.497]$ . The integrated bounds of Propositions 1 and 2 do not fit the scaling as a function of  $D$  nearly as well.

Figure 5 shows the empirical survival function of the max error for  $D = 500$ , along with the bounds of Propositions 1 and 2 and those of Propositions 5 and 6 using the empirical mean. The latter bounds are tighter than the former for low  $\varepsilon$ , especially for low  $D$ , but have a lower slope.

Figure 4:  $\mathbb{E}\|f\|_\infty$  for the Gaussian kernel on  $[-3, 3]$  with  $\sigma = 1$ , based on the mean of 1000 evaluations and on numerical integration of the bounds from Propositions 1 and 2. (“Tight” refers to the bound with constants depending on  $d$ , and “loose” the second version; “old” is the version from Rahimi and Recht (2007).)

The mean of the mean squared error, on the other hand, exactly follows the expectation of Section 2.3 using  $\mu$  as the uniform distribution on  $\mathcal{X}^2$ : in this case,  $\mathbb{E}\|f\|_\mu \approx 0.66/D$ ,  $\mathbb{E}\|f\|_\mu \approx 0.83/D$ . (This is natural, as the expectation is exact.) Convergence to that mean, however, is substantially faster than guaranteed by the McDiarmid bound of Propositions 7 and 8. We omit the plot due to space constraints.

## 4.2 MAXIMUM MEAN DISCREPANCY

We now turn to the problem of computing the MMD with a Fourier embedding. Specifically, we consider the problem of distinguishing the standard normal distribution  $\mathcal{N}(0, I_p)$  from the two-dimensional mixture  $0.95\mathcal{N}(0, I_2) + 0.05\mathcal{N}(0, \frac{1}{4}I_2)$ . We take fixed sample sets  $X$  and  $Y$  each of size 1000 and compute the biased MMD estimate with varying  $D$  for both  $\tilde{z}$  and  $\check{z}$ , we used a Gaussian kernel of bandwidth 1. The mean absolute errors of the resulting estimates are shown in Figure 6.  $\tilde{z}$  performs mildly better than  $\check{z}$ .

Again, the McDiarmid bound of Section 3.3 predicts that the mean absolute error decays as  $O(1/\sqrt{D})$ , but with too high a multiplicative constant; the 95% confidence interval for the exponent of  $D$  is  $[-0.515, -0.468]$  for  $\tilde{z}$  and  $[-0.520, -0.486]$  for  $\check{z}$ . We also know that the expected root mean squared error decays like  $O(1/\sqrt{D})$  via (12).

## 5 DISCUSSION

We provide a novel investigation of the approximation error of the popular random Fourier features, tightening ex-

Figure 5:  $\Pr(\mathbb{E}\|f\|_\infty > \varepsilon)$  for the Gaussian kernel on  $[-3, 3]$  with  $\sigma = 1$  and  $D = 500$ , based on 1000 evaluations (black), numerical integration of the bounds from Propositions 1 and 2 (same colors as Figure 4), and the bounds of Propositions 5 and 6 using the empirical mean (yellow).

Figure 6: Mean absolute error of the biased estimator for  $\text{MMD}(X, Y)$ , based on 100 evaluations.

isting bounds and showing new ones, including an analytic bound on  $\mathbb{E}\|f\|_\infty$  and exponential concentration about its mean, as well as an exact form for  $\mathbb{E}\|f\|_\mu$  and exponential concentration in that case as well. We also extend previous results on the change in learned models due to kernel approximation. We verify some aspects of these bounds empirically for the Gaussian kernel. We also point out that, of the two embeddings provided by Rahimi and Recht (2007), the  $\tilde{z}$  embedding (with half as many sampled frequencies, but no additional noise due to phase shifts) is superior in the most common case of the Gaussian kernel.

## Abstract

While much work has explored probabilistic graphical models for independent data, less attention has been paid to time series. The goal in this setting is to determine conditional independence relations between entire time series, which for stationary series, are encoded by zeros in the inverse spectral density matrix. We take a Bayesian approach to structure learning, placing priors on (i) the graph structure and (ii) spectral matrices given the graph. We leverage a Whittle likelihood approximation and define a conjugate prior—the *hyper complex inverse Wishart*—on the complex-valued and graph-constrained spectral matrices. Due to conjugacy, we can analytically marginalize the spectral matrices and obtain a closed-form marginal likelihood of the time series given a graph. Importantly, our analytic marginal likelihood allows us to avoid inference of the complex spectral matrices themselves and places us back into the framework of standard (Bayesian) structure learning. In particular, combining this marginal likelihood with our graph prior leads to efficient inference of the time series graph itself, which we base on a stochastic search procedure, though any standard approach can be straightforwardly modified to our time series case. We demonstrate our methods on analyzing stock data and neuroimaging data of brain activity during various auditory tasks.

## 1 INTRODUCTION

Probabilistic graphical models (PGMs)—which compactly encode a set of conditional independence statements—have become a defacto tool for defining probabilistic models over large sets of random variables. When faced with time series, dynamic Bayesian networks (DBNs) are commonly deployed and specify sparse between- and within-time de-

pendencies, often encoded by a *template model* replicated across time to straightforwardly model the growing set of random variables [1]. Learning template models requires specifying the set of dependency lags to be considered [2, 3]. In many applications, one instead aims to infer conditional independence between entire data streams accounting for interactions at all possible lags, represented by a *time series graphical model* (TGM). For example, imagine recording brain activity from multiple regions of the brain over time. Inference of a TGM in this setting would provide insight into the functional connectivity of different brain regions, an object of substantial scientific interest [4, 5]. TGMs have also been applied to intensive care monitoring [6] and financial time series [7].

The pioneering work of Dahlhaus [8] introduced the concept of undirected graphical models for stationary time series. The key insight was to transform the series to the *frequency domain* and express the graph relationships in the resulting spectral representation. For jointly Gaussian stationary time series, Dahlhaus [8] showed that conditional independencies between time series are encoded by zeros in the inverse spectral density matrices. This result is the frequency-domain analog to Gaussian graphical modeling in the i.i.d. (non-time-series) setting, where zeros in the inverse covariance matrix, or *precision matrix*, encode the conditional independencies between observed dimensions [9]. Dahlhaus’ insight was first exploited to perform independent hypothesis tests of conditional independence between each pair of time series [8], with more recent work correcting for multiple comparisons [10, 11].

A likelihood-based approach leveraging the *Whittle approximation* [12] has also been introduced [13]. The Whittle approximation casts the likelihood in the frequency domain with terms depending on the spectral density matrices critical to TGM structure learning, and independently so across frequencies. One approach scores graphs using AIC [13]. A recent penalized likelihood variant [14] places a joint graphical lasso [15] across frequencies to enforce a common zero pattern in the spectral density matrices. A penalized likelihood approach restricted to finite vector au-

to regressive processes has also been considered [7].

We instead consider a Bayesian approach to TGM structure learning, with all the benefits garnered from the Bayesian paradigm, including modeling within a generative framework where information from multiple sources can be integrated and combined with available prior knowledge. For example, neural data are notoriously noisy, and robust inferences often rely on integrating time series across multiple trials and individuals or recording platforms (e.g., EEG/MEG). Our approach also leverages the Whittle likelihood. We then introduce a novel hyper Markov law [16], the *hyper complex inverse Wishart* distribution, that serves as a conjugate prior for the spectral density matrices whose inverses have a zero pattern specified by a graph. For decomposable graphs, this formulation leads to a closed-form expression for the marginal likelihood of a multivariate time series given a graph. By placing a prior on graph structures, we achieve a fully Bayesian approach to TGM structure learning for stationary time series. For our graph prior, we consider a multiplicity correcting prior [17]. Our analytic expression for the marginal likelihood is critical to the practicality of our approach since we can avoid inference of the large set of high-dimensional, complex spectral density matrices. In particular, for a length  $T$  series of dimension  $p$ , there are  $T$   $p \times p$  spectral matrices to consider. In the i.i.d. setting, inference of just a single  $p \times p$  graph-constrained covariance matrix is challenging; in this setting, inference of the  $T$   $p \times p$  matrices is prohibitive.

Hyper Markov laws based on the hyper inverse Wishart are a popular tool for Bayesian graphical model selection in the i.i.d. setting [18, 19]. Indeed, many powerful Bayesian structure learning algorithms based on this framework have been developed, both for decomposable [20, 21] and non-decomposable [22, 23] graphs. By framing TGM structure learning in this common framework, we are able to apply existing state-of-the-art inference machinery for standard structure learning to the time series case. In this paper we use the feature-inclusion stochastic search (FINCS) procedure [20] for inference in decomposable models; however, many other MCMC and search schemes may be used. Importantly, future computational advances in Bayesian inference for i.i.d. graphical models may be easily extended using our framework to the time series case.

We test our methods on data simulated from vector autoregressive models with randomly generated TGMs. Our approach reaches almost perfect TGM recovery as the length of the time series or number of independent replicates increases. We then demonstrate the utility of our methods on a global stock indices dataset and MEG neuroimaging data of auditory attention switching tasks. In both cases we find meaningful, intuitive structure in the data.

Our paper is organized as follows. We provide background on graphical models and stationary time series in Sec. 2.

Our proposed TGM method is in Sec. 3, first introduced in the context of multiple independent realizations and then adapted to perform efficient inference of the TGM from only a single realization. In Sec. 5, we discuss how existing Bayesian structure learning methods may be modified to fit our formulation. Simulated results are in Sec. 6, with our stock and MEG analyses in Secs. 7 and 8, respectively.

## 2 BACKGROUND

### 2.1 Graphs

Let  $G = (V, E)$  be an undirected graph with vertex set  $V = \{1, \dots, p\}$  and edge set  $E$ , where  $E \subset \{(i, j) \in V \times V : i \neq j\}$ . Nodes  $i$  and  $j$  are adjacent, or *neighbors*, if  $(i, j) \in E$ . A *complete graph* is one having  $(i, j) \in E$  for every  $i, j \in V$  and complete subgraphs  $C \subset V$  are termed *cliques*. A triple of subgraphs  $(A, S, B)$  where  $V = A \cup B$  and  $S = A \cap B$  with  $S$  complete is called a *decomposition* if every path from a node in  $A$  to a node in  $B$  must pass through  $S$ , the *separator*. Recursively decomposing  $A$  and  $B$  in this fashion results in the *prime components* of a graph. If the prime components are complete then the graph is *decomposable*. We let the sets  $\mathcal{C} = \{C_1, \dots, C_K\}$  and  $\mathcal{S} = \{S_2, \dots, S_K\}$  each denote the prime components and their separators, respectively, generated by the decomposition. For simplicity, we restrict our attention to decomposable graphs but stress that our formulation is extensible to the non-decomposable case (see Sec. 9).

### 2.2 Hyper Markov distributions

For a given set of random variables  $X$ , with realization  $x \in \mathcal{X}$ , dimensionality  $p$ , and joint density  $p(x)$ , an undirected graphical model  $G$  can be constructed by stating that an edge  $(i, j) \notin E$  if  $X_i$  and  $X_j$  are conditionally independent given the remaining variables, i.e.  $X_j \perp\!\!\!\perp X_i | X_{Z_{ij}}$  where  $Z_{ij} = V \setminus \{i, j\}$ . If the graph is decomposable, the joint density decomposes over cliques and separators:

$$p(x) = \frac{\prod_{C \in \mathcal{C}} p(x_C)}{\prod_{S \in \mathcal{S}} p(x_S)} \quad (1)$$

where  $p(x_A)$  for  $A \subset V$  denotes the marginal distribution of the set of variables  $x_A$ .

A hyper Markov law [16] is a distribution over probability measures that is concentrated on distributions that obey the Markov properties specified by  $G$ . Examples include the hyper Wishart and hyper Dirichlet distribution [16, 18]. Such distributions have proven pivotal in Bayesian graphical modeling by serving as conjugate priors for the graph parameters conditioned on the graph structure  $G$ . For example, in Gaussian graphical models (GGMs), the hyper inverse Wishart distribution provides a conjugate prior for covariance matrices that obey a zero pattern in the precision, as specified by  $G$ . By integrating over the hyper

Markov distribution, one can obtain the *marginal likelihood* of the data conditioned on the structure  $G$  alone.

### 2.3 Stationary time series

Let  $X(t) = (X_1(t), \dots, X_p(t))^T \in \mathbb{R}^p$  for  $t \in \mathbb{Z}$  be a multivariate Gaussian stationary time series such that:

$$E(X(t)) = \mu \quad \forall t \in \mathbb{Z} \quad (2)$$

$$\text{Cov}(X(t), X(t+h)) = \Gamma(h) \quad \forall t, h \in \mathbb{Z}. \quad (3)$$

A time series probabilistic graphical model (TGM),  $G = (V, E)$ , may be constructed by letting  $(i, j) \notin E$  denote that the entire time series  $X_i(\cdot)$  and  $X_j(\cdot)$  are conditionally independent given the remaining collection of time series  $X_{Z_{ij}}$  where  $Z_{ij} = V \setminus \{i, j\}$ . For the Gaussian stationary series we consider, one can show that conditional independence holds between time series iff [8]

$$\text{Cov}(X_i(t), X_j(t+h) | X_{Z_{ij}}) = 0 \quad \forall h \in \mathbb{Z}. \quad (4)$$

The *spectral density matrix* of a stationary time series is defined as the Fourier transform of the lagged covariance matrices,  $\Gamma(h) = \text{Cov}(X(t), X(t+h))$ :

$$S(\lambda) = \sum_{h=-\infty}^{\infty} \Gamma(h) e^{-i\lambda h} \quad (5)$$

for  $\lambda \in [0, 2\pi]$  and  $S(\lambda) \in \mathbb{C}^{p \times p}$  and Hermitian positive definite. The marginal dependencies between time series are captured by  $S(\lambda)$ , and from Eq. (5),  $S(\lambda)_{ij} = 0$  for all  $\lambda \in [0, 2\pi]$  iff  $\Gamma(h)_{ij} = 0$  for all  $h \in \mathbb{Z}$ . Furthermore, conditional independence between Gaussian stationary time series holds iff

$$S(\lambda)_{ij}^{-1} = 0 \quad \forall \lambda \in [0, 2\pi], \quad (6)$$

implying that inferring zeros in the inverse spectral density matrices across frequencies equates with inferring the TGM structure [8]. More background on the spectral approach to time series is presented in the Supplement.

## 3 A BAYESIAN APPROACH

There are two standard approaches to Bayesian inference in graphical models: (1) placing a prior that jointly specifies the graph structure and associated parameters or (2) placing a prior on graph structures and then a prior on parameters given a graph; both rely on specifying a likelihood model. We opt for the second approach and describe the various components in this section. At a high level, our methods combine existing Whittle likelihood based methods [13, 14] with the hyper Markov framework to Bayesian graphical modeling [19, 18]. In the context of our TGMs, we introduce a conjugate *hyper complex inverse Wishart* prior on graph-constrained spectral density matrices. By integrating out the spectral density matrices, we obtain a

marginal likelihood of the time series given the graph structure,  $G$ , allowing us to straightforwardly leverage state-of-the-art computational methods for i.i.d. Bayesian structure learning.

### 3.1 Whittle likelihood

Let  $\mathbf{X} = [X(1), \dots, X(T)]$ , with  $x(t) \in \mathbb{R}^p$  a realization of a  $p$ -dimensional stationary Gaussian time series observed at  $T$  time points, and  $\mathbf{X}_{1:N} = \{\mathbf{X}^1, \dots, \mathbf{X}^N\}$  be the collection of  $N$  independent realizations. We move to the frequency domain by transforming each  $\mathbf{X}^i$  using a discrete Fourier transform. Let  $d_{nk} \in \mathbb{C}^p$  denote the discrete Fourier coefficient associated with the  $n$ th time series at frequency  $\lambda_k = \frac{2\pi k}{T}$ :

$$d_{nk} = \frac{1}{T} \sum_{t=0}^{T-1} x_n(t) e^{-i\lambda_k t}. \quad (7)$$

The Whittle approximation [12] assumes the Fourier coefficients are independent *complex normal random variables* with mean zero and covariance given by the corresponding spectral density matrix  $S_k = S(\lambda_k)$ :

$$d_{nk} \sim \mathcal{N}_c(0, S_k) \quad k = 0, \dots, T-1, \quad (8)$$

such that the likelihood of  $\mathbf{X}_{1:N}$  is approximated as

$$p(\mathbf{X}_{1:N} | S_{0:T-1}) \approx \prod_{n=1}^N \prod_{k=0}^{T-1} \frac{1}{\pi^p |S_k|} e^{-d_{nk}^* S_k^{-1} d_{nk}}, \quad (9)$$

where  $\frac{1}{\pi^p |S|} e^{-z^* S^{-1} z}$  is the density of a complex normal distribution,  $\mathcal{N}_c(0, S)$ , with  $S \in \mathbb{C}^{p \times p}$  and Hermitian positive definite. See the Supplement. The Whittle approximation holds asymptotically with large  $T$  [24, 25, 12]. This approximation has been used in the Bayesian context in [26, 27]

Recall that conditional independencies are encoded in the off diagonal elements of  $S_k^{-1}$ . If time series  $X_i(t)$  and  $X_j(t)$  are conditionally independent, then the Whittle approximation says that as  $T$  gets large the  $i$ th and  $j$ th elements of the Fourier coefficients  $d_{nk}$  are conditional independent across all frequencies. Thus, if  $G$  is decomposable, Eq. (9) can be rewritten as

$$p(\mathbf{X}_{1:N} | G, S_{0:(T-1)}) \approx \prod_{k=0}^{T-1} \frac{\prod_{C \in \mathcal{C}} \frac{1}{\pi^{N|C|} |S_{kC}|^N} e^{-\text{tr} P_{kC} S_{kC}^{-1}}}{\prod_{S \in \mathcal{S}} \frac{1}{\pi^{N|S|} |S_{kS}|^N} e^{-\text{tr} P_{kS} S_{kS}^{-1}}} \quad (10)$$

where

$$P_k = \sum_{n=1}^N d_{nk} d_{nk}^* \quad (11)$$

is the aggregate *periodogram* over the  $N$  time series at frequency  $\frac{2\pi k}{T}$ . For  $A \subset V$ ,  $S_{kA}$  and  $P_{kA}$  are the restriction of both matrices to the elements in  $A$  and  $|A|$  denotes the cardinality of the set  $A$ .

### 3.2 Hyper complex inverse Wishart prior on graph-constrained spectral density matrices

We seek a prior for the spectral density matrices,  $S_k$ , whose inverses each have zeros dictated by a graph  $G$ . Recall that these  $S_k$  matrices are complex-valued and restricted to be Hermitian positive definite. As discussed in Sec. 2.2, the hyper inverse Wishart distribution serves as a prior for real-valued, positive-definite matrices with pre-specified zeros in the inverse, and is a conjugate prior for the covariance of a zero-mean GGM. Motivated by the connection between GGMs and our TGMs, and the analogous structure of our TGM-based Whittle likelihood of Eq. (10) to that of a GGM with  $N$  i.i.d. observations, we propose a novel *hyper complex inverse Wishart* prior with density function

$$p(\Sigma|\delta, W, G) \propto \mathbf{1}_{\Sigma \in M^+(G)} |\Sigma|^{-(\delta+2p)} e^{-\text{tr}W\Sigma^{-1}} \quad (12)$$

for *degrees of freedom*  $\delta > 0$ , *scale matrix*  $W \in \mathbb{C}^{p \times p}$  positive definite and Hermitian, and graph  $G$ . We have used an analogous parameterization to that of the hyper inverse Wishart [16]. Here,  $\Sigma \in M^+(G)$  denotes that  $\Sigma$  is in the set of all Hermitian positive-definite matrices with  $(\Sigma^{-1})_{ij} = 0$  for all  $(i, j) \notin E$ . When  $G$  is decomposable, the normalization constant is available and the density decomposes over cliques and separators:

$$\begin{aligned} p(\Sigma|\delta, W, G) &= \frac{\prod_{C \in \mathcal{C}} \text{IW}_c(\Sigma_C|\delta, W_C)}{\prod_{S \in \mathcal{S}} \text{IW}_c(\Sigma_S|\delta, W_S)} \quad (13) \\ &= \frac{\prod_{C \in \mathcal{C}} B(W_C, \delta) |\Sigma_C|^{-(\delta+2|C|)} e^{-\text{tr}W_C\Sigma_C^{-1}}}{\prod_{S \in \mathcal{S}} B(W_S, \delta) |\Sigma_S|^{-(\delta+2|S|)} e^{-\text{tr}W_S\Sigma_S^{-1}}}, \quad (14) \end{aligned}$$

where  $\text{IW}_c$  denotes the complex inverse Wishart [25] detailed in the Supplement with normalizer

$$B(W, \delta) = \frac{|W|^{\delta+p}}{\pi^{\frac{p(p-1)}{2}} \prod_{j=1}^p (\delta+p-j)!}. \quad (15)$$

We denote our proposed prior as  $HIW_c(\delta, W, G)$  and specify

$$S_k | G \sim HIW_c(\delta_k, W_k, G) \quad k = 0, \dots, T-1. \quad (16)$$

In the Supplement, we show that this prior specification is *conjugate* to the TGM-based Whittle likelihood of Eq. (10). Also note that the graph,  $G$ , is shared across all frequencies.

### 3.3 Marginal likelihood

Due to conjugacy of our proposed hyper complex inverse Wishart prior, the marginal likelihood of the time series  $\mathbf{X}_{1:N}$  given a decomposable graph  $G$ , integrating out the spectral density matrices  $S_{0:T-1}$ , has a closed form which is derived in the Supplement and given by

$$p(\mathbf{X}_{1:N}|G) \approx \pi^{-NTp} \prod_{k=0}^{T-1} \frac{h(W_k, \delta_k, G)}{h(W_k^*, \delta_k^*, G)}. \quad (17)$$

Here,  $\delta_k^* = \delta_k + N$ ,  $W_k^* = W_k + P_k$ , and

$$h(W, \delta, G) = \frac{\prod_{C \in \mathcal{C}} B(W_C, \delta)}{\prod_{S \in \mathcal{S}} B(W_S, \delta)}. \quad (18)$$

From the definition of  $\delta_k^*$ , we see that  $N$ , the number of time series, acts as the effective number of observations in this case. For the i.i.d. GGM,  $N$  represents the number of independent vector-valued observations; in our TGM,  $N$  plays the same role, but represents the number of independent *time series* observations. Likewise, as in standard inverse Wishart based modeling of covariances for i.i.d. Gaussian data, based on a set of  $N$  i.i.d. complex normal observations of Fourier coefficients  $d_{nk}$  with covariance  $S_k$  (see Eq. (9)), we update the prior scale matrix  $W_k$  with the outer product  $P_k = \sum_{n=1}^N d_{nk}d_{nk}^*$ , which is the aggregate *periodogram* (see Eq. (11)).

Having an analytic marginal likelihood of the time series given a PGM allows us to perform inference directly over graphs, sidestepping any thorny issues with inference directly on the  $T p \times p$  spectral density matrices themselves. This is a critical feature of the practicality of our approach.

### 3.4 Fractional priors for model selection

Marginal likelihoods used for model comparison [28] are notoriously sensitive to the choice of prior parameters, or *hyperparameters*. In our case, the marginal likelihood in Eq. (17) depends strongly on the hyper complex inverse Wishart scale matrix,  $W_k$ . Since the scale and shape of the spectral density matrices are not known a priori, and vary dramatically across frequencies, we employ *fractional priors* [29] over each  $S_k$ . Fractional priors effectively hold out some fraction of the data, and utilize that fraction to determine an adequate hyperparameter setting for each model. The rest of the data are then used for model comparison. Fractional priors have been deployed for graphical model selection in i.i.d. graphs and have a number of desirable properties such as information consistency and demonstrated robustness [20]. In our case, under a fractional prior with parameter  $g \in (0, 1)$ , the fractional marginal likelihood is

$$p(\mathbf{X}_{1:N}|g, G) = \pi^{-NTp} \prod_{k=0}^{T-1} \frac{h(gP_k, gN, G)}{h(P_k, N, G)}. \quad (19)$$

Here, we see that  $g$  controls the fraction of data used for prior formulation versus model comparison. Importantly, we now have just a single, scalar, and interpretable parameter  $g$  to tune. Default settings are suggested in [29, 20].

### 3.5 Graph prior

There are two common approaches in the literature to specifying a prior distribution on graphs. The first approach places a uniform distribution on the space of all possible

graphs [18, 30, 31]. As noted in [32], this prior puts high weight on graphs with a medium number of edges and significantly less weight on graphs with small or many edges. In response to this problem, it has been proposed to place a prior directly on the size of the graph and then consider a conditionally uniform prior on all graphs of the same size [32, 33, 19]. We follow this later approach and place a binomial distribution on the number of edges,  $k$ :

$$p(G) \propto r^k (1-r)^{m-k}, \quad (20)$$

where  $r$  is the prior probability that each of  $m = \frac{p(p-1)}{2}$  possible undirected edges  $(i, j) \in V \times V$  is included. Since  $r$  is unknown, we further place a  $\text{Beta}(a, b)$  prior over  $r$ . Integrating out  $r$  gives the marginal prior over graphs

$$p(G) \propto \frac{\beta(a+k, b+m-k)}{\beta(a, b)} \quad (21)$$

where  $\beta(\cdot, \cdot)$  is the beta function. As explored in [20], this is a multiplicity correcting prior [34] over graphs with the desirable property of diminishing false positive edge discoveries as extra unconnected nodes are added to the graph.

## 4 METHODS FOR SINGLE TIME SERIES

In some applications of interest one observes only a single multivariate time series,  $N = 1$ , from which the graph must be inferred. Two challenges arise in this setting: (1) the effective number of observations informing Eq. (17) is just one and (2) the periodogram used in computing  $W_k^*$  is noisy regardless of the length of the series,  $T$ . The periodogram is a notoriously poor estimator of the spectral density, and when the spectral density itself is of primary interest, a common frequentist method is to smooth the periodogram to obtain a consistent spectral density estimator [14, 13, 8]. One could imagine using the smoothed periodogram as a plug-in estimator in Eq. (17), scaled by the effective degrees of freedom (see the Supplement for more details on this plug-in estimator for our formulation). An alternative variance-reduction technique is the Bartlett method [35], that divides the length  $T$  series into  $M$  shorter series of length  $\frac{T}{M}$  and averages the resulting  $M$  periodograms, but at the cost of reduced resolution (i.e., number of considered frequencies). This approach mimics the implicit smoothing that occurs when we compute the periodogram based on  $N$  truly independent series each of length  $T$ , as in Eq. (11).

In contrast to a plug-in estimator, a natural Bayesian approach enforces smoothing across frequencies via a prior distribution over the set of spectral densities [26]. Previous approaches have coupled elements of a Cholesky decomposition of each spectral density matrix across frequencies, however this approach is unsuitable to our case since

1) it does not enforce sparsity in the inverse spectral density and 2) a prior of this form will remove the simple marginal likelihood structure in Eq. (17) that we harness for efficient inference. Motivated by our aims to both share information across frequencies and maintain the form of the marginal, we utilize a piecewise constant prior over spectral densities given a graph,  $G$ . We partition the interval  $[0, 2\pi]$  into  $M$  intervals  $w_1 = [0, \frac{2\pi}{M})$ ,  $\dots$ ,  $w_j = [\frac{2\pi(j-1)}{M}, \frac{2\pi j}{M})$ ,  $\dots$ ,  $w_M = [\frac{2\pi(M-1)}{M}, 2\pi]$  and then draw a separate positive definite Hermitian matrix from a  $HIW_c$  distribution for each interval:

$$\tilde{S}_j \sim HIW_c(\delta, W_j, G) \quad j = 1, \dots, M. \quad (22)$$

Our resulting spectral density is simply

$$S(\lambda) = \sum_{j=1}^M \mathbf{1}_{\lambda \in w_j} \tilde{S}_j \quad \forall \lambda \in [0, 2\pi]. \quad (23)$$

Under this prior, the marginal likelihood for the single ( $N = 1$ ) time series becomes

$$p(\mathbf{X}|G) \approx \pi^{-Mp} \prod_{j=1}^M \frac{h(W_j, \delta_j, G)}{h(W_j^*, \delta_j^*, G)} \quad (24)$$

where  $\delta_j^* = \delta_j + \sum_{k=0}^{T-1} \mathbf{1}_{\lambda_k \in w_j}$  and  $W_j^* = W_j + \sum_{k=0}^{T-1} \mathbf{1}_{\lambda_k \in w_j} P_k$ . By setting  $M = \lfloor \sqrt{T} \rfloor$ , we obtain an asymptotically approximate nonparametric prior distribution over continuous spectral density matrices: for  $T$  large enough the prior puts positive support on spectral density matrices arbitrarily close to any continuous spectral density over  $[0, 2\pi]$ . Furthermore, under this setting as  $T \rightarrow \infty$ , the number of Fourier frequencies, and thus number of samples  $\sum_{k=0}^{T-1} \mathbf{1}_{\lambda_k \in w_j}$ , within each interval grows as  $\sqrt{T}$ .

## 5 INFERENCE

Bayesian structural learning algorithms for decomposable graphs come in two flavors: MCMC samplers and stochastic search procedures [20, 22]. By placing decomposable graphical inference for time series in the same framework as for the i.i.d. case via our analytic  $p(\mathbf{X}_{1:N} | G)$ , we can easily modify both types of existing methods for the time series case.

Classical MCMC samplers for decomposable graphs sample from the posterior over graphs via Metropolis-Hastings (MH) by proposing single edge addition and deletion moves that keep the graph decomposable [18, 32]. While it is possible to obtain any decomposable graph from any other decomposable graph via a sequence of edge additions and deletions, the path may be hard to reach leading to prohibitive converge times for even a moderate number of vertices  $p$ . More recent graph samplers add more global moves by either randomly generating new decomposable graphs [36] or by generating from a Markov chain

over a junction tree representation of the graph [21]. To compute the MH acceptance ratio, these samplers rely on computing ratios of present and proposed marginal likelihoods. For simple edge additions and deletions, this ratio simplifies into a function of only the cliques and separators that change between moves. For our case, the ratio expands into a product over frequencies of the same affected cliques and separators, allowing simple modifications to the existing implementations of these samplers to handle TGMs.

All current MCMC samplers struggle to scale to even moderate numbers of nodes. In contexts where point estimates suffice, we can instead consider stochastic search procedures. We utilize a modification of the efficient feature-inclusion stochastic search (FINCS) [20] for inference in our TGMs. FINCS interleaves three moves: 1) single edge addition and deletion moves for local changes to the graph, 2) global sampling moves where edges are added independently to an empty graph and the final graph is triangulated to maintain decomposability, and 3) resampling at step  $t$  a full graph from a list of past visited models,  $\{G_1, G_2, \dots, G_{t-1}\}$ , in proportion to their posterior probabilities. In steps 1) and 2), to enforce exploration of high probability regions, edge additions that tend to continually improve the model probability are preferentially selected in proportion to a current heuristic estimate of the posterior edge probability

$$\hat{q}_{ij}(t) = \frac{\sum_{k=1}^t 1_{\{i,j\} \in E_t} p(X_{1:N}|G_t) p(G_t)}{\sum_{k=1}^t p(X_{1:N}|G_t)}, \quad (25)$$

where  $E_t$  is the current edge set. Edge deletions are performed proportional to  $\hat{q}_{ij}^{-1}(t)$ . As in MCMC samplers [18, 32], the junction tree representation of the graph can be efficiently updated after each local move since the two graphs only differ by a single clique and its corresponding separators, allowing a quick computation of the marginal likelihood of a proposed graph in Eq. (17). Importantly, the FINCS algorithm depends on the data only through the marginal likelihoods of the cliques  $C$ —used to compute the full graph marginal likelihood—which in our TGM case is a product over  $T$  frequencies:

$$\prod_{k=0}^{T-1} \frac{B(W_{k,C}, \delta)}{B(W_{k,C}^*, \delta^*)}. \quad (26)$$

That is, our implementation simply modifies the original FINCS definition of the clique marginal likelihood.

## 6 SIMULATIONS

To test our TGM methods, we consider simulated setups for both  $N > 1$  and  $N = 1$  time series each generated from an order-1 vector autoregressive process, denoted VAR(1), for  $p = 20$  dimensions. Specifically, we simulated data from the model

$$x(t) = Ax(t-1) + \epsilon(t), \quad (27)$$

where  $x(t) \in \mathbb{R}^p$ ,  $A \in \mathbb{R}^{p \times p}$ , and  $\epsilon(t) \sim N(0, I_{p \times p})$ . The inverse spectral density of a VAR(1) process is given by [7]

$$S(\lambda)^{-1} = I + A^T A + e^{-i\lambda} A + e^{i\lambda} A^T. \quad (28)$$

Random sparse TGMs were generated by first restricting  $A$  to be upper triangular. Following the simulated setup in [7], we set the diagonal elements to a constant  $A_{ii} = .5$  and sample the upper diagonal elements as  $a_{ij} \sim .5\delta_{ij}$ , where  $\delta_{ij} \sim \text{Binomial}(\rho)$  with  $\rho = .2$  for all simulations. The graph  $G$  was then determined by identifying the zeros in  $S(\lambda)^{-1}$  using Eq. (28). Proposed  $A$  matrices were accepted when both the absolute value of all eigenvalues of  $A$  were less than one, making the series stationary, and the graph  $G$  determined by  $A$  was decomposable.

We note that since our formulation reduces to a standard structure learning problem, our emphasis is less on assessing performance with respect to  $p$ , which should follow from whichever structure learning algorithm is selected; instead, our focus is on  $N$  and  $T$ , which are specific to the time series and spectral analysis. For example, in the FINCS algorithm [20], it is quoted that the method can handle graphs with up to roughly  $p = 100$  nodes.

### 6.1 Multiple time series

To analyze how our TGM structure learning performance varies with the number of time series replicates,  $N$ , we simulated data for  $N \in \{20, 50, 100, 150, 200, 250, 300, 350\}$  and  $T \in \{25, 50, 100, 500, 1000, 1500, 2000\}$ . This process was repeated 200 times for each combination of  $N$  and  $T$ . Each time series is first decomposed into its discrete Fourier components. We then ran 10,000 iterations of the FINCS algorithm using the fractional marginal likelihood in Eq. (19) with  $g = \frac{4}{N}$ , a default setting [29, 20]. Our graph prior followed the multiplicity correcting form in Eq. (21) with  $a = b = 1$ . The graph visited with highest posterior probability was then selected and true and false positive rates were computed. Results are displayed in Fig. 1. Across  $T$ , the true positive rate increases quickly with the number of series,  $N$ , achieving an almost perfect true positive rate by about  $N = 150$ . We also see that the rate of increase in the true positive rate increases with the length of the series  $T$ , which relates to the number of considered Fourier frequencies. It is interesting to note that for all  $T$  under consideration, the false positive rate tends to start very low ( $\approx .005$ ) for  $N = 20$  replicates then spike at  $N \in \{50, 100\}$  before declining again. This occurs due to the fact that at low  $N$ , very few edges are introduced at all, perhaps due to an Occam’s razor type effect of marginal likelihoods penalizing model complexity. As  $N$  starts to increase, more edges are introduced, both correct and incorrect, and as  $N$  further increases, the false edges are pruned and true edges are retained, leading to a decline in the false positive rate. Note that the false positive spike tends to be more pronounced for time series of

Figure 1: **Top:** As a function of the number of time series  $N$ , and plotted for various values of their length  $T$ , (left) mean true positive rate, (middle) median false positive rate, and (right) mean running time computed across the 200 replicates. Standard error bars are small relative to the scale of the plots and are omitted for clarity. **Bottom:** Same plots as a function of  $T$  for a single time series ( $N = 1$ ), and plotted for various periodogram smoothing techniques.

smaller length,  $T \in \{25, 50\}$ . One would expect to see significant improvements, especially for small  $N$ , by leveraging the piecewise constant prior of Sec. 4 and explored in Sec. 6.2 where we show that we are able to learn graphs from just  $N = 1$  time series. However, we chose not to include this prior in this analysis so as not to confound its effect with our performance. Here, the noisy periodogram is smoothed implicitly by averaging over  $N$ .

Finally, in Fig. 1 we see that runtime increases as a function of  $T$  due to the dependence on  $T$  in the marginal likelihood computation of Eq. (17), though significant cost reductions can be achieved through parallelizations leveraging the product form.

## 6.2 Single time series: comparison of methods

To assess the performance of our single-time-series methods outlined in Sec. 4, we simulated a time series with  $T \in \{500, 1000, 2500, 5000, 7500, 10000\}$ . For the piecewise constant prior method, we use  $M = \lfloor \sqrt{T} \rfloor$  pieces. We compare against the Bartlett time-series-splitting approach with the number of splits set to  $\lfloor \sqrt{T} \rfloor$ . We also examine a smoothed plug-in estimator of the spectral density using a Daniell smoother outlined in the Supplement with  $m = \lfloor \frac{\sqrt{T}}{2} \rfloor$  for a total window size of  $2 \lfloor \frac{\sqrt{T}}{2} \rfloor + 1 \approx \lfloor \sqrt{T} \rfloor$ . For each method, the FINCS algorithm was run for 10,000 iterations and the highest scoring graph was selected and used to compute true and false positive rates. This process was repeated 200 times with results displayed in Fig. 1

with a replicate representative of our median performance shown in Fig. 2. The true positive rate increases for all three methods as a function of  $T$ , achieving a final value of about .9 for both the plug-in and piecewise constant prior methods and .79 for the Bartlett method at  $T = 10000$ . All methods maintain a low false positive rate around .02. Overall, the Bartlett method performs uniformly worse in terms of both true and false positive performance, while the piecewise prior method performs on par with the plug-in method, but at a fraction of the computational cost. Further experimental simulations are given in the Supplement.

## 7 GLOBAL STOCK INDICES

We explore the utility of our method in discovering conditional independencies between countries inherent in the global financial system. A similar experiment was conducted in [7] using a penalized-likelihood approach to learn TGMs, but restricted to finite-order VAR models with pre-specified order. (Recall that our method only assumes Gaussian stationarity, which includes the class of possibly infinite order VAR processes.) Using [www.globalfinancialdata.com](http://www.globalfinancialdata.com), we acquired the daily closing prices of 17 stock indices in US dollars for various countries around the world (see the Supplement for the full list) from June 3, 1997 to June 30, 1999. Missing prices were backfilled and only days where all exchanges traded were considered which resulted in time series of length 542. Following standard practice when analyzing stock prices, we converted the closing prices,  $p_t$ , on day  $t$  to log-returns according to

Figure 2: Example evolution of error types for the piecewise prior method as a function of series length,  $T \in \{1000, 2500, 5000, 10000\}$  and  $N = 1$ , for a selected graph. **Blue, red, black,** and white entries indicate true positives, false negatives, false positives, and true negatives, respectively. The graph was selected by choosing the graph out of 200 replications with median true positive rate at  $T = 2500$ .

$$r_t = 100 \log(p_t/p_{t-1}).$$

We compare the graphical models inferred under two settings: (i) treating the log-returns as independent (as in [20]) and (ii) using our methods to learn a TGM treating the log-returns as a time series. The best graphical models learned in each scenario are depicted in Fig. 3.

For our TGM algorithm, we computed the periodogram for the 17-dimensional time series, resulting in 542 complex-valued matrices of dimension  $17 \times 17$ . Since we only have one realization of the time series, we smoothed the periodogram using the techniques and settings discussed in Sec. 6.2. We then ran the FINCS algorithm for 100,000 iterations. We compare the resulting highest-probability graph (see Fig. 3) to that learned treating the time series as independent based on the model in [20], again using 100,000 iterations of the FINCS algorithm, but in its originally proposed form for non-temporal data.

In Figure 3, we see that in both cases we recover some geographical relationships between countries. However, the independent model returns a significantly denser graph than that learned by our TGM approach. Since the independent model is not taking the temporal nature of the data into account, some edges are likely spurious due to random correlations. The TGM, on the other hand, provides an interpretable and intuitive structure with strong geographic connections. For example, there is a distinct United Kingdom / eurozone cluster of Germany ‘DE’, Finland ‘FI’, Netherlands ‘NL’, Belgium ‘BE’, Switzerland ‘CH’, Austria ‘AT’, Spain ‘ES’, Italy ‘IT’, Portugal ‘PT’, and the United Kingdom ‘UK’. Another distinct cluster includes the United States ‘US’, Canada ‘CA’, Hong Kong ‘HK’ (whose currency is linked to the USD), and Australia ‘AU’ (whose currency is correlated with the US S&P), with Japan ‘JP’ hanging off this cluster. One perhaps strange missing link is between Ireland ‘IE’ and the UK, though the US and Ireland have a long history of economic connections possibly explaining why Ireland is included in the separator between these two distinct clusters.

In the Supplement, we include (i) a comparison of our

Figure 3: Graphical models with the highest posterior probability for the stock index data. **Left:** Treating the log-returns as independent. **Right:** Using our TGM algorithm. In both cases, we see regional connections, but our TGM algorithm results in a sparser and more interpretable graph.

learned graph with that of Songsiri et. al. [7], and (ii) further details on the stock data itself.

## 8 MAGNETOENCEPHALOGRAPHY DATA

Next we learn TGMs to capture the structure of underlying cortical dynamics from magnetoencephalography (MEG) data collected from ten subjects who were asked to perform a task while maintaining focus on an audio stream and then again while switching focus [37]. Our goal is to discover differences in the underlying TGMs between the non-switching and switching attention conditions. Such differences provide further understanding into the neural underpinnings of auditory selective selection, an important constituent to communication.

The data were collected for each subject performing the experiment in the *switching* (S) and *non-switching* (N) attention conditions. For both S and N conditions, each subject performed the task under an auditory condition of *high* (U) and *low* (D) pitch, and spatial conditions of *left* (L) and *right* (R) attending. For each of the eight possible conditions, MEG recordings were collected resulting in a 150-dimensional time series of length 992 where each dimen-

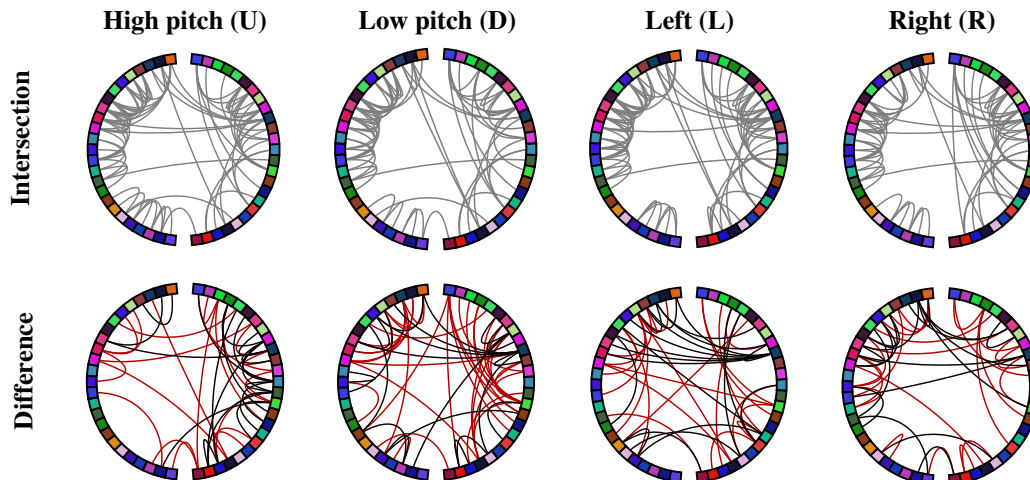

Figure 4: Learned TGMs for different MEG conditions. Each node on the periphery represents a brain region with location indicating anatomical location. **Top:** Intersection of learned edges between switching and non-switching conditions. **Bottom:** *Black* edges indicating those in the non-switching condition but not in the switching and *red* vice versa.

sion corresponds to a localized region of the brain. We have between 17 and 30 trials for each subject, resulting in about 200 replicate time series per condition.

Often with MEG data, many of the dimensions are dominated by noise due to limited brain activity in that region. We reduced the number of brain regions we studied from 150 to 50 by only considering those with largest variance. In particular, for each trial we mean-centered all of the time-series and computed the variance and retained the top 50 most volatile regions.

We computed the periodogram for each trial and averaged across trials within each condition, resulting in eight periodograms. We ran our spectral TGS version of the FINCS algorithm on these periodograms for 100,000 iterations with fractional prior parameter  $4/N_c$ , where  $N_c$  is the number of trials for condition  $c \in \{S, N\} \times \{U, D, L, R\}$ . We also ran the algorithm for 1.7 million iterations and saw no difference in the resulting graphs.

In Figure 4, we depict the intersections and differences between the learned graphs for each experimental condition. We see in the top row that there are a lot of shared connections between the switching and non-switching conditions for each auditory condition. In the bottom row, the differences between the switching and non-switching conditions are depicted where red edges are those in the switching condition but not the non-switching, and black edges are the reverse. The difference plots show that there seems to be substantial “rewiring” for many of the conditions with many edges connecting frontal to back regions. Interestingly, we again see consistencies in these rewirings across conditions. Additionally, we reliably uncover local connections between adjacent brain regions across experimental conditions. Such observations provide guidance for developing experiments and methods to discern the underlying mechanisms that give rise to these different structures.

## 9 DISCUSSION

We introduced a Bayesian approach to graphical model structure learning for time series. In particular, we propose a prior—the *hyper complex inverse Wishart* distribution—for the spectral density matrices in a Whittle likelihood approximation. For decomposable graphs, this prior is conjugate and leads to a closed-form expression of the marginal likelihood of the time series given the graph, marginalizing the spectral density matrices across frequencies. Being able to integrate out this large collection of complex matrices—one for each time point—is critical to developing a practical and scalable inference algorithm. For this, exploiting the fact that our marginal likelihood is analogous to that for i.i.d. Gaussian graphical models [19] but with a product over the number of Fourier frequencies, allows us to deploy straightforward modifications to existing MCMC and stochastic search algorithms. Our simulations show that when many time series are observed, our method recovers the correct graph. When a single time series is observed, we proposed a method to increase robustness of our graph estimation using a piecewise constant prior. Our results on the stock and MEG datasets demonstrated our ability to discover intuitive and interpretable structure in these datasets, importantly leveraging the temporal dependencies.

Extensions to non-decomposable graphs are possible using the i.i.d. graph approaches in both [31] and [22]. A Laplace approximation to the marginal likelihood for non-decomposable graphs is proposed in [22], which we could similarly utilize to approximate the frequency-specific marginal at each term in Equation (17). Parallelizing the Laplace approximation computation across frequencies would lead to a scalable method for inference in non-decomposable time series graphs.

## Abstract

We consider graphs that represent pairwise marginal independencies amongst a set of variables (for instance, the zero entries of a covariance matrix for normal data). We characterize the directed acyclic graphs (DAGs) that faithfully explain a given set of independencies, and derive algorithms to efficiently enumerate such structures. Our results map out the space of faithful causal models for a given set of pairwise marginal independence relations. This allows us to show the extent to which causal inference is possible without using conditional independence tests.

## 1 INTRODUCTION

DAGs and other graphical models encode conditional independence (CI) relationships in probability distributions. Therefore, CI tests are a natural building block of algorithms that infer such models from data. For example, the PC algorithm for learning DAGs (Kalisch and Bühlmann, 2007) and the FCI (Spirtes et al., 2000) and RFCI (Colombo et al., 2012) algorithms for learning maximal ancestral graphs are all based on CI tests.

CI testing is still an ongoing research topic, to which the UAI community is contributing (e.g. Zhang et al., 2011; Doran et al., 2014). But at least for continuous variables, CI testing will always remain more difficult than testing marginal independence for quite fundamental reasons (Bergsma, 2004). Intuitively, the difficulty is that two variables  $x$  and  $y$  could be dependent “almost nowhere”, e.g., for only a few values of the conditioning variable  $z$ . This suggests a two-staged approach to structure learning: first try to learn as much as possible from simpler independence tests before applying CI tests. Here, we present a theoretical basis for extracting as much information as possible from the simplest kind of stochastic independence – pairwise marginal independence.

Figure 1: (a) A *marginal independence graph*  $\mathcal{U}$  whose missing edges represent pairwise marginal independencies. (b) A *faithful DAG*  $\mathcal{G}$  entailing the same set of pairwise marginal independencies as  $\mathcal{U}$ . (c) A graph for which no such faithful DAG exists.

More precisely, we will consider the following problem. We are given the set of pairwise marginal independencies that hold amongst some variables of interest. Such sets can be represented as graphs whose missing edges correspond to independencies (Figure 1a). We call such graphs *marginal independence graphs*. We wish to find DAGs on the same variables that entail exactly the given set of pairwise marginal independencies (Figure 1b). We call such DAGs *faithful*. Sometimes no such DAGs exist (e.g., Figure 1c). Else, we are interested in finding the set of *all* faithful DAGs, hoping that this set will be substantially smaller than the set of all possible DAGs on the same variables. Those candidate DAGs could then be probed further by using joint marginal or conditional independence tests.

Other authors have represented marginal (in)dependencies using bidirected graphs (Drton and Richardson, 2003; Richardson, 2003; Drton and Richardson, 2008b), instead of undirected graphs like we do here. We hope that the reader is compensated for this small departure from community standards by the lower amount of clutter in our figures, and the greater ease to link our work to standard graph theoretical results. We also emphasize that we model only pairwise, and not higher-order joint dependencies. However, for Gaussian data, pairwise independence entails joint independence. In that case, our marginal independence graphs are equivalent to *covariance graphs* (Cox and Wermuth, 1993; Pearl and Wermuth, 1994; Drton and Richardson, 2003, 2008a; Peña, 2013), whose missing edges represent zero covariances.

Our results generalize the work of Pearl and Wermuth (1994) who showed (but did not prove) how to find *some* faithful DAGs for a given covariance graph. We review these and other connections to related work in Section 3 where we also link our problem to the theory of partially ordered sets (posets). This connection allows us to identify certain maximal and minimal faithful DAGs. Based on these “boundary DAGs” we then derive a characterization of all faithful DAGs (Section 4), and construct related enumeration algorithms (Section 5). We use these algorithms to explore the combinatorial structure of faithful DAG models (Section 6) which leads, among other things, to a quantification of how much pairwise marginal independencies reduce structural causal uncertainty. Finally, we ask what happens when a set of independencies can *not* be explained by any DAG. How many additional variables will we need? We prove that this problem is NP-hard (Section 7).

Preliminary versions of many of the results presented in this paper were obtained in the Master’s thesis of the second author (Idelberger, 2014).

## 2 PRELIMINARIES

In this paper we use the abbreviation *iff* for the connective “if and only if”. A graph  $\mathcal{G} = (V, E)$  consists of a set of nodes (variables)  $V$  and set of edges  $E$ . We consider undirected graphs (which we simply refer to as graphs), directed graphs, and mixed graphs that can have both undirected edges (denotes as  $x - y$ ) and directed edges (denoted as  $x \rightarrow y$ ). Two nodes are *adjacent* if they are linked by any edge. A *clique* in a graph is a node set  $C \subseteq V$  such that all  $u, v \in C$  are adjacent. Conversely, an *independent set* is a node set  $I \subseteq V$  in which no two nodes  $u, v \in I$  are adjacent. A *maximal clique* is a clique for which no proper superset of nodes is also a clique. For any  $v \in V$ , the *neighborhood*  $N(v)$  is the set of nodes adjacent to  $v$  and the *boundary*  $Bd(v)$  is the neighborhood of  $v$  including  $v$ , i.e.  $Bd(v) = N(v) \cup \{v\}$ . A node  $v$  is called *simplicial* if  $Bd(v)$  is a clique. Equivalently,  $v$  is simplicial iff  $Bd(v) \subseteq Bd(w)$  for all  $w \in N(v)$  (Kloks et al., 2000). A clique that contains simplicial nodes is called a *simplex*. Every simplex is a maximal clique, and every simplicial node belongs to exactly one simplex. The *degree*  $d(v)$  of a node  $v$  is  $|N(v)|$ . If for two graphs  $\mathcal{G} = (V, E(\mathcal{G}))$  and  $\mathcal{G}' = (V, E(\mathcal{G}'))$  we have  $E(\mathcal{G}) \subseteq E(\mathcal{G}')$ , then  $\mathcal{G}$  is an *edge subgraph* of  $\mathcal{G}'$  and  $\mathcal{G}'$  is an *edge supergraph* of  $\mathcal{G}$ . The *skeleton* of a directed graph  $\mathcal{G}$  is obtained by replacing every edge  $u \rightarrow v$  by an undirected edge  $u - v$ .

A *path* of length  $n - 1$  is a sequence of  $n$  distinct nodes in which successive nodes are pairwise adjacent. A *directed path*  $x \rightarrow \dots \rightarrow y$  consists of directed edges that all point towards  $y$ . In a directed graph, a node  $u$  is an *ancestor* of another node  $v$  if  $u = v$  or if there is a directed path

$u \rightarrow \dots \rightarrow v$ . For each edge  $u \rightarrow v$ , we say that  $u$  is a *parent* of  $v$  and  $v$  is a *child* of  $u$ . If two nodes  $u, v$  in a directed graph have a common ancestor  $w$  (which can be  $u$  or  $v$ ), then the path  $u \leftarrow \dots \leftarrow w \rightarrow \dots \rightarrow v$  is called a *trek* connecting  $u$  and  $v$ . A DAG is called *transitive* if, for all  $u \neq v$ , it contains an edge  $u \rightarrow v$  whenever there is a directed path from  $u$  to  $v$ . Given a DAG  $\mathcal{G}$ , the *transitive closure* is the unique transitive graph that implies the same ancestor relationships as  $\mathcal{G}$ , whereas the *transitive reduction* is the unique edge-minimal graph that implies the same ancestor relationships.

In this paper we encounter several well-known graph classes, e.g., chordal graphs and trivially perfect graphs. We will give brief definitions when appropriate, but we direct the reader to the excellent survey by Brandstädt et al. (1999) for further details.

## 3 SIMPLE MARGINAL INDEPENDENCE GRAPHS

In this section we define the class of graphs which can be explained using a directed acyclic graph (DAG) on the same variables. We will refer to such graphs as *simple marginal independence graphs* (SMIGs).

**Definition 3.1.** A graph  $\mathcal{U} = (V, E(\mathcal{U}))$  is called the *simple marginal independence graph* (SMIG), or *marginal independence graph* of a DAG  $\mathcal{G} = (V, E(\mathcal{G}))$  if for all  $v, w \in V$ ,  $v - w \in E(\mathcal{U})$  iff  $v$  and  $w$  have a common ancestor in  $\mathcal{G}$ . If  $\mathcal{U}$  is the marginal independence graph of  $\mathcal{G}$  then we also say that  $\mathcal{G}$  is *faithful* to  $\mathcal{U}$ . **SMIG** is the set of all graphs  $\mathcal{U}$  for which there exists a faithful DAG  $\mathcal{G}$ . Note that each DAG has exactly one marginal independence graph.

Again, we point out that marginal independence graphs are often called (and drawn as) *bidirected graphs* in the literature, though the term “marginal independence graph” has also been used by various authors (e.g. Tan et al., 2014).

### 3.1 SMIGs and Dependency Models

In this subsection we recall briefly the general setting for modeling (in)dependencies proposed by Pearl and Verma (1987) and show the relationship between that model and SMIGs. In the definitions below  $V$  denotes a set of variables and  $X, Y$  and  $Z$  are three disjoint subsets of  $V$ .

**Definition 3.2** (Pearl and Verma (1987)). A *dependency model*  $\mathcal{M}$  over  $V$  is any subset of triplets  $(X, Z, Y)$  which represent independencies, that is,  $(X, Z, Y) \in \mathcal{M}$  asserts that  $X$  is independent of  $Y$  given  $Z$ .

A probabilistic dependency model  $\mathcal{M}_P$  is defined in terms of a probability distribution  $P$  over  $V$ . By definition  $(X, Z, Y) \in \mathcal{M}_P$  iff for any instantiation  $\hat{x}, \hat{y}$  and  $\hat{z}$  of the variables in these subsets  $P(\hat{x} \mid \hat{y} \hat{z}) = P(\hat{x} \mid \hat{z})$ .

A directed acyclic graph dependency model  $\mathcal{M}_{\mathcal{G}}$  is defined in terms of a DAG  $\mathcal{G}$ . By definition  $(X, Z, Y) \in \mathcal{M}_{\mathcal{G}}$  iff  $X$  and  $Y$  are  $d$ -separated by  $Z$  in  $\mathcal{G}$  (for a definition of  $d$ -separation by a set  $Z$  see Pearl and Verma (1987)).

We define a *marginal* dependency model, resp. marginal probabilistic and marginal DAG dependency model, analogously as Pearl and Verma (1987) with the restriction that the second component of any triple  $(X, Z, Y)$  is the empty set. Thus, such marginal dependency models are sets of pairs  $(X, Y)$ . It is easy to see that the following properties are satisfied.

**Lemma 3.3.** *Let  $\mathcal{M}$  be a marginal probabilistic dependency model or a marginal DAG dependency model. Then  $\mathcal{M}$  is closed under:*

*Symmetry:*  $(X, Y) \in \mathcal{M} \Leftrightarrow (Y, X) \in \mathcal{M}$  and

*Decomposition:*  $(X, Y \cup W) \in \mathcal{M} \Rightarrow (X, Y) \in \mathcal{M}$ .

*Moreover, if  $\mathcal{M}$  is a marginal DAG dependency model then it is also closed under*

*Union:*  $(X, Y), (X, W) \in \mathcal{M} \Rightarrow (X, Y \cup W) \in \mathcal{M}$ .

The marginal probabilistic dependency model is not closed under union in general. For instance, consider two independent, uniformly distributed binary variables  $y$  and  $w$  and let  $x = y \oplus w$ , where  $\oplus$  denotes xor of two bits. For the model  $\mathcal{M}_{\mathcal{P}}$  defined in terms of probability over  $x, y, w$  we have that  $(\{x\}, \{y\})$  and  $(\{x\}, \{w\})$  belong to  $\mathcal{M}_{\mathcal{P}}$  but  $(\{x\}, \{y, w\})$  does not.

In this paper we will *not* assume that the marginal independencies in the data are closed under union. Instead, we only consider pairwise independencies, which we formalize as follows.

**Definition 3.4.** *Let  $\mathcal{M}$  be a marginal probabilistic dependency model over  $V$ . Then the simple marginal independence graph  $\mathcal{U} = (V, E(\mathcal{U}))$  of  $\mathcal{M}$  is the graph in which  $x - y \in E(\mathcal{U})$  iff  $(\{x\}, \{y\}) \notin \mathcal{M}$ .*

Thus, in general, marginal independence graphs do not contain any information on higher-order *joint* independencies present in the data. However, under certain common parametric assumptions, dependency models would be closed under union as well. This holds, for instance, if the data are normally distributed. In that case, marginal independence is equivalent to zero covariance, pairwise independence implies joint independence, and marginal independence graphs become covariance graphs.

The following is not difficult to see.

**Proposition 3.5.** *A marginal dependency model  $\mathcal{M}$  which is closed under symmetry, decomposition, and union coincides with the transitive closure of  $\{(\{x\}, \{y\}) : x, y \in V\} \cap \mathcal{M}$  over symmetry and union.*

This Proposition entails that if the marginal dependencies in the data are closed under these properties, then the entire

marginal dependency model is represented by the marginal independence graph.

### 3.2 SMIGs and Partially Ordered Sets

To reach our aim of a complete and constructive characterization of the DAGs faithful to a given SMIG, it is useful to observe that marginal independence graphs are invariant with respect to the insertion or deletion of transitive edges from the DAG. We formalize this as follows.

**Definition 3.6.** *A (labelled) poset  $\mathcal{P}$  is a DAG that is identical to its transitive closure.*

**Proposition 3.7.** *The marginal independence graphs of a DAG  $\mathcal{G}$  and its transitive closure  $\mathcal{P}(\mathcal{G})$  are identical.*

*Proof.* Two nodes are not adjacent in the marginal independence graph iff they have no common ancestor in the DAG. Transitive edges do not influence ancestral relationships.  $\square$

We thus restrict our attention to finding *posets* that are faithful to a given SMIG. Note that faithful DAGs can then be obtained by deleting transitive edges from faithful posets; since no DAG obtained in this way can be an edge subgraph of two different posets, this construction is unique and well-defined. In particular, by deleting *all* transitive edges from a poset, we obtain a sparse graphical representation of the poset as defined below.

**Definition 3.8.** *Given a poset  $\mathcal{P} = (V, E)$ , its transitive reduction is the unique DAG  $\mathcal{G}_{\mathcal{P}} = (V, E')$  for which  $\mathcal{P}(\mathcal{G}) = \mathcal{P}$  and  $E'$  is the smallest set where  $E' \subseteq E$ .*

Transitive reductions are also known as *Hasse diagrams*, though Hasse diagrams are usually unlabeled. Different posets can have the same marginal independence graphs, e.g. the posets with Hasse diagrams  $\mathcal{P}_1 = x \rightarrow y \rightarrow z$  and  $\mathcal{P}_2 = x \leftarrow y \rightarrow z$ . Similarly, Markov equivalence is a sufficient but not necessary condition to inducing the same marginal independence graphs (adding an edge  $x \rightarrow z$  to  $\mathcal{P}_2$  changes the poset and the Markov equivalence class, but not the marginal independence graph).

### 3.3 Recognizing SMIGs

We first recall existing results that show which graphs admit a faithful DAG at all, and how to find such DAGs if possible. Note that many of these results have been stated without proof (Pearl and Wermuth, 1994), but our connection to posets will make some of these proofs straightforward. The following notion related to posets is required.

**Definition 3.9** (Bound graph (McMorris and Zaslavsky, 1982)). *For a poset  $\mathcal{P} = (V, E)$ , the bound graph  $\mathcal{B} = (V, E')$  of  $\mathcal{P}$  is the graph where  $x - y \in E'$  iff  $x$  and  $y$  share a lower bound, i.e., have a common ancestor in  $\mathcal{P}$ .*

Figure 2: Relation between chordal graphs, trivially perfect graphs, and SMIG. In graph theory, SMIG is known as the class of (upper/lower) *bound graphs* (Cheston and Jap, 2006).

**Theorem 3.10.** SMIG is the set of all graphs for which every edge is contained in a simplex.

*Proof.* This is Theorem 2 in Pearl and Wermuth (1994) (who referred to simplexes as “exterior cliques”). Alternatively, we can observe that the marginal independence graph  $\mathcal{U}$  of a poset  $\mathcal{P}$  (Definition 3.1) is equal to its bound graph (Definition 3.9). The characterization of bound graphs as “edge simplicial” graphs has been proven by McMorris and Zaslavsky (1982) by noting that simplicial nodes in  $\mathcal{U}$  correspond to possible minimal elements in  $\mathcal{P}$ . We note that this result predates the equivalent statement in Pearl and Wermuth (1994).  $\square$

Though all bound graphs have a faithful poset, not all bound graphs have one with the same skeleton; see Figure 1a,b for a counterexample. However, the graphs for which a poset with the same skeleton can be found are nicely characterizable in terms of forbidden subgraphs.

**Theorem 3.11** (Pearl and Wermuth (1994)). *Given a graph  $\mathcal{U}$ , a DAG  $\mathcal{G}$  that is faithful to  $\mathcal{U}$  and has the same skeleton exists iff  $\mathcal{U}$  is trivially perfect (i.e.,  $\mathcal{U}$  has no  $P_4 = \text{---}$  nor a  $C_4 = \square$  as induced subgraph).*

It is known that the trivially perfect graphs are the intersection of the bound graphs and the chordal graphs (Figure 2; Cheston and Jap, 2006).

This nice result begs the question whether a similar characterization is also possible for SMIG. As the following observation shows, that is not the case.

**Proposition 3.12.** Every graph  $\mathcal{U}$  is an induced subgraph of some graph  $\mathcal{U}' \in \text{SMIG}$ .

*Proof.* Take any graph  $\mathcal{U} = (V, E)$  and construct a new graph  $\mathcal{U}'$  as follows. For every edge  $e = u - v$  in  $\mathcal{U}$ , add a new node  $v_e$  to  $V$  and add edges  $v_e - u$  and  $v_e - v$ . Obviously  $\mathcal{U}$  is an induced subgraph of  $\mathcal{U}'$ . To see that  $\mathcal{U}'$  is in SMIG, consider the DAG  $\mathcal{G}$  consisting of the nodes in  $\mathcal{U}'$  and the edges  $v \leftarrow v_e \rightarrow u$  and for each newly added

node in  $\mathcal{U}'$ . Then  $\mathcal{U}$  is the marginal independence graph of  $\mathcal{G}$ .  $\square$

The graph class characterization implies efficient recognition algorithms for SMIGs.

**Theorem 3.13.** It can be tested in polynomial time whether a graph  $\mathcal{U}$  is a SMIG.

*Proof.* Verifying the graphical condition of Theorem 3.10 amounts to testing whether all edges reside within a simplex. However, knowing that SMIGs are bound graphs, we can apply an efficient algorithm for bound graph recognition that uses radix sort and simplex elimination and achieves a runtime of  $\mathcal{O}(n + sm)$  (Skowrońska and Sysło, 1984), where  $s \leq n$  is the number of simplexes in the graph. This is typically better than  $\mathcal{O}(n^3)$  because large  $m$  implies small  $s$  and vice versa. Alternatively, we can apply known fast algorithms to find all simplicial nodes (Kloks et al., 2000).  $\square$

## 4 FINDING FAITHFUL POSETS

We now ask how to find faithful DAGs for simple marginal independence graphs. We observed that marginal independence graphs cannot distinguish between transitively equivalent DAGs, so a perhaps more natural question is: which posets are faithful to a given graph? As pointed out before, we can obtain all DAGs from faithful posets in a unique manner by removing transitive edges. A further advantage of the poset representation will turn out to be that the “smallest” and “largest” faithful posets can be characterized uniquely (up to isomorphism); as we shall also see, this is not as easy for DAGs, except for marginal independence graphs in a certain subclass.

### 4.1 Maximal Faithful Posets

Our first aim is to characterize the “upper bound” of the faithful set. That is, we wish to identify those posets for which no edge supergraph is also faithful. We will show that a construction described by Pearl and Wermuth (1994) solves exactly this problem.

**Definition 4.1.** For a graph  $\mathcal{U} = (V, E(\mathcal{U}))$ , the sink graph  $S(\mathcal{U}) = (V, E(S(\mathcal{U})))$  is constructed as follows: for each edge  $u - v$  in  $\mathcal{U}$ , add to  $E(S(\mathcal{U}))$ : (1) an edge  $u \rightarrow v$  if  $Bd(u) \subsetneq Bd(v)$ ; (2) an edge  $u \leftarrow v$  if  $Bd(u) \supsetneq Bd(v)$ ; (3) an edge  $u - v$  if  $Bd(u) = Bd(v)$ .

For instance, the sink graph of the graph in Figure 1a is the graph in Figure 1b.

**Definition 4.2** (Pearl and Wermuth (1994)). A sink orientation of a graph  $\mathcal{U}$  is any DAG obtained by replacing every undirected edge of  $S(\mathcal{U})$  by a directed edge.

We first need to state the following.

**Lemma 4.3.** *Every sink orientation of  $\mathcal{U}$  is a poset.*

*Proof.* Fix a sink orientation  $\mathcal{G}$  and consider any chain  $x \rightarrow y \rightarrow z$ . By construction, this implies that  $\text{Bd}(x) \subsetneq \text{Bd}(z)$ . Hence, if  $x$  and  $z$  are adjacent in the sink graph, then the only possible orientation is  $x \rightarrow z$ . There can be two reasons why  $x$  and  $z$  are not adjacent in the sink graph: (1) They are not adjacent in  $\mathcal{U}$ . But then  $\mathcal{G}$  would not be faithful, since  $\mathcal{G}$  implies the edge  $x - z$ . (2) The edge was not added to the sink graph. But this contradicts  $\text{Bd}(x) \subsetneq \text{Bd}(z)$ .  $\square$

This Lemma allows us to strengthen Theorem 2 by Pearl and Wermuth (1994) in the sense that we can replace “DAG” by “maximal poset” (emphasized):

**Theorem 4.4.**  *$\mathcal{P}$  is a maximal poset faithful to  $\mathcal{U}$  iff  $\mathcal{P}$  is a sink orientation of  $\mathcal{U}$ .*

The following is also not hard to see.

**Lemma 4.5.** *For a SMIG  $\mathcal{U}$ , every DAG  $\mathcal{G}$  that is faithful to  $\mathcal{U}$  is a subgraph of some sink orientation of  $\mathcal{U}$ .*

*Proof.* Obviously the skeleton of  $\mathcal{G}$  cannot contain edges that are not in  $\mathcal{U}$ . So, suppose  $x \rightarrow y$  is an edge in  $\mathcal{G}$  but conflicts with the sink orientation; that is, the sink graph contains the edge  $y \rightarrow x$ . That is the case only if  $\text{Bd}_{\mathcal{U}}(y)$  is a proper subset of  $\text{Bd}_{\mathcal{U}}(x)$ . However, in the marginal independence graph of  $\mathcal{G}$ , any node that is adjacent to  $x$  (has a common ancestor) must also be adjacent to  $y$ . Thus, the marginal independence graph of  $\mathcal{G}$  cannot be  $\mathcal{U}$ .  $\square$

Every maximal faithful poset for  $\mathcal{U}$  can be generated by first fixing a topological ordering of  $\mathcal{S}(\mathcal{U})$  and then generating the DAG that corresponds to that ordering, an idea that has also been mentioned by Drton and Richardson (2008a). This construction makes it obvious that all maximal faithful posets are isomorphic.

For curiosity of the reader, we note that  $\mathcal{S}(\mathcal{U})$  can also be viewed as a *complete partially directed acyclic graph* (CPDAG), which represents the Markov equivalence class of edge-maximal DAGs that are faithful with  $\mathcal{U}$ . CPDAGs are used in the context of inferring DAGs from data (Spirtes et al., 2000; Chickering, 2003; Kalisch and Bühlmann, 2007), which is only possible up to Markov equivalence.

## 4.2 Minimal Faithful Posets

A minimal faithful poset to  $\mathcal{U}$  is one from which no further relations can be deleted without entailing more independencies than are given by  $\mathcal{U}$ .

**Definition 4.6.** *Let  $\mathcal{U} = (V, E)$  be a graph and let  $I \subseteq V$  be an independent set. Then  $I_{\mathcal{U}}^{\rightarrow}$  is the poset consisting of the nodes in  $I$ , their neighbors in  $\mathcal{U}$ , and directed edges  $i \rightarrow j$  for each  $i, j$  where  $j \in N(i)$ .*

Figure 3: (a) A graph  $\mathcal{U}$  with three simplicial nodes  $I$  (open circles). (b) Its unique minimal faithful poset  $I_{\mathcal{U}}^{\rightarrow}$ . (c,d) The unique faithful DAGs with minimum (c) or maximum (d) numbers of edges.

For example, Figure 3b shows the unique  $I_{\mathcal{U}}^{\rightarrow}$  for the graph in Figure 3a.

**Theorem 4.7.** *Let  $\mathcal{U} = (V, E) \in \mathcal{U}$ . Then a poset  $\mathcal{P}$  is a minimal poset faithful to  $\mathcal{U}$  iff  $\mathcal{P} = I_{\mathcal{U}}^{\rightarrow}$  for a set  $I$  consisting of one simplicial vertex for each simplex.*

*Proof.* We first show that if  $I$  is a set consisting of one simplicial node for each simplex, then  $I_{\mathcal{U}}^{\rightarrow}$  is a minimal faithful poset. Every edge  $e \in E(\mathcal{U})$  resides in a simplex, so it is either adjacent to  $I$  or both of its endpoints are adjacent to some  $i \in I$ . In both cases,  $I_{\mathcal{U}}^{\rightarrow}$  implies  $e$ . Also  $I_{\mathcal{U}}^{\rightarrow}$  does not imply more edges than are in  $\mathcal{U}$ . Now, suppose we delete an edge  $i \rightarrow x$  from  $I_{\mathcal{U}}^{\rightarrow}$ . This edge must exist in  $\mathcal{U}$ , else  $i$  was not simplicial. But now  $I_{\mathcal{U}}^{\rightarrow}$  no longer implies this edge. Thus,  $I_{\mathcal{U}}^{\rightarrow}$  is minimal. Second, assume that  $\mathcal{P}$  is a minimal faithful poset. Assume  $\mathcal{P}$  would contain a sequence of two directed edges  $x \rightarrow y \rightarrow z$ . Then  $\mathcal{P}$  would also contain the edge  $x \rightarrow z$ . But then  $y \rightarrow z$  could be deleted from  $\mathcal{P}$  without changing the dependency graph, and  $\mathcal{P}$  was not minimal. So,  $\mathcal{P}$  does not contain any directed path of length more than 1. Next, observe that for each simplex in  $\mathcal{U}$ , the nodes must all have a common ancestor in  $\mathcal{P}$ . Without paths of length  $> 1$ , this is only possible if one node  $i$  in the simplex is a parent of all other nodes, and there are no edges among the child nodes of  $i$ . Finally, each such  $i$  must be a simplicial node in  $\mathcal{U}$ ; otherwise, it would reside in two or more simplexes, and would have to be the unique parent in those simplexes. But then the children of  $i$  would form a single simplex in  $\mathcal{U}$ .  $\square$

Like the maximal posets, all minimal posets are thus isomorphic. We point out that the minimal posets contain no transitive edges and therefore, they are also edge-minimal faithful DAGs. However, this does not imply that minimal posets have the smallest possible number of edges amongst all faithful DAGs (Figure 3). There appears to be no straightforward characterization of the DAGs with the smallest number of edges for marginal independence graphs in general. However, a beautiful one exists for the subclass of trivially perfect graphs.

**Definition 4.8.** *A tree poset is a poset whose transitive reduction is a tree (with edges pointing towards the root).*

**Theorem 4.9.** *A connected SMIG  $\mathcal{U}$  has a faithful tree poset iff it is trivially perfect.*

*Proof.* The bound graph of a tree poset is identical to its *comparability graph* (Brandstädt et al., 1999), which is the skeleton of the poset. Comparability graphs of tree posets coincide with trivially perfect graphs (Wolk, 1965).  $\square$

Since no connected graph on  $n$  nodes can have fewer edges than the transitive reduction of a tree poset on the same nodes (i.e.,  $n - 1$ ), tree posets coincide with faithful DAGs having the smallest possible number of edges.

How do we construct a tree for a given trivially perfect graph? Every such graph must have a *central point*, which is a node that is adjacent to all other nodes. We set this node as the sink of the tree, and continue recursively with the subgraphs obtained after removing the central point. Each subgraph is also trivially perfect and can thus be oriented into a tree. After we are done, we link the sinks of the trees of the subgraphs to the original central point to obtain the full tree (Wolk, 1965).

## 5 FINDING FAITHFUL DAGS

If a given marginal independence graph  $\mathcal{U}$  admits faithful DAG models, then it is of interest to enumerate these. A trivial enumeration procedure is the following: start with the sink graph of  $\mathcal{U}$ , choose an arbitrary edge  $e$ , and form all 2 or 3 subgraphs obtained by keeping  $e$  (if it is directed), orienting  $e$  (if it is undirected), or deleting it. Apply the procedure recursively to these subgraphs. During the recursion, do not touch edges that have been previously chosen. If the current graph is a DAG that is faithful to  $\mathcal{U}$ , output it; otherwise, stop the recursion.

However, we can do better by exploiting the results of the previous section, which will allow us to derive enumeration algorithms that generate representations of multiple DAGs at each step.

### 5.1 Enumeration of Faithful DAGs

Having characterized the maximal and minimal faithful posets, we are now ready to construct an enumeration procedure for all DAGs that are faithful to a given graph. We first state the following combination of Theorem 4.4 and Theorem 4.7.

**Proposition 5.1.** A DAG  $\mathcal{G} = (V, E(\mathcal{G}))$  is faithful to a SMIG  $\mathcal{U} = (V, E(\mathcal{U}))$  iff (1)  $\mathcal{G}$  is an edge subgraph of some sink orientation of  $\mathcal{U}$  and (2) the transitive closure of  $\mathcal{G}$  is an edge supergraph of  $I_{\mathcal{U}}^{\rightarrow}$  for some node set  $I$  consisting of one simplicial node for each simplex.

From this observation, we can derive our first construction procedure for faithful DAGs.

**Proposition 5.2.** A DAG  $\mathcal{G}$  is faithful to a SMIG  $\mathcal{U} = (V, E(\mathcal{U}))$  iff it can be generated by the following steps. (1) Pick any set  $I \subseteq V$  consisting of one simplicial node

Figure 4: Example of the procedure in Proposition 5.2 that, given a SMIG (a), enumerates all faithful DAGs (b). For brevity, only the graphs that correspond to a fixed topological ordering are displayed. Only one set  $I$  (open circles) can be chosen in step (1). Thick edges and filled nodes highlight the DAG  $\mathcal{G}$ . Mandatory edges (solid) link  $I$  to the sources of  $\mathcal{G}$ ; if any such edge was absent, one of the relationships in the poset  $I_{\mathcal{U}}^{\rightarrow}$  would be missing. Optional edges (dashed) are transitively implied from the mandatory ones and  $\mathcal{G}$ .

for each simplex. (2) Generate any DAG on the nodes  $V \setminus I$  that is an edge subgraph of some sink orientation of  $\mathcal{U}$ . (3) Add any subset of edges from  $I_{\mathcal{U}}^{\rightarrow}$  such that the transitive closure of the resulting graph contains all edges of  $I_{\mathcal{U}}^{\rightarrow}$ .

While step (3) may seem ambiguous, Figure 4 illustrates that after step (2), the edges from  $I_{\mathcal{U}}^{\rightarrow}$  decompose nicely into *mandatory* and *optional* ones. This means that we can in fact stop the construction procedure after step (2) and output a “graph pattern”, in which some edges are marked as optional. This is helpful in light of the potentially huge space of faithful models, because every graph pattern can represent an exponential number of DAGs.

### 5.2 Enumeration of Faithful Posets

The DAGs resulting from the procedure in Proposition 5.2 are in general redundant because no care is taken to avoid generating transitive edges. By combining Propositions 5.1 and 5.2, we obtain an algorithm that generates sparse, non-redundant representations of the faithful DAGs.

**Theorem 5.3.** A poset  $\mathcal{P}$  is faithful to  $\mathcal{U} = (V, E(\mathcal{U}))$  iff it can be generated by the following steps. (1) Pick any set  $I \subseteq V$  consisting of one simplicial node for each simplex. (2) Generate a poset  $\mathcal{P}$  on the nodes  $V \setminus I$  that is an edge subgraph of some sink orientation of  $\mathcal{U}$ . (3) Add  $I_{\mathcal{U}}^{\rightarrow}$  to  $\mathcal{P}$ .

A nice feature of this construction is that step (3) is unambiguous: every choice for  $I$  in step (1) and  $\mathcal{P}$  in step (2) yields exactly one poset. Figure 5 gives an explicit pseudocode for an algorithm that uses Theorem 5.3 to enumerate all faithful posets.

Our algorithm is efficient in the sense that at every inter-

```

function FAITHFULPOSETS( $\mathcal{U} = (V(\mathcal{U}), E(\mathcal{U}))$ )
  function LISTPOSETS( $\mathcal{G}, \mathcal{S}, R, I_{\mathcal{U}}^{\rightarrow}$ )
    if  $\mathcal{G}$  is acyclic and atransitive then
      Output  $\mathcal{G} \cup I_{\mathcal{U}}^{\rightarrow}$ 
      if skeleton of  $\mathcal{G} \subsetneq$  skeleton of  $\mathcal{S}$  then
         $e \leftarrow$  some edge consistent with  $E(\mathcal{S}) \setminus R$ 
        LISTPOSETS( $\mathcal{G}, \mathcal{S}, R \cup \{e\}, I_{\mathcal{U}}^{\rightarrow}$ )
         $E(\mathcal{G}) \leftarrow E(\mathcal{G}) \cup \{e\}$ 
        LISTPOSETS( $\mathcal{G}, \mathcal{S}, R \cup \{e\}, I_{\mathcal{U}}^{\rightarrow}$ )
  for all node sets  $I$  of  $\mathcal{U}$  consisting of one simplicial
  node per simplex do
     $\mathcal{G} \leftarrow$  empty graph on nodes of  $V(\mathcal{U}) \setminus I$ 
     $\mathcal{S} \leftarrow$  sink graph of  $\mathcal{U}$  on nodes of  $V(\mathcal{U}) \setminus I$ 
    LISTPOSETS( $\mathcal{G}, \mathcal{S}, \emptyset, I_{\mathcal{U}}^{\rightarrow}$ )

```

Figure 5: Enumeration algorithm for faithful posets.

Figure 6: (a) A graph  $\mathcal{U}$  and its sink graph. (b) Transitive reductions of all 6 faithful posets that are generated by Algorithm FAITHFULPOSETS for the input graph (a).

nal node in its recursion tree, it outputs a faithful poset. At every node we need to evaluate whether the current  $\mathcal{G}$  is acyclic and atransitive (i.e., contains no transitive edges), which can be done in polynomial time. Also simplexes and their simplicial vertices can be found in polynomial time Kloks et al. (2000). Thus, our algorithm is a *polynomial delay enumeration algorithm* similar to the ones used to enumerate adjustment sets for DAGs (Textor and Liškiewicz, 2011; van der Zander et al., 2014). Figure 6 shows an example output for this algorithm.

## 6 EXAMPLE APPLICATIONS

In this section, we apply the previous results to explore some explicit combinatorial properties of SMIGs and their faithful DAGs.

| $n$ | connected graphs | conn. SMIGs | unique DAG |
|-----|------------------|-------------|------------|
| 2   | 1                | 1           | 0          |
| 3   | 2                | 2           | 1          |
| 4   | 6                | 4           | 1          |
| 5   | 21               | 10          | 2          |
| 6   | 112              | 27          | 4          |
| 7   | 853              | 88          | 10         |
| 8   | 11,117           | 328         | 27         |
| 9   | 261,080          | 1,460       | 90         |
| 10  | 11,716,571       | 7,799       | 366        |

Table 1: Comparison of the number of unlabeled connected graphs with  $n$  nodes to the number of such graphs that are also SMIGs. For  $n = 13$  (not shown), non-SMIGs outnumber SMIGs by more than  $10^7 : 1$ .

### 6.1 Counting SMIGs

We revisit the question: when can a marginal independence graph allow a causal interpretation (Pearl and Wermuth, 1994)? More precisely, we ask *how many* marginal independence graphs on  $n$  variables are SMIGs. We reformulate this question into a version that has been investigated in the context of poset theory. Let the *height* of a poset  $\mathcal{P}$  be the length of a longest path in  $\mathcal{P}$ . The following is an obvious implication of Theorem 4.7.

**Corollary 6.1.** *The number  $M(n)$  of non-isomorphic SMIGs with  $n$  nodes is equal to the number of non-isomorphic posets on  $n$  variables of height 1.*

Enumeration of posets is a highly nontrivial problem, and an intensively studied one. The online encyclopedia of integer sequences (OEIS) tabulates  $M(n)$  for  $n$  up to 40 (Wambach, 2015). We give the first 10 entries of the sequence in Table 1 and compare it to the number of graphs in general (up to isomorphism). As we observe, the fraction of graphs that admit a DAG on the same variables decreases swiftly as  $n$  increases.

### 6.2 Graphs with a Unique Faithful DAG

From a causal inference viewpoint, the best we can hope for is a SMIG to which only single, unique DAG is faithful. The classical example is the graph  $\cdot - \cdot - \cdot$ , which for more than 3 nodes generalizes to a “star” graph. However, for 5 or more nodes there are graphs other than the star which also induce a single unique DAG. Combining Lemma 4.5 and Theorem 4.7 allows for a simple characterization of all such SMIGs.

**Corollary 6.2.** *A SMIG  $\mathcal{U}$  with  $n$  nodes has a unique faithful DAG iff each of its simplexes contains only one simplicial node and its sink orientation equals  $I_{\mathcal{U}}^{\rightarrow}$ .*

Based on this characterization, we computed the number of

| $n$ | posets with $n$ nodes | faithful to $C_n$ |
|-----|-----------------------|-------------------|
| 1   | 1                     | 1                 |
| 2   | 3                     | 2                 |
| 3   | 19                    | 9                 |
| 4   | 219                   | 76                |
| 5   | 4,231                 | 1,095             |
| 6   | 130,023               | 25,386            |
| 7   | 6,129,859             | 910,161           |
| 8   | 431,723,379           | 49,038,872        |
| 9   | 44,511,042,511        | 3,885,510,411     |
| 10  | 6,611,065,248,783     | 445,110,425,110   |

Table 2: Possible labelled posets on  $n$  variables before and after observing a complete SMIG  $C_n$ .

SMIGs with unique DAGs for  $n$  up till 9 (Table 1). Interestingly, this integer sequence does not seem to correspond to any known one.

### 6.3 Information Content of a SMIG

How much information does a marginal independence graph contain? Let us denote the number of posets on  $n$  variables by  $P(n)$ . After observing a marginal independence graph  $\mathcal{U}$ , the number of models that are still faithful to the data reduces to size  $P(n) - k(\mathcal{U})$ , where  $k(\mathcal{U}) \leq P(n)$  (indeed, quite often  $k(\mathcal{U}) = P(n)$  as we can see in Table 1). Of course, the number  $k(\mathcal{U})$  strongly depends on the structure of the SMIG  $\mathcal{U}$ . But even in the worst case when  $\mathcal{U}$  is a complete graph, the space of possible models is still reduced because not all DAGs entail a complete marginal independence graph.

Thus, the following simple consequence of Theorem 4.7 helps to derive a worst-case bound on how much a SMIG reduces structural uncertainty with respect to the model space of posets with  $n$  variables.

**Corollary 6.3.** *The number of faithful posets with respect to a complete graph with  $n$  nodes is  $n$  times the number of posets with  $n - 1$  nodes.*

Table 2 lists the number of possible posets before and after observing a complete SMIG for up to 10 variables. In this sense, at  $n = 10$ , the uncertainty is reduced about 15-fold.

We note that a similar but more technical analysis is possible for uncertainty reduction with respect to DAGs instead of posets. We omit this due to space limitations.

## 7 MODELS WITH LATENT VARIABLES

In this section we consider situations in which a graph  $\mathcal{U}$  is not a SMIG (which can be detected using the algorithm in Theorem 3.13). Similarly to the definition proposed in Pearl and Verma (1987) for the general dependency models, to obtain faithful DAGs for such graphs we will extend

the DAGs with some auxiliary nodes. We generalize Definition 3.1 as follows.

**Definition 7.1.** *Let  $\mathcal{U} = (V, E(\mathcal{U}))$  be a graph and let  $Q$ , with  $Q \cap V = \emptyset$ , be a set of auxiliary nodes. A DAG  $\mathcal{G} = (V \cup Q, E(\mathcal{G}))$  is faithful to  $\mathcal{U}$  if for all  $v, w \in V$ ,  $v - w \in E(\mathcal{U})$  iff  $v$  and  $w$  have a common ancestor in  $\mathcal{G}$ .*

The result below follows immediately from Proposition 3.12.

**Proposition 7.2.** *For every graph  $\mathcal{U}$  there exists a faithful DAG  $\mathcal{U}$  with some auxiliary nodes.*

Obviously, if  $\mathcal{U} \in \text{SMIG}$  then there exists a faithful DAG to  $\mathcal{U}$  with  $Q = \emptyset$ . For  $\mathcal{U} \notin \text{SMIG}$ , from the proof of Proposition 3.12 it follows that there exists a set  $Q$  of at most  $|E(\mathcal{U})|$  nodes and a DAG  $\mathcal{G}$  such that  $\mathcal{G}$  is faithful to  $\mathcal{U}$  with auxiliary nodes  $Q$ . But the problem arises to minimize the cardinality of  $Q$ .

**Theorem 7.3.** *The problem to decide if for a given graph  $\mathcal{U}$  and an integer  $k$ , there exists a faithful DAG with at most  $k$  auxiliary nodes, is NP-complete.*

*Proof.* It is easy to see that the problem is in NP. To prove that it is NP-hard, we show a polynomial time reduction from the edge clique cover problem, that is known to be NP-complete (Karp, 1972). Recall that the problem edge clique cover is to decide if for a graph  $\mathcal{U}$  and an integer  $k$  there exist a set of  $k$  subgraphs of  $\mathcal{U}$ , such that each subgraph is a clique and each edge of  $\mathcal{U}$  is contained in at least one of these subgraphs?

Let  $\mathcal{U} = (V, E)$  and  $k$  be an instance of the edge clique cover problem, with  $V = \{v_1, \dots, v_n\}$ . We construct the marginal independence graph  $\mathcal{U}'$  as follows. Let  $W = \{w_1, \dots, w_n\}$ . Then  $V(\mathcal{U}') = V \cup W$  and  $E(\mathcal{U}') = E \cup \{v_i - w_i : i = 1, \dots, n\}$ . Obviously,  $\mathcal{U}'$  can be constructed from  $\mathcal{U}$  in polynomial time. We claim that  $\mathcal{U} = (V, E)$  can be covered by  $\leq k$  cliques iff for  $\mathcal{U}'$  there exists a faithful DAG  $\mathcal{G}$  with at most  $k$  auxiliary nodes.

Assume first that  $\mathcal{U} = (V, E)$  can be covered by at most  $k$  cliques, let us say  $C_1, \dots, C_{k'}$ , with  $k' \leq k$ . Then we can construct a faithful DAG  $\mathcal{G}$  for  $\mathcal{U}'$  with  $k'$  auxiliary nodes as follows. Its set of nodes is  $V(\mathcal{G}) = V \cup W \cup Q$ , where  $Q = \{q_1, \dots, q_{k'}\}$ . The edges  $E(\mathcal{G})$  can be defined as

$$\{w_i \rightarrow v_i : i = 1, \dots, n\} \cup \bigcup_j \{q_j \rightarrow v : v \in C_j\}.$$

It is easy to see that  $\mathcal{G}$  is faithful to  $\mathcal{U}'$ .

Now assume that a DAG  $\mathcal{G}$ , with at most  $k$  auxiliary nodes  $Q$ , is faithful to  $\mathcal{U}'$ . From the construction of  $\mathcal{U}'$  it follows that for all different nodes  $v_i, v_j \in V$  there is no directed path from  $v_i$  to  $v_j$  in  $\mathcal{G}$ . If such a path exists, then  $v_i$  is an ancestor of  $v_j$  in  $\mathcal{G}$ . Since  $v_i - w_i$  is an edge of  $\mathcal{U}'$ , the nodes  $v_i$  and  $w_i$  have a common ancestor in  $\mathcal{G}$ , which must be also

a common ancestor of  $w_i$  and  $v_j$  – a contradiction because  $w_i$  and  $v_j$  are not incident in  $\mathcal{U}'$ . Thus, all treks connecting pairs of nodes from  $V$  in  $\mathcal{G}$  must contain auxiliary nodes.

Next, we slightly modify  $\mathcal{G}$ : for each  $w_i$  we remove all incident edges and add the new edge  $w_i \rightarrow v_i$ . The resulting graph  $\mathcal{G}'$ , is a DAG which remains faithful to  $\mathcal{U}'$ . Indeed, we cannot obtain a directed cycle in the  $\mathcal{G}'$  since no  $w_i$  has an in-edge and the original  $\mathcal{G}$  was a DAG. To see that the obtained DAG remains faithful to  $\mathcal{U}'$  note first that after the modifications,  $w_i$  and  $v_i$  have a common ancestor in  $\mathcal{G}$  whereas  $w_i$  and  $v_j$ , with  $i \neq j$ , do not. Otherwise, it would imply a directed path from  $v_i$  to  $v_j$  since  $w_i$  is the only possible ancestor of both nodes – a contradiction. Finally, note that any trek connecting  $v_i$  and  $v_j$  in  $\mathcal{G}$  cannot contain a node from  $W$ . Similarly, no trek between  $v_i$  and  $v_j$  in  $\mathcal{G}'$  contains a node from  $W$ . We get that  $v_i$  and  $v_j$  have a common ancestor in  $\mathcal{G}$  iff they have a common ancestor in  $\mathcal{G}'$ .

Thus, in  $\mathcal{G}'$  the auxiliary nodes  $Q$  are incident to  $V$ , but not to nodes from  $W$ . Below we modify  $\mathcal{G}'$  further and obtain a DAG  $\mathcal{G}''$ , in which every auxiliary node is incident with a node in  $V$  via an out-edge only. To this aim we remove from  $\mathcal{G}'$  all edges going out from a node in  $V$  to a node in  $Q$ .

Obviously, if  $v_i$  and  $v_j$  have a common ancestor in  $\mathcal{G}''$ , then they also have a common ancestor in  $\mathcal{G}'$ , because  $E(\mathcal{G}'') \subseteq E(\mathcal{G}')$ . The opposite direction follows from the fact we have shown at the beginning of this proof that for all different nodes  $v_i, v_j \in V$  there is no directed path from  $v_i$  to  $v_j$  in  $\mathcal{G}$ . This is true also for  $\mathcal{G}'$ . Thus, if  $v_i$  and  $v_j$  have a common ancestor, say  $x$ , in  $\mathcal{G}'$  then  $x \in Q$  and there exist directed paths  $x \rightarrow y_1 \rightarrow \dots \rightarrow y_r \rightarrow v_i$  and  $x \rightarrow y'_1 \rightarrow \dots \rightarrow y'_{r'} \rightarrow v_j$  such that also all  $y_1, \dots, y_r$  and  $y'_1, \dots, y'_{r'}$  belong to  $Q$ . But from the construction of  $\mathcal{G}''$  it follows that both paths belong also to  $\mathcal{G}''$ .

Since  $\mathcal{G}''$  is faithful to  $\mathcal{U}$ , for every auxiliary node  $Q$  the subgraph induced by its children  $Ch(Q) \cap V$  in  $\mathcal{G}''$  is a clique in  $\mathcal{U}'$ . Moreover every edge  $v_i - v_j$  of the graph  $\mathcal{U}$  belongs to at least one such clique. Thus the subgraphs induced by  $Ch(q_1) \cap V, \dots, Ch(q_{k'}) \cap V$ , with  $k' \leq k$ , are cliques that cover  $\mathcal{U}$ .  $\square$

## 8 DISCUSSION

Given a graph that represents a set of pairwise marginal independencies, which causal structures on the same variables might have generated this graph? Here we characterized all these structures, or alternatively, all maximal and minimal ones. Furthermore, we have shown that it is possible to deduce how many exogenous variables (which correspond to simplicial nodes) the causal structure might have, and even to tell whether it might be a tree. For graphs that do not admit a DAG on the same variables, we have studied

the problem of explaining the data with as few additional variables as possible, and proved it to be NP-hard. This may be surprising; the related problem of finding a mixed graph that is Markov equivalent to a bidirected graph and has as few bidirected edges as possible is efficiently solvable (Drton and Richardson, 2008a).

The connection to posets emphasizes that sets of faithful DAGs have complex combinatorics. Indeed, if there are no pairwise independent variables, then we obtain the classical poset enumeration problem (Brinkmann and McKay, 2002). Our current, unoptimized implementation of the algorithm in Figure 5 allows us to deal with dense graphs up to about 12 nodes (sparse graphs are easier to deal with). We point out that our enumeration algorithms operate with a “template graph”, i.e., the sink orientation. It is possible to incorporate certain kinds of background knowledge, like a time-ordering of the variables, into this template graph by deleting some edges. Such further constraints could greatly reduce the search space. Another additional constraint that could be used for linear models is the precision matrix (Cox and Wermuth, 1993; Pearl and Wermuth, 1994), though finding DAGs that explain a given precision matrix is NP-hard in general (Verma and Pearl, 1993),

We observed that the pairwise marginal independencies substantially reduce structural uncertainty even in the worst case (Table 1). Causal inference algorithms could exploit this to reduce the number of CI tests. The PC algorithm (Kalisch and Bühlmann, 2007), for instance, forms the marginal independence graph as a first stage before performing any CI tests. At that stage, it could be immediately tested if the resulting graph is a SMIG, and if not, the algorithm can terminate as no faithful DAG exists.

In summary, we have mapped out the space of causal structures that are faithful to a given set of pairwise marginal independencies using constructive criteria that lead to well-structured enumeration procedures. The central idea underlying our results is that faithful models for marginal independencies are better described by posets than by DAGs. Our results allow to quantify how much our uncertainty about a causal structure is reduced when we invoke the faithfulness assumption and observe a set of marginal independencies.

In future work, it would be interesting to extend our approach to small (instead of empty) conditioning sets, which would cover cases where we only wish to perform CI tests with low dimensionality.

## Abstract

Many inference problems in structured prediction are naturally solved by augmenting a tractable dependency structure with complex, non-local auxiliary objectives. This includes the mean field family of variational inference algorithms, soft- or hard-constrained inference using Lagrangian relaxation or linear programming, collective graphical models, and forms of semi-supervised learning such as posterior regularization. We present a method to discriminatively *learn* broad families of inference objectives, capturing powerful non-local statistics of the latent variables, while maintaining tractable and provably fast inference using non-Euclidean projected gradient descent with a distance-generating function given by the Bethe entropy. We demonstrate the performance and flexibility of our method by (1) extracting structured citations from research papers by learning soft global constraints, (2) achieving state-of-the-art results on a widely-used handwriting recognition task using a novel learned non-convex inference procedure, and (3) providing a fast and highly scalable algorithm for the challenging problem of inference in a collective graphical model applied to bird migration.

## 1 INTRODUCTION

Structured prediction has shown great success in modeling problems with complex dependencies between output variables. Practitioners often use undirected graphical models, which encode conditional dependency relationships via a graph. However, the tractability of exact inference in these models is limited by the graph’s *treewidth*, often yielding a harsh tradeoff between model expressivity and tractability.

---

\* Equal contribution.

Graphical models are good at modeling local dependencies between variables, such as the importance of surrounding context in determining the meaning of words or phrases. However, their sensitivity to cyclic dependencies often renders them unsuitable for modeling preferences for certain globally consistent states. For example, in the canonical NLP task of part-of-speech tagging, there is no clear way to enforce the constraint that every sentence have at least one verb without increasing the likelihood that *every* token is predicted to be a verb.

Concretely, exact marginal inference in a discrete graphical model can be posed as the following optimization problem

$$\boldsymbol{\mu}^* = \arg \min_{\boldsymbol{\mu} \in \mathcal{M}} -H(\boldsymbol{\mu}) - \langle \boldsymbol{\theta}, \boldsymbol{\mu} \rangle, \quad (1)$$

where  $\boldsymbol{\mu}$  is a concatenated vector of node and clique marginals,  $H(\boldsymbol{\mu})$  is the entropy,  $\mathcal{M}$  is the marginal polytope, and  $\boldsymbol{\theta}$  are parameters. Here we face a tradeoff: adding long-range dependencies directly to the model increases the clique size and thus the complexity of the problem and size of  $\boldsymbol{\mu}$ , rendering inference intractable. However, the linear scoring function  $\boldsymbol{\theta}$  breaks down over cliques, preventing us from enforcing global regularities in any other way. In this work, we propose to augment the inference objective (1) and instead optimize

$$\boldsymbol{\mu}^* = \arg \min_{\boldsymbol{\mu} \in \mathcal{M}} -H(\boldsymbol{\mu}) - \langle \boldsymbol{\theta}, \boldsymbol{\mu} \rangle + L_{\psi}(\boldsymbol{\mu}). \quad (2)$$

Here,  $L_{\psi}$  is some arbitrary parametric function of the entire concatenated marginal vector, where  $\psi$  may depend on input features. Since  $L_{\psi}$  is non-linear, it can enforce many types of non-local properties. Interestingly, whenever  $L_{\psi}$  is convex, and whenever inference is easy in the underlying model, i.e., solving (1) is tractable, we can solve (2) using non-Euclidean projected gradient methods using the Bethe entropy as a distance-generating function. Unlike many message-passing algorithms, our procedure maintains primal feasibility across iterations, allowing its use as an *any-time* algorithm. Furthermore, for non-convex  $L_{\psi}$ , we also show convergence to a local optimum of (2). Finally, we

present algorithms for discriminative learning of the parameters  $\psi$ . In a slight abuse of terminology, we call  $L_\psi$  a *non-local energy function*.

Ours is not the first work to consider modeling global preferences by augmenting a tractable base inference objective with non-local terms. For example, generalized mean-field variational inference algorithms augment a tractable distribution (the  $Q$  distribution) with a non-linear, non-convex global energy function that scores terms in the full model (the  $P$  distribution) using products of marginals of  $Q$  (Wainwright & Jordan, 2008). This is one special case of our non-local inference framework, and we present algorithms for solving the problem for much more general  $L_\psi$ , with compelling applications.

Additionally, the modeling utility provided by global preferences has motivated work in *dual decomposition*, where inference in loopy or globally-constrained models is decomposed into repeated calls to inference in tractable independent subproblems (Komodakis et al., 2007; Sontag et al., 2011). It has seen wide success due to its ease of implementation, since it reuses existing inference routines as black boxes. However, the technique is restricted to modeling linear constraints, imposed *a priori*. Similarly, these types of constraints have also been imposed on expectations of the posterior distribution for use in semi-supervised learning, as in *posterior regularization* and *generalized expectation* (Ganchev et al., 2010; Mann & McCallum, 2010). In contrast, our methods are designed to discriminatively learn expressive inference procedures, with minimal domain knowledge required, rather than regularizing inference and learning.

First, we provide efficient algorithms for solving the marginal inference problem (2) and performing MAP prediction in the associated distribution, for both convex and non-convex global energy functions. After that, we provide a learning algorithm for  $\theta$  and the parametrized  $L_\psi$  functions using an interpretation of (2) as approximate variational inference in a probabilistic model. All of our algorithms are easy to implement and rely on simple wrappers around black-box inference subroutines.

Our experiments demonstrate the power and generality of our approach by achieving state-of-the-art results on several tasks. We extract accurate citations from research papers by learning discriminative global regularities of valid outputs, outperforming a strong dual decomposition-based baseline (Anzaroot et al., 2014). In a benchmark OCR task (Taskar et al., 2004), we achieve state-of-the-art results with a learned non-convex, non-local energy function, that guides output decodings to lie near dictionary words. Finally, our general algorithm for solving (2) provides large speed improvements for the challenging task of inference in chain-structured *collective graphical models* (CGMs), applied to bird migration (Sheldon & Dietterich, 2011).

## 2 BACKGROUND

Let  $\mathbf{y} = (y_1, \dots, y_n)$  denote a set of discrete variables and  $\mathbf{x}$  be a collection of input features. We define the conditional distribution  $P_\theta(\mathbf{y}|\mathbf{x}) = \exp(\langle \theta(\mathbf{x}), S(\mathbf{y}) \rangle) / Z$ , where  $S(\mathbf{y})$  is a mapping from  $\mathbf{y}$  to a set of sufficient statistics,  $\theta(\mathbf{x})$  is a differentiable vector-valued mapping, and  $Z = \sum_{\mathbf{y}} \exp(\langle \theta, S(\mathbf{y}) \rangle)$ . Conditional random fields (CRFs) assume that  $(y_1, \dots, y_n)$  are given a graph structure and  $S(\mathbf{y})$  maps  $\mathbf{y}$  to a 0-1 vector capturing joint settings of each clique (Lafferty et al., 2001). Going forward, we often suppress the explicit dependency of  $\theta$  on  $\mathbf{x}$ . For fixed  $\theta$ , the model is called a Markov random field (MRF).

Given a distribution  $P(\mathbf{y})$ , define the expected sufficient statistics operator  $\mu(P) = \mathbb{E}_P[S(\mathbf{y})]$ . For the CRF statistics  $S(\mathbf{y})$  above,  $\mu$  is a concatenated vector of node and clique marginals. Therefore, *marginal inference*, the task of finding the marginal distribution of  $P_\theta(\mathbf{y}|\mathbf{x})$  over  $\mathbf{y}$ , is equivalent to computing the expectation  $\mu(P_\theta(\mathbf{y}|\mathbf{x}))$ .

For tree-structured graphical models,  $P_\theta(\mathbf{y}|\mathbf{x}) \leftrightarrow \mu(P_\theta(\mathbf{y}|\mathbf{x}))$  is a bijection, though this is not true for general graphs. Furthermore, for trees the entropy  $H(P_\theta(\mathbf{y}|\mathbf{x}))$  is equal to the Bethe entropy  $H_B(\mu(P_\theta(\mathbf{y}|\mathbf{x})))$ , defined, for example, in Wainwright & Jordan (2008). The *marginal polytope*  $\mathcal{M}$  is the set of  $\mu$  that correspond to some  $P_\theta$ .

As mentioned in the introduction, marginal inference can be posed as the optimization problem (1). MAP inference finds the joint setting  $\mathbf{y}$  with maximum probability. For CRFs, this is equivalent to

$$\arg \min_{\mathbf{y}} \langle -\theta(\mathbf{x}), S(\mathbf{y}) \rangle. \quad (3)$$

For tree-structured CRFs, marginal and MAP inference can be performed efficiently using dynamic programming. Our experiments focus on such graphs. However, the inference algorithms we present can be extended to general graphs wherever marginal inference is tractable using a convex entropy approximation and a local polytope relaxation.

## 3 MARGINAL INFERENCE WITH NON-LOCAL ENERGIES

We move beyond the standard inference objective (1), augmenting it with a non-local energy term as in (2):

$$\mu^* = \arg \min_{\mu \in \mathcal{M}} -H_B(\mu) - \langle \theta, \mu \rangle + L_\psi(\mu).$$

Here,  $L_\psi$  is some arbitrary parametrized function of the marginals, and  $\psi$  may depend on input features  $\mathbf{x}$ .

Intuitively, we are augmenting the inference objective (1) by allowing it to optimize a broader set of tradeoffs – not

only between expected node scores, clique scores, and entropy, but also global functions of the marginals. To be concrete, in our citation extraction experiments (Section 8.1), for example, we employ the simple structure:

$$L_\psi(\boldsymbol{\mu}) = \sum_j \psi_j \ell_j(\boldsymbol{\mu}), \quad (4)$$

Where each  $\ell_j$  is a univariate convex function and each  $\psi_j$  is constrained to be non-negative, in order to maintain the overall convexity of  $L_\psi$ . We further employ

$$\ell_j(\boldsymbol{\mu}) = \tilde{\ell}_j(a_j^\top \boldsymbol{\mu}), \quad (5)$$

where  $a_j$  encodes a ‘linear measurement’ of the marginals and  $\tilde{\ell}_j$  is some univariate convex function.

#### 4 VARIATIONAL INTERPRETATION AND MAP PREDICTION

We next provide two complementary interpretations of (2) as variational inference in a class of tractable probability distributions over  $\mathbf{y}$ . They yield precisely the same variational expression. However, both are useful because the first helps motivate a MAP prediction algorithm, while the second helps characterize our learning algorithm in Section 7 as (approximate) variational EM.

**Proposition 1.** *For fixed  $\boldsymbol{\theta}$  and  $L_\psi$ , the output  $\boldsymbol{\mu}^*$  of inference in the augmented objective (2) is equivalent to the output of standard inference (1) in an MRF with the same clique structure as our base model, but with a modified parameter  $\tilde{\boldsymbol{\theta}} = \boldsymbol{\theta} - \nabla L_\psi(\boldsymbol{\mu}^*)$ .*

*Proof.* Forming a Lagrangian for (2), the stationarity conditions with respect to the variable  $\boldsymbol{\mu}$  are:

$$0 = -(\boldsymbol{\theta} - \nabla L_\psi(\boldsymbol{\mu}^*)) - \nabla H_B(\boldsymbol{\mu}^*) + \nabla_\mu C(\boldsymbol{\mu}, \boldsymbol{\lambda}), \quad (6)$$

where  $C(\boldsymbol{\mu}, \boldsymbol{\lambda})$  are collected terms relating to the marginal polytope constraints. The proposition follows because (6) is the same as the stationarity conditions for

$$\boldsymbol{\mu}^* = \arg \min_{\boldsymbol{\mu} \in \mathcal{M}} -\langle \boldsymbol{\theta} - \nabla L_\psi(\boldsymbol{\mu}^*), \boldsymbol{\mu} \rangle - H_B(\boldsymbol{\mu}). \quad \square \quad (7)$$

Therefore, we can characterize a joint distribution over  $\mathbf{y}$  by first finding  $\boldsymbol{\mu}^*$  by solving (2) and then defining an MRF over  $\mathbf{y}$  with parameters  $\tilde{\boldsymbol{\theta}}$ . Even more conveniently, our inference technique in Section 6 iteratively estimates  $\tilde{\boldsymbol{\theta}}$  on the fly, namely via the dual iterate  $\boldsymbol{\theta}_t$  in Algorithm 1.

Ultimately, in many prediction problems we seek a single output configuration  $\mathbf{y}$  rather than an inferred distribution over outputs. Proposition 1 suggests a simple prediction procedure: first, find the variational distribution over  $\mathbf{y}$  parametrized as an MRF with parameter  $\tilde{\boldsymbol{\theta}}$ . Then, perform

MAP in this MRF. Assuming an available marginal inference routine for this MRF, we assume the tractability of MAP – for example using a dynamic program. We avoid predicting  $\mathbf{y}$  by locally maximizing nodes’ marginals, since this would not necessarily yield feasible outputs.

Instead of solving (2), we could have introduced global energy terms to the MAP objective (3) that act directly on values  $S(\mathbf{y})$  rather than on expectations  $\boldsymbol{\mu}$ , as in (2). However, this yields a difficult combinatorial optimization problem for prediction and does not yield a natural way to learn the parametrization of the global energy. Section 8.1 demonstrates that using energy terms defined on marginals, and performing MAP inference in the associated MRF, performs as well or better than an LP technique designed to directly perform MAP subject to global penalty terms.

Our second variational interpretation characterizes  $\boldsymbol{\mu}^*$  as a variational approximation to a complex joint distribution:

$$P_c(\mathbf{y}|\mathbf{x}) = (1/Z_{\boldsymbol{\theta},\psi})P_\theta(\mathbf{y}|\mathbf{x})P_\psi(\mathbf{y}|\mathbf{x}). \quad (8)$$

We assume that isolated marginal inference in  $P_\theta(\mathbf{y}|\mathbf{x})$  is tractable, while  $P_\psi(\mathbf{y}|\mathbf{x})$  is an alternative structured distribution over  $\mathbf{y}$  for which we do not have an efficient inference algorithm. Specifically, we assume that (1) can be solved for  $P_\theta$ . Furthermore, we assume that  $P_\psi(\mathbf{y}|\mathbf{x}) \propto \exp(L_\psi(S(\mathbf{y}); \mathbf{x}))$ , where  $L_\psi(\cdot; \mathbf{x})$  is a convex function, conditional on input features  $\mathbf{x}$ . Going forward, we will often suppress the dependence of  $L_\psi$  on  $\mathbf{x}$ . Above,  $Z_{\boldsymbol{\theta},\psi}$  is the normalizing constant of the combined distribution. Note that if  $L$  was linear, inference in both  $P_\psi(\mathbf{y}|\mathbf{x})$  and  $P_c(\mathbf{y}|\mathbf{x})$  would be tractable, since the distribution would decompose over the same cliques as  $P_\theta(\mathbf{y}|\mathbf{x})$ .

Not surprisingly, (8) is intractable to reason about, due to the non-local terms in (2), so we approximate it with a variational distribution  $Q(\mathbf{y})$ . The connection between this variational approximation and Proposition 1 is derived in Appendix A. Here, we assume no clique structure on  $Q(\mathbf{y})$ , but show that minimizing a variational upper bound on  $KL(Q(\mathbf{y})||P_c(\mathbf{y}|\mathbf{x}))$ , for a given  $\mathbf{x}$ , yields a  $Q$  that is parametrized compactly as the MRF in Proposition 1. We discuss the relationship between this and general mean-field inference in Section 5.

Although the analysis of this section assumes convexity of  $L_\psi$ , our inference techniques can be applied to non-convex  $L_\psi$ , as discussed in Section 6.3, and our learning algorithm produces state-of-the-art results even in the non-convex regime for a benchmark OCR task.

#### 5 RELATED MODELING TECHNIQUES

**Mean field** variational inference in undirected graphical models is a particular application of our inference framework, with a non-convex  $L_\psi$  (Wainwright & Jordan, 2008).

The technique estimates marginal properties of a complex joint distribution  $P$  using the clique marginals  $\mu$  of some tractable base distribution  $Q$ , not necessarily fully factorized. This induces a partitioning of the cliques of  $P$  into those represented directly by  $\mu$  and those where we define clique marginals as a product distribution of the relevant nodes' marginals in  $\mu$ . To account for the energy terms of the full model involving cliques absent in the simple base model, the energy  $\langle \theta, \mu \rangle$  of the base model is augmented with an extra function of  $\mu$ .

$$L(\mu) = - \sum_{c \in \mathcal{C}} \left\langle \theta_c, \bigotimes_{n \in c} \mu_n \right\rangle \quad (9)$$

where  $\mathcal{C}$  is the set of cliques not included in the tractable sub-model,  $\theta_c$  are the potentials of the original graphical model corresponding to the missing cliques, and  $\bigotimes_n \mu_n$  represents a repeated outer (tensor) product of the node marginals for the nodes in those cliques.

Note  $L(\mu)$  is non-linear and non-convex. Our work generalizes (9) by allowing arbitrary non-linear interaction terms between components of  $\mu$ . This is very powerful – for example, in our citation extraction experiments in Section 8.1, expressing these global terms in a standard graphical model would require many factors touching all variables. Local coordinate ascent mean-field can be frustrated by these rigid global terms. Our gradient-based method avoids these issues by updating all marginals simultaneously.

**Dual decomposition** is a popular method for performing MAP inference in complex structured prediction models by leveraging repeated calls to MAP in tractable submodels (Komodakis et al., 2007; Sontag et al., 2011). The family of models solvable with dual decomposition is limited, however, because the terms that link the submodels must be expressible as linear constraints. Similar MAP techniques (Ravikumar et al., 2010; Martins et al., 2011; Fu & Banerjee, 2013) based on the alternating direction method of multipliers (ADMM) can be adapted for marginal inference, in problems where marginal inference in submodels is tractable. However, the non-local terms are defined as linear functions on settings of graphical model nodes, while our non-linear  $L_\psi(\mu)$  terms provide practitioners with an expressive means to learn and enforce regularities of the inference output.

**Posterior regularization** (PR) (Ganchev et al., 2010), **learning from measurements** (LFM) Liang et al. (2009), and **generalized expectations** (GE) (Mann & McCallum, 2010), are a family of closely-related techniques for performing unsupervised or semi-supervised learning of a conditional distribution  $P_\theta(y|x)$  or a generative model  $P_\theta(x|y)$  using expectation-maximization (EM), where the E-step for latent variables  $y$  does not come directly from inference in the model, but instead from projection onto a set of expectations obeying global regularity properties. In PR

and GE, this yields a projection objective of the form (2), where the  $L_\psi$  terms come from a Lagrangian relaxation of regularity constraints, and  $\psi$  corresponds to dual variables. Originally, PR employed linear constraints on marginals, but He et al. (2013) extend the framework to arbitrary convex differentiable functions. Similarly, in LFM such an inference problem arises because we perform posterior inference assuming that the observations  $y$  have been corrupted under some noise model. Tarlow & Zemel (2012) also present a method for learning with certain forms of non-local losses in a max-margin framework.

Our goals are very different than the above learning methods. We do not impose non-local terms  $L_\psi$  in order to regularize our learning process or allow it to cope with minimal annotation. Instead, we use  $L_\psi$  to increase the expressivity of our model, performing inference for every test example, using a different  $\psi$ , since it depends on input features. Since we are effectively ‘learning the regularizer,’ on fully-labeled data, our learning approach in Section 7 differs from these methods. Finally, unlike these frameworks, we employ non-convex  $L_\psi$  terms in some of our experiments. The algorithmic consequences of non-convexity are discussed in Section 6.3.

## 6 OPTIMIZING THE NON-LOCAL MARGINAL INFERENCE OBJECTIVE

We now present an approach to solving (2) using non-Euclidean projected gradient methods, which require access to a procedure for marginal inference in the base distribution (which we term the *marginal oracle*), as well as access to the gradient of the energy function  $L_\psi$ . We pose these algorithms in the *composite minimization* framework, which gives us access to a wide variety of algorithms that are discussed in the supplementary material.

### 6.1 CONVEX OPTIMIZATION BACKGROUND

Before presenting our algorithms, we review several definitions from convex analysis (Rockafellar, 1997).

We call a function  $\varphi$   $\sigma$ -strongly convex with respect to a norm  $\|\cdot\|_P$ , if for all  $x, y \in \text{dom}(\varphi)$ ,

$$\varphi(y) \geq \varphi(x) + \nabla\varphi(x)^T(y-x) + \frac{\sigma}{2}\|y-x\|_P^2.$$

**Proposition 2** (e.g. Beck & Teboulle (2003)). *The negative entropy function  $-H(x) = \sum_i x_i \log x_i$  is 1-strongly convex with respect to the 1-norm  $\|\cdot\|_1$  over the interior of the simplex  $\Delta$  (restricting  $\text{dom}(H)$  to  $\text{int}(\Delta)$ ).*

Given a smooth and strongly convex function  $\varphi$ , we can also define an associated generalized (asymmetric) distance measure called the *Bregman divergence* (Bregman, 1967)

---

**Algorithm 1** Bethe-RDA

---

**Input:** parameters  $\theta$ , energy function  $L_{\psi}(\mu)$   
 set  $\theta_0 = \theta$   
 set  $\mu_0$  to prox-center MARGINAL-ORACLE( $\theta_0$ )  
 $\bar{g}_0 = 0$   
**repeat**  
 $\beta_t = \text{constant} \geq 0$   
 $\bar{g}_t = \frac{t-1}{t}\bar{g}_{t-1} + \frac{1}{t}\nabla L(\mu_t)$   
 $\theta_t = \theta - \frac{t}{t+\beta_t}\bar{g}_t$   
 $\mu_t = \text{MARGINAL-ORACLE}(\theta_t)$   
**until** CONVERGED( $\mu_t, \mu_{t-1}$ )

---

generated by  $\varphi$ ,

$$B_{\varphi}(x, x_0) = \varphi(x) - \varphi(x_0) - \langle \nabla \varphi(x_0), x - x_0 \rangle.$$

For example, the KL divergence is the Bregman divergence associated to the negative entropy function, and the squared Euclidean distance is its own associated divergence.

*Composite minimization* (Passty, 1979) is a family of techniques for minimizing functions of the form  $h = f + R$ , where we have an oracle that allows us to compute minimizations over  $R$  in closed form (usually  $R$  here takes the form of a regularizer). Problems of this form are often solved with an algorithm called *proximal gradient*, which minimizes  $h(x)$  over some convex set  $X$  using:

$$x_{t+1} = \arg \min_{x \in X} \langle \nabla f(x_t), x \rangle + \frac{1}{2\eta_t} \|x - x_t\|_2^2 + R(x),$$

for some decreasing sequence of learning rates  $\eta_t$ . Note that because of the requirement  $x \in X$ , proximal gradient generalizes projected gradient descent – since unconstrained minimization might take us out of the feasible region  $X$ , computing the update requires projecting onto  $X$ .

But there is no reason to use the squared Euclidean distance when computing our updates and performing the projection. In fact, the squared term can be replaced by any Bregman divergence. This family of algorithms includes the *mirror descent* and *dual averaging* algorithms (Beck & Teboulle, 2003; Nesterov, 2009).

We base our projected inference algorithms on *regularized dual averaging* (RDA) (Xiao, 2010). The updates are:

$$x_{t+1} = \arg \min_{x \in X} \langle \bar{g}_t, x \rangle + \frac{\beta_t}{t} \varphi(x) + R(x), \quad (10)$$

where  $\bar{g}_t = \frac{1}{t} \sum_k^t \nabla f(x_k)$  is the average gradient of  $f$  encountered so far. One benefit of RDA is that it does not require the use of a learning rate parameter ( $\beta_t = 0$ ) when using a strongly convex regularizer. RDA can be interpreted as doing a projection onto  $X$  using the Bregman divergence generated by the strongly convex function  $\varphi + R$ .

## 6.2 OUR ALGORITHM

These non-Euclidean proximal algorithms are especially helpful when we are unable to compute a projection in terms of Euclidean distance, but can do so using a different Bregman divergence. We will show that this is exactly the case for our problem of projected inference: the marginal oracle allows us to project in terms of KL divergence.

However, to maintain tractability we avoid using the entropy function  $H$  on the exponentially-large simplex  $\Delta$ , and instead optimize over the structured, factorized marginal polytope  $\mathcal{M}$  and its corresponding structured Bethe entropy  $H_{\mathcal{B}}$ . For tree-structured models,  $H$  and  $H_{\mathcal{B}}$  have identical values, but different inputs. It remains to show the strong convexity of  $-H_{\mathcal{B}}$  so we can use it in RDA.

**Proposition 3.** *For trees with  $n$  nodes, the negative Bethe entropy function  $-H_{\mathcal{B}}$  is  $\frac{1}{2}(2n-1)^{-2}$ -strongly convex with respect to the 2-norm over the interior of the marginal polytope  $\mathcal{M}$ .*

*Proof.* Consequence of Lemma 1 in Fu & Banerjee (2013).

With these definitions in hand, we present Bethe-RDA projected inference Algorithm 1. This algorithm corresponds to instantiating (10) with  $R = -H_{\mathcal{B}} - \langle \theta, \mu \rangle$  and  $\varphi = -H_{\mathcal{B}}$ . Note the simplicity of the algorithm when choosing  $\beta_t = 0$ . It is intuitively appealing that the algorithm amounts to no more than calling our marginal inference oracle with iteratively modified parameters.

**Proposition 4.** *For convex energy functions and convex  $-H_{\mathcal{B}}$ , the sequence of primal averages of Algorithm 1 converges to the optimum of the variational objective (2) with suboptimality of  $O(\frac{\ln(t)}{t})$  at time  $t$ .*

*Proof.* This follows from Theorem 3 of Xiao (2010) along with the strong convexity of  $-H_{\mathcal{B}}$ .  $\square$

If we have more structure in the energy functions, specifically a Lipschitz-continuous gradient, we can modify the algorithm to use Nesterov’s acceleration technique and achieve a convergence of  $O(\frac{1}{t^2})$ . Details can be found in Appendix D. Additionally, in practice these problems need not be solved to optimality and give stable results after a few iterations, as demonstrated in Figure 8.1.

## 6.3 INFERENCE WITH NON-CONVEX, NON-LOCAL ENERGIES

An analogy can be made here to loopy belief propagation – even in the case of non-convex loss functions (and even non-convex entropy functions with associated inexact marginal oracles), the updates of our inference (and learning) algorithms are well-defined. Importantly, since one of our motivations for developing non-local inference was to

generalize mean field inference, and the additional penalty terms are non-convex in that case, we would like our algorithms to work for the non-convex case as well.

Unlike loopy belief propagation, however, since we derive our algorithms in the framework of composition minimization, we have access to a wealth of theoretical guarantees. Based on results from the theory of optimization with first-order surrogate loss functions (Mairal, 2013), in Appendix C we propose a small modification to Algorithm 1 with an asymptotic convergence condition even for non-convex energies. In practice we find that the unmodified Algorithm 1 also works well for these problems, and experimentally in Section 8.2, we see good performance in both inference and learning with non-convex energy functions.

## 7 LEARNING MODELS WITH NON-LOCAL ENERGIES

We seek to learn the parameters  $\theta$  and  $\psi$  of the underlying CRF base model and  $L_\psi$ , respectively. Let  $S = \{\mathbf{y}_i, \mathbf{x}_i\}$  be  $n$  training examples. Let  $Q(\mathbf{y}_i; \mu_i)$  be the variational distribution for  $\mathbf{y}_i$  resulting from applying Proposition 1. Namely,  $Q(\mathbf{y}_i; \mu_i)$  is an MRF with parameters

$$\rho_i := \theta - \nabla_{\mu} L_\psi(\mu_i). \quad (11)$$

We employ the notation  $Q(\mathbf{y}_i; \mu_i)$  to highlight the role of  $\mu_i$ : for a given  $(\mathbf{y}_i, \mathbf{x}_i)$  pair, the family of variational distributions over  $\mathbf{y}_i$  is indexed by possible values of  $\mu_i$  (recall we suppress the explicit dependence of  $\theta$  and  $\psi$  on  $\mathbf{x}$ ). Finally, define the shorthand  $M = \{\mu_1, \dots, \mu_n\}$ .

$\psi$  interacts with the data in a complex manner that prevents us from using standard learning techniques for the exponential family. Namely, we can not easily differentiate a likelihood with respect to  $\psi$ , since this requires differentiating the output  $\mu$  of a convex optimization procedure, and the extra  $L_\psi$  term in (2) prevents the use of conjugate duality relationships available for the exponential family. We could have used automatic methods to differentiate the iterative inference procedure (Stoyanov et al., 2011; Domke, 2012), but found our learning algorithm works well.

We employ a variational learning algorithm, presented in Algorithm 2, alternately updating the parameters  $M$  of our tractable CRF-structured variational distributions, and updating the parameters  $(\theta, \psi)$  assuming the following surrogate likelihood given by these CRF approximations:

$$L(\theta, \psi; M) = \sum_i \log Q(\mathbf{y}_i; \mu_i). \quad (12)$$

Given  $\theta$  and  $\psi$ , we update  $M$  using Algorithm 1. Given  $M$ , we update  $\theta$  and  $\psi$  by taking a single step in the direction of the gradient of the surrogate likelihood (12). We avoid taking more than one gradient step, since the gradients for  $\theta$  and  $\psi$  depend on  $M$  and an update to  $\theta$  and  $\psi$  will break the property that  $\mu(Q(\mathbf{y}; \mu_i)) = \mu_i$ . Therefore, we recompute  $\mu_i$  every time we update the parameters.

Overall, it remains to show how to compute gradients of (12). For  $\theta$ , we have the standard CRF likelihood gradient (Sutton & McCallum, 2006):

$$\nabla_\theta L(\theta, \psi; M) = \sum_i S(\mathbf{y}_i) - \mu_i. \quad (13)$$

For  $\psi$ , we have:

$$\nabla_\psi L(\theta, \psi; M) = \sum_i \frac{d\rho_i}{d\psi} \frac{d}{d\rho_i} \log Q(\mathbf{y}_i; \mu_i). \quad (14)$$

From (11),  $\frac{d}{d\rho_i} \log Q(\mathbf{y}_i; \mu_i)$  is also  $S(\mathbf{y}_i) - \mu_i$  and

$$\frac{d\rho_i}{d\psi} = \frac{d}{d\psi} \frac{d}{d\mu} L_\psi(\mu) \quad (15)$$

Clearly, this depends on the structure of  $L_\psi$ . Consider the parametrization (4). With this, we have:

$$\frac{\partial}{\partial \psi_j} \frac{d}{d\boldsymbol{\mu}} L_\psi(\boldsymbol{\mu}) = \nabla \ell_j(\boldsymbol{\mu}) \frac{d}{d\boldsymbol{\mu}} \ell_j(\boldsymbol{\mu}) \quad (16)$$

Therefore, we have  $\frac{\partial}{\partial \psi_j} \log Q(\mathbf{y}_i; \boldsymbol{\mu}_i) = \nabla \ell_j(\boldsymbol{\mu}) \frac{d}{d\boldsymbol{\mu}} \ell_j(\boldsymbol{\mu})^\top (S(\mathbf{y}) - \boldsymbol{\mu}_i)$ . For linear measurements (5), this amounts to

$$\nabla \ell(\boldsymbol{\mu}) (a_j^\top S(\mathbf{y}) - a_j^\top \boldsymbol{\mu}_i). \quad (17)$$

This has a simple interpretation: the gradient with respect to  $\psi_j$  equals the gradient of the scalar loss  $\ell_j$  at the current marginals  $\boldsymbol{\mu}_j$  times the difference in linear measurements between the ground truth labels and the inferred marginals.

Algorithm 2 has an expensive double-loop structure. In practice it is sufficient to employ a ‘doubly-stochastic’ version given in Algorithm 3, where we sample a training example  $(\mathbf{x}_i, \mathbf{y}_i)$  and use this to only perform a single gradient step on  $\boldsymbol{\theta}$  and  $\psi$ . To demonstrate the simplicity of implementing our learning algorithm, we avoid any abstract derivative notation in Algorithm 3 by specializing it to the case of (17). In our experiments, however, we sometimes do not use linear measurements. Overall, all our experiments use the fast doubly-stochastic approach of Algorithm 3 solely, since it performs well. In general, our learning algorithms are not guaranteed to converge because we approximate the complex interaction between  $\psi$  and  $\boldsymbol{\mu}$  with alternating updates. In practice, however, terminating after a fixed number of iterations yields models that generalize well.

Finally, recall that the notation  $L_\psi(\boldsymbol{\mu}_i)$  suppresses the potential dependence of  $\psi$  on  $\mathbf{x}_i$ . We assume each  $\psi_j$  is a differentiable function of features of  $\mathbf{x}_i$ . Therefore, in our experiments where  $\psi$  depends on  $\mathbf{x}_i$ , we perform gradient updates for the parametrization of  $\psi(\mathbf{x})$  via further application of the chain rule.

## 8 EXPERIMENTS

### 8.1 CITATION EXTRACTION

| Model                            | F1    |
|----------------------------------|-------|
| Our Baseline                     | 94.47 |
| Non-local Energies               | 95.47 |
| Baseline (Anzaroot et al., 2014) | 94.41 |
| Soft-DD (Anzaroot et al., 2014)  | 95.39 |

Table 1: Comparison of F1 scores on Citation Extraction dataset. We compare MAP inference F1 scores of our non-local energy model and the specialized dual decomposition model of Anzaroot et al. (2014). Both variants learn global regularities that significantly improve performance.

Figure 1: Citation extraction F1 when limiting maximum number of test-time inference iterations. Most of our accuracy gain is captured within the first 5-10 iterations.

We first apply our algorithm to the NLP task of performing text field segmentation on the UMass citation dataset (Anzaroot & McCallum, 2013), which contains strings of citations from research papers, segmented into fields (author, title, etc.). Our modeling approach, closely follows Anzaroot et al. (2014), who extract segmentations using a linear-chain segmentation model, to which they add a large set of ‘soft’ linear global regularity constraints.

Let  $\mathbf{y}$  be a candidate labeling. Imagine, for example, that we constrain predicted segmentations to have no more predicted last names than first names. Then, the numbers of first and last names can be computed by linear measurements  $a_{\text{first}}^\top S(\mathbf{y})$  and  $a_{\text{last}}^\top S(\mathbf{y})$ , respectively. A hard constraint on  $\mathbf{y}$  would enforce  $a_{\text{first}}^\top S(\mathbf{y}) - a_{\text{last}}^\top S(\mathbf{y}) = 0$ . This is relaxed in Anzaroot et al. (2014) to a penalty term

$$c \ell_h (a_{\text{first}}^\top S(\mathbf{y}) - a_{\text{last}}^\top S(\mathbf{y})) \quad (18)$$

that is added to the MAP inference objective, where  $\ell_h(x) = \max(1 - x, 0)$  is a hinge function. For multiple soft constraints, the overall prediction problem is

$$\arg \min_{\mathbf{y}} \langle -\boldsymbol{\theta}, S(\mathbf{y}) \rangle + \sum_j c_j \ell_h (a_j^\top S(\mathbf{y})), \quad (19)$$

where  $\boldsymbol{\theta}$  are the parameters of the underlying linear-chain model. They use a dual decomposition style algorithm for solving (19), that crucially relies on the specific structure of the hinge terms  $\ell_h$ . They learn the  $c_j$  for hundreds of ‘soft constraints’ using a perceptron-style algorithm.

We consider the same set of measurement vectors  $a_j$ , but impose non-local terms that act on *marginals*  $\boldsymbol{\mu}$  rather than specific values  $\mathbf{y}$ . Further, we use *smoothed* hinge functions, which improve the convergence rate of inference (Rennie, 2005). We find the variational distribution by solving the marginal inference version of (19), an instance of our inference framework with linear measurements (5):

$$\arg \min_{\boldsymbol{\mu}} \langle -\boldsymbol{\theta}, \boldsymbol{\mu} \rangle - H_B(\boldsymbol{\mu}) + \sum_j c_j \ell_h (a_j^\top \boldsymbol{\mu}), \quad (20)$$

As in Anzaroot et al. (2014), we first learn chain CRF parameters  $\theta$  on the training set. Then, we learn the  $c_j$  parameters on the development set, using Algorithm 3, and tune hyperparameters for development set performance. At both train and test time, we ignore any terms in (20) for which  $c_j < 0$ .

We present our results in Table 1, measuring segment-level F1. We can see that our baseline chain has slightly higher accuracy than the baseline approach of Anzaroot et al. (2014), possibly due to optimization differences. Our augmented model (Non-Local Energies) matches and very slightly beats their soft dual decomposition (Soft-DD) procedure. This is especially impressive because they employ a specialized linear-programming solver and learning algorithm adapted to the task of MAP inference under hinge-loss soft constraints, whereas we simply plug in our general learning and inference algorithms for non-local structured prediction – applicable to any set of energy functions.

Our comparable performance provides experimental evidence for our intuition that preferences about MAP configurations can be expressed (and “relaxed”) as functions of expectations. Anzaroot et al. (2014) solve a penalized MAP problem directly, while our prediction algorithm first finds a distribution satisfying these preferences, and then performs standard MAP inference in that distribution.

Finally, in Figure 1 we present results demonstrating that our algorithm’s high performance can be obtained using only 5-10 calls per test example to inference in the underlying chain model. In Section B, we analyze the empirical convergence behavior of Algorithm 1.

## 8.2 HANDWRITING RECOGNITION

| $L_{\psi}^w$ (MM)        | <b>98.83</b> |
| 55-Class Classifier (MM) | 86.06        |

Table 3: Character-wise accuracy of our baselines, and models using learned non-local energies on Handwriting Recognition dataset. Note that word classifier baseline is also given in character-wise accuracy for comparison.

We next apply our algorithms to the widely-used handwrit-

ing recognition dataset of Taskar et al. (2004). We follow the setup of Weiss et al. (2012), splitting the data into 10 equally sized folds, using 9 for training and one to test. We report the cross-validation results across all 10 folds.

The *structured prediction cascades* of Weiss et al. (2012) achieve high performance on this dataset by using extremely high order cliques of characters (up to 6-grams), for which they consider only a small number of candidate outputs. Their state-of-the-art results are reproduced in Table 2. The excellent performance of these large-clique models is consequence of the fact that the data contains only 55 unique words, written by 150 different people. Once the model has access to enough higher-order context, the problem becomes much easier to solve.

With this in mind, we design two non-convex, non-local energy functions. These energies are intended to regularize our predictions to lie close to known elements of the vocabulary. Our base model is a standard linear-chain CRF with image features on the nodes, and no features on the bigram edge potentials. Let  $U(\mu) = \sum_n \mu_n$  be a function that takes the concatenated vector of node and edge marginals and sums up all of the node marginals, giving the global unigram expected sufficient statistics. Let  $\{u_i\} = \{U(\mu(y_i))\}$  indicate the set of all such unique vectors when applying  $U$  to the train set empirical sufficient statistics for each data case  $y_i$ . Simply, this gives 55 vectors  $u_i$  of length 26 containing the unigram counts for each unique word in the train set.

Our intuition is that we would like to be able to “nudge” the results of inference in our chain model by pulling the inferred  $U(\mu)$  to be close to one of these global statistics vectors. We add the following non-convex non-local energy function to the model:

$$L_{\psi}^u(\mu) = \psi \min_i \|u_i - U(\mu)\|_1. \quad (21)$$

We learn two variants of this model, which differently parametrize the dependence of  $\psi$  on  $x$ . The first has a single bias feature on the non-local energy. The second conditions on a global representation of the sequence: concretely, we approximate the RBF *kernel mean map* (MM) (Smola et al., 2007) using random Fourier features (RFF) (Rahimi & Recht, 2007). This simply involves multiplying each image feature vector in the sequence by a random matrix with  $\sim 1000$  rows, applying a pointwise non-linearity, and taking  $\psi$  to be a linear function of the average vector.

Results of these experiments can be seen in Table 3. Adding the non-local energy brings our performance well above the baseline bigram chain model, and our training procedure is able to give substantially better performance when  $\psi$  depends on the above input features.

The energy  $L_{\psi}^u$ , based on unigram sufficient statistics, is not able to capture the relative ordering of letters in the vocabulary words, which the structured prediction cascades

| $s$        | 625  | 10k | 50k |
|------------|------|-----|-----|
| Our Method | 0.19 | 2.7 | 14  |
| IP         | 2.8  | 93  | 690 |

Table 4: Comparison of runtime (in seconds, averaged over 10 trials) between the interior point solver (IP) of Sheldon et al. (2013) v.s. Algorithm 1 on different CGM problem sizes  $s$ , the cardinality of the edge potentials in the underlying graphical model, where marginal inference is  $O(s)$ .

models do capture. This motivates us to consider another energy function. Let  $\{w_i\} = \{\mu_n(y_i)\}$  be the set of unique vectors of concatenated node marginal statistics for the train set. This gives 55 vectors of length  $l_i * 26$ , where  $l_i$  is the length of the  $i$ th distinct train word. Next, we define a different energy function to add to our base chain model:

$$L_{\psi}^w(\mu) = \psi \min_i \|w_i - \mu\|_1. \quad (22)$$

Once again we implement featurized and non-featurized versions of this model. As noted in structured prediction cascades, giving the model access to this level of high-order structure in the data makes the inference problem extremely easy. Our model outperforms the best structured prediction cascades results, and we note again an improvement from using the featurized over the non-featurized  $\psi$ .

Of course, since the dataset has only 55 actual labels, and some of those are not valid for different input sequences due to length mismatches, this is arguably a classification problem as much as a structured prediction problem. To address this, we create another baseline, which is a constrained 55-class logistic regression classifier (constrained to only allow choosing output classes with appropriate lengths given the input). We use our same global mean-map features from the  $L_{\psi}^*$  ( $MM$ ) variants of the structured model and report these results in Table 3. We also tune the number of random Fourier features as a hyperparameter to give the classifier as much expressive power as possible. As we can see, the performance is still significantly below the best structured models, indicating that the interplay between local and global structure is important.

### 8.3 COLLECTIVE GRAPHICAL MODELS

Next, we demonstrate that that our proximal gradient-based inference framework dramatically speeds up approximate inference in *collective graphical models* (CGMs) (Sheldon & Dietterich, 2011). CGMs are a method for structured learning and inference with noisy aggregate observation data. The large-scale dependency structure is represented via a graphical model, but the nodes represent not just single variables, but aggregate sufficient statistics of large sets of underlying variables, corrupted by some noise model. In previous work, CGMs have been successfully applied to modeling bird migration. Here, the base model is a lin-

ear chain representing a time series of bird locations. Each observed variable corresponds to counts from bird watchers in different locations. These observations are assumed to be Poisson distributed with rate proportional to the true count of birds present. The CGM MAP task is to infer the underlying migration patterns.

Sheldon et al. (2013) demonstrate that MAP in CGMs is NP-hard, *even for trees*, but that approximate MAP can be performed by solving a problem of the form (2):

$$\mu^* = \arg \max_{\mu} \langle \theta, \mu \rangle + H_B(\mu) + \sum_i^n P_i(\mu_i | \psi y_i) \quad (23)$$

where  $P_i$  are (concave) Poisson log-likelihoods and each  $y_i$  is an observed bird count.

For the case where the underlying CGM graph is a tree, the ‘hard EM’ learning algorithm of Sheldon et al. (2013) is the same as Algorithm 2 specialized to their model. Therefore, Sheldon et al. (2013) provide additional experimental evidence that our alternating surrogate-likelihood optimization works well in practice.

The learning procedure of Sheldon et al. (2013) is very computationally expensive because they solve instances of (23) using an interior-point solver in the inner loop. For the special case of trees, Algorithm 1 is directly applicable to (23). Using synthetic data and code obtained from the authors, we compare their generic solver to Algorithm 1 for solving instances of (23). In Table 4, we see that our method achieves a large speed-up with no loss in solution accuracy (since it solves the same convex problem).

## 9 DISCUSSION AND FUTURE WORK

Our results show that our inference and learning framework allows for tractable modeling of non-local dependency structures, resistant to traditional probabilistic formulations. By approaching structured modeling not via independence assumptions, but as arbitrary penalty functions on the marginal vectors  $\mu$ , we open many new modeling possibilities. Additionally, our generic gradient-based inference method can achieve substantial speedups on pre-existing problems of interest. In future work, we will apply our framework to new problems and new domains.

## Abstract

Split-merge moves are a standard component of MCMC algorithms for tasks such as multi-target tracking and fitting mixture models with unknown numbers of components. Achieving rapid mixing for split-merge MCMC has been notoriously difficult, and state-of-the-art methods do not scale well. We explore the reasons for this and propose a new split-merge kernel consisting of two sub-kernels: one combines a “smart” split move that proposes plausible splits of heterogeneous clusters with a “dumb” merge move that proposes merging random pairs of clusters; the other combines a dumb split move with a smart merge move. We show that the resulting smart-dumb/dumb-smart (SDDS) algorithm outperforms previous methods. Experiments with entity-mention models and Dirichlet process mixture models demonstrate much faster convergence and better scaling to large data sets.

## 1 INTRODUCTION

Markov Chain Monte Carlo (MCMC) algorithms have become a central pillar of statistical inference and machine learning. MCMC algorithms repeatedly apply a stochastic *kernel* transformation to an initial state, generating a random walk through the sample space whose stationary distribution matches a desired target distribution. Within the general Metropolis-Hastings (MH) family of MCMC methods, which includes many specific algorithms that have proven useful in practice, the kernel is built from a *proposal* step followed by a stochastic *acceptance* step whose probability is determined by the chosen proposal distribution. One key to efficient MH inference, then, is proposal design.<sup>1</sup>

---

<sup>1</sup>Other approaches include parallelization [Chang and Fisher, 2013; Williamson *et al.*, 2013] and taking advantage of symme-

This paper focuses on MH proposal design for *split-merge* moves. Split and merge moves, which form a complementary pair comprising a kernel, are useful for problems where an MCMC state can be thought of as consisting of a number of components or clusters, each of which is responsible for some subset of observations. The canonical example is the family of *mixture models*: a split move in such a model converts one mixture component into two, dividing the observations of the original component between the two new components; a merge move combines two components and their observations into a single component [Dahl, 2003; Pasula *et al.*, 2003; Jain and Neal, 2004]. Split-merge moves are also common in multitarget tracking, where a “component” is a single track joining together observations of an object over multiple time steps [Pasula *et al.*, 1999; Khan *et al.*, 2005]. The state of the art for split-merge MCMC in mixture models is considered to be the *restricted Gibbs split-merge* (RGSM) algorithm of Jain and Neal [2004].

The general idea followed in most MH proposal designs is to make the proposal “smart” by preferentially proposing states with higher probability according to the target distribution. This tends to give higher acceptance probabilities. The Gibbs sampler [Geman and Geman, 1984] is the quintessential smart proposal: by proposing values for some subset of variables exactly in proportion to their probability, Gibbs sampling has an acceptance probability of 1. In the context of split-merge moves, a smart split would be one that favors splitting a heterogeneous cluster to produce two more homogeneous ones, and a smart merge would favor merging similar clusters to ensure a homogeneous result. As our analysis and experiments show, however, combining smart split and merge moves does not lead to high acceptance probabilities and rapid convergence. The reason is the asymmetry between subspaces with  $K$  and  $K + 1$  components: there are far more states in the latter than the former, whereas in the case of Gibbs sampling the source and target subspaces are identical.

---

try [Niepert and Domingos, 2014]. The work reported in this paper can easily be combined with these approaches.

Our proposed solution, the smart-dumb/dumb-smart (SDDS) algorithm, combines two kernels in parallel: one has a smart split move and a “dumb” merge move that proposes merging random pairs of clusters; the other combines a dumb split move with a smart merge move. We show that the resulting algorithm performs well in practice, maintaining high acceptance rates and converging reasonably quickly even for large data sets with many clusters, where RGSM and other algorithms fail. To our knowledge, the closest relative of SDDS is a parallel-computation MCMC algorithm due to Chang and Fisher [2013], who mention the use of a random split move as the complement of a merge move in one part of a rather complex algorithm. A second contribution of our paper is a fast, exact method for sampling a split move from the posterior over all possible splits of a given component, i.e., an efficient block-Gibbs proposal for splits.

The paper begins (Section 2) with background material on MCMC. Section 3 describes, for expository purposes, the *entity/mention model* (EMM), a very simple Bayesian mixture model with observations that are discrete tokens, and examines split-merge MCMC in the context of the EMM. Section 4 describes the SDDS algorithm in detail. Finally, Section 5 evaluates SDDS in comparison to other approaches, both on EMM data and on data from a Dirichlet process mixture model (DPMM).

## 2 MCMC METHODS

Here we provide a brief review of the relevant aspects of Metropolis–Hastings MCMC. Let  $\mathcal{X}$  be a sample space (a set of possible worlds); a sample point  $\mathbf{x} \in \mathcal{X}$  will be called a *state*. Let  $\pi(\cdot)$  be a *target distribution* of interest, such as the posterior distribution on  $\mathcal{X}$  given some evidence. The goal is to generate samples from  $\pi$ , or something close to it, so as to answer queries. A standard MCMC algorithm constructs a Markov chain from a *transition kernel*  $P(\mathbf{x}'|\mathbf{x})$ , such that the unique stationary distribution of the chain is  $\pi$ ; of primary concern is the rate of convergence of the Markov chain to its stationary distribution.

The Metropolis–Hastings (MH) algorithm [Metropolis *et al.*, 1953; Hastings, 1970] is a general template for building transition kernels with the desired property. Each transition is built from two steps: first, a new state  $\mathbf{x}'$  is proposed from a *proposal distribution*  $q(\mathbf{x}'|\mathbf{x})$ , then the new state is accepted with a probability given by

$$\alpha(\mathbf{x}'|\mathbf{x}) = \min\left\{1, \frac{\pi(\mathbf{x}')}{\pi(\mathbf{x})} \frac{q(\mathbf{x}|\mathbf{x}')}{q(\mathbf{x}'|\mathbf{x})}\right\}. \quad (1)$$

(If the proposal is not accepted, the new state is the same as the current state.) The ratio appearing in this expression is called the *MH ratio*; we have written it as the product of the *state ratio*  $\pi(\mathbf{x}')/\pi(\mathbf{x})$  and the *proposal ratio*  $q(\mathbf{x}|\mathbf{x}')/q(\mathbf{x}'|\mathbf{x})$ . The only “free parameter” in designing

an MH algorithm is the proposal  $q(\cdot|\cdot)$ , and it is this that determines the rate of convergence.

Gibbs sampling can be understood as a special case of MH [Gelman, 1992]. In its simplest form, it chooses a variable  $X_i$  uniformly at random from the set of  $n$  variables whose values define the state  $\mathbf{x}$  and proposes a value  $x'_i$  from the distribution  $\pi(X_i|\mathbf{x}_{-i})$ , where  $\mathbf{x}_{-i}$  denotes the current values for all variables other than  $X_i$ . Because this proposal distribution is proportional to the state probability, the proposal ratio for Gibbs is exactly the inverse of the state ratio. For the case where  $x_i$  and  $x'_i$  coincide, both ratios are 1; when they differ, we have

$$\begin{aligned} \frac{q(\mathbf{x}|\mathbf{x}')}{q(\mathbf{x}'|\mathbf{x})} &= \frac{q(x_i, \mathbf{x}_{-i}|x'_i, \mathbf{x}_{-i})}{q(x'_i, \mathbf{x}_{-i}|x_i, \mathbf{x}_{-i})} = \frac{\frac{1}{n}\pi(x_i|\mathbf{x}_{-i})}{\frac{1}{n}\pi(x'_i|\mathbf{x}_{-i})} \\ &= \frac{\pi(x_i, \mathbf{x}_{-i})\pi(\mathbf{x}_{-i})}{\pi(x'_i, \mathbf{x}_{-i})\pi(\mathbf{x}_{-i})} = \frac{\pi(\mathbf{x})}{\pi(\mathbf{x}')}. \end{aligned} \quad (2)$$

Hence the acceptance probability in (1) is therefore exactly 1 for Gibbs sampling.

Having a high acceptance probability—or at least, one bounded away from zero—is a necessary but not sufficient condition for rapid mixing in MH. Moves can be accepted with high probability but if those moves fail to lead the chain from one local maximum in  $\pi$  to another, overall mixing may still be slow. Thus, good proposal design is concerned with both acceptance probabilities and the ability to traverse the state space without getting stuck in local maxima.

## 3 THE ENTITY/MENTION MODEL

The entity/mention model or EMM is a very simple form of mixture model, defined here for the purposes of exposition. The EMM posits a certain (unknown) number of entities that are referred to by some set of mentions. For example, there is a person who may variously be referred to as “Barack Obama”, “the President”, “POTUS”, and so on. Given a collection of mentions of various entities—for example, in newspaper text—the task is to figure out how many entities exist, which mentions refer to which entities, and thence the ways in which any given entity may be mentioned. In its simplest form, the EMM assumes that each mention is a token with no internal structure, drawn from a fixed, known set of tokens. This renders the model less interesting than the models used in NLP research, but has the advantage of simplifying the analysis.

### 3.1 The EMM probability model

We assume  $N$  mentions and  $L$  possible tokens. An EMM model is composed from the following variables and conditional distributions:

- $K$ , the number of entities, drawn from a prior  $P(K)$ .

- For each entity  $k$ , a *dictionary*  $\theta_k$ , i.e., a categorical distribution over  $L$  tokens, drawn from a *Dirichlet*( $\alpha_k$ ). The set of dictionaries  $\{\theta_1, \dots, \theta_K\}$  is represented by  $\Theta$ .
- For each mention  $m_n$ , the entity  $S_n$  for that mention is drawn u.a.r. from the set of  $K$  entities, and the token for that entity is drawn from  $\theta_{S_n}$ . The (unknown) entities  $\{S_1, \dots, S_N\}$  are represented by  $\mathbf{S}$  and the observed mentions  $\{m_1, \dots, m_N\}$  by  $\mathbf{m}$ .

The EMM resembles a topic model for a single document with an unknown number of topics (entities).

In the experiments described below, we use a broad prior for  $K$ , namely a discretized log-normal distribution with the location parameter  $\mu$  and the scale parameter  $\sigma$  on a logarithmic scale:

$$P(K) = \frac{1}{C} \frac{1}{K\sigma\sqrt{2\pi}} e^{-(\log K - \mu)^2 / 2\sigma^2}$$

where  $C$  is an additional normalization factor arising from discretizing the distribution.

Because the entity for any given mention is assumed to be chosen u.a.r. from the available entities, we have

$$P(\mathbf{S}|K) = \left(\frac{1}{K}\right)^N.$$

Rather than sample the dictionaries, we will integrate them out exactly, taking advantage of properties of the Dirichlet. In particular, we have

$$\int_{\Theta} P(\mathbf{m}, \Theta|K, \mathbf{S}) = \prod_{k \in \{1:K\}} \frac{B(\alpha_k + \mathbf{n}_k)}{B(\alpha_k)}$$

where  $B(\cdot)$  is the Beta function and  $\alpha_k$  and  $\mathbf{n}_k$  are both vectors of size  $L$ , representing respectively the Dirichlet prior counts and the observed counts of each token in the dictionary.

### 3.2 Gibbs sampling for the EMM

Basic Gibbs sampling samples one variable at a time, which means, in our entity/mention model, sampling a new entity assignment  $S_n$  for some mention  $m_n$ , conditioned on all other current assignments  $\mathbf{S}_{-n}$  of mentions to entities. The initial assignment is chosen at random, then the Gibbs sampler is repeated for  $I$  iterations, each cycling through all the mentions; see Algorithm 1.

The probability  $P(S_n = k|K, \mathbf{S}_{-n}, \mathbf{m})$  is calculated by:

$$P(S_n = k|K, \mathbf{S}_{-n}, \mathbf{m}) \propto \frac{\alpha_{k,l} + n_{k,l}}{\sum_{l' \in L} (\alpha_{k,l'} + n_{k,l'})}$$

where  $\alpha_{k,l}$  and  $n_{k,l}$  are respectively the prior counts for the token  $l$  (the mention  $m_n = l$ ) and observed counts for

---

### Algorithm 1 Gibbs sampling for an entity/mention model

---

```

1: procedure GIBBS SAMPLING
2:   for n=1 to N do
3:     Sample  $S_n$  u.a.r. from  $\{1, \dots, K\}$ 
4:   end for
5:   for i=1 to I do
6:     for n=1 to N do
7:       Sample  $S_n$  from  $P(S_n|K, \mathbf{S}_{-n}, \mathbf{m})$ 
8:     end for
9:   end for
10: end procedure

```

---

token  $l$  assigned to  $E_k$ . It is divided by the sum of the prior and observed counts for all the  $L$  tokens.

Each step of the Gibbs sampler is relatively easy to compute, but of course the algorithm cannot change the number of entities; moreover, it tends to get stuck on local maxima because of the local nature of the changes [Celex *et al.*, 2000]. Despite these drawbacks, Gibbs steps are an important element used in association with split-merge steps in order to optimize the allocation of mentions to entities.

### 3.3 Split–merge MCMC for the EMM

One way to explore states with different numbers of entities is to use *birth* and *death* moves. A birth moves creates a new entity with no mentions, while a death move kills off an entity that has no mentions. While such moves, combined with Gibbs moves, do connect the entire state space, they lead to very slow mixing because death moves can only occur when Gibbs moves have removed all the mentions from an entity, which is astronomically unlikely when  $N$  is much larger than  $K$ —unless the entity being killed is one that was just born.

Split and merge moves simultaneously change the number of entities and change the assignments of multiple mentions in one go. The simplest approach is to pick an entity at random and split it into two, randomly assigning the mentions to the two new entities; the merge move operates in reverse by picking two entities and merging into one, along with their mentions. A naive implementation of this idea often fails to work, because random splits often yield a state with a very low probability, preventing acceptance. Pasula *et al.* [2003] suggested a *random mixing* procedure that chooses two entities and randomly assigns each of their mentions to one of two new entities. A split occurs when the two chosen entities happen to coincide, and a merge happens when one of the new entities receives no mentions and is discarded. The approach was effective for medium-sized data sets in their experiments (300-400 mentions, 60-80 entities) but fails when each entity has many mentions: merges become exponentially unlikely to be proposed.

Jain and Neal [2004] proposed a Restricted Gibbs Split–

Merge (RGSM) algorithm to generate splits that are consistent with data. Two random elements are chosen in the beginning. A split is proposed if these two elements belong to the same component and otherwise a merge is proposed. To split the component  $c_k$ , RGSM algorithm first assigns the elements randomly into two new components  $c_1^{launch}$  and  $c_2^{launch}$  as the launch state. Restricted Gibbs is then applied for  $t$  times inside the launch state, re-assigning elements to one of the components. The modified launch state after  $t$  Restricted Gibbs steps is used for generating the split. The resulting split reflects the data to some extent and tends to have a higher likelihood. However, these intermediate Restricted Gibbs steps are rather computationally expensive, especially for large data sets. Dahl [2003] proposed an allocation procedure, which works by assigning elements sequentially to two components. It starts with creating two new components  $c_1$  and  $c_2$  with two random elements. The remaining elements are sequentially allocated to either  $c_1$  or  $c_2$  using the Restricted Gibbs sampler conditioned on those previously assigned elements. This procedure is more efficient than preparing the launch state in RGSM.

Split–merge has been applied to different models such as the Beta Process Hidden Markov Model [Hughes *et al.*, 2012] and the Hierarchical Dirichlet Process [Wang and Blei, 2012; Rana *et al.*, 2013]; on the other hand, the split–merge method itself has not been improved since RGSM was first proposed in 2004. In the next section, we examine the interaction of the MH algorithm with split–merge moves and propose a new combination of moves that seems to work better.

## 4 SMART AND DUMB PROPOSALS

In general, smart proposals that lead to high-probability states are preferred, as they lead to faster convergence of MCMC. What Jain and Neal [2004] did for RGSM is to avoid the low-probability states generated by random splits. As we mentioned in Section 1, “smart” proposals propose states with higher probability according to the target distribution. The Gibbs sampler is smart in this sense, because its proposal distribution is proportional to the state probability and hence the MH acceptance probability is always 1 (Eq. 2). Consequently, we may instinctively conclude that the convergence efficiency might be significantly improved if we concentrate on the design of smart proposals. However, this is not true for MH in general. The MH ratio in the case of a smart merge proposal will be analyzed as an example.

Let  $q(\mathbf{x}'|\mathbf{x})$  and  $q(\mathbf{x}|\mathbf{x}')$  be respectively a smart merge proposal and a smart split proposal. Each first picks a subset of the variables to merge (or split) with probability  $P_m$  (or  $P_s$ ). It then proposes a particular merge (or split) according to the target distribution  $f_m$  (or  $f_s$ ), where  $f_m$  and  $f_s$  are

proportional to state probabilities:

$$f_m = \frac{\pi(\mathbf{x}')}{\sum_{\omega \in W(\mathbf{x})} \pi(\omega)}, f_s = \frac{\pi(\mathbf{x})}{\sum_{\omega \in W(\mathbf{x}')} \pi(\omega)}, \quad (3)$$

where  $W(\mathbf{x})$  and  $W(\mathbf{x}')$  are respectively the set of states for all possible merges and the set of states for all possible splits given  $P_s$  and  $P_m$ .

The MH ratio is then given by

$$\begin{aligned} \frac{q(\mathbf{x}|\mathbf{x}') \pi(\mathbf{x}')}{q(\mathbf{x}'|\mathbf{x}) \pi(\mathbf{x})} &= \frac{P_s \frac{\pi(\mathbf{x})}{\sum_{\omega \in W(\mathbf{x}')} \pi(\omega)} \pi(\mathbf{x}')}{P_m \frac{\pi(\mathbf{x}')}{\sum_{\omega \in W(\mathbf{x})} \pi(\omega)} \pi(\mathbf{x})} \\ &= \frac{P_s \sum_{\omega \in W(\mathbf{x})} \pi(\omega)}{P_m \sum_{\omega \in W(\mathbf{x}')} \pi(\omega)} \end{aligned} \quad (4)$$

When both split and merge are smart, the ratio  $\frac{P_s}{P_m}$  will be very low due to a quite small  $P_s$ . It is because that the smart split would not give a big probability mass to the part a smart merge prefers to merge (detailed examples given in the next subsection). The second part in Formula 4, namely space ratio, is important in split–merge case because of the space asymmetry.  $\sum_{\omega \in W(\mathbf{x})}$  on the top is just  $\pi(\mathbf{x})$  since when we have chosen two entities to merge ( $P_m$ ), there is only one merge possibility. However,  $\sum_{\omega \in W(\mathbf{x}')}$  contain  $2^n$  possible splits ( $n$  is the number of mentions assigned to the picked entity).

The  $\frac{P_s}{P_m}$  ratio gives the first idea about why smart proposals have conflicts with inverse smart proposals. In case of space asymmetry, a smart–smart proposal suffers also from the space ratio in addition to the  $\frac{P_s}{P_m}$  ratio.

### 4.1 Why smart proposals do not work by themselves: A simple example

Let’s take a concrete example of split and merge to illustrate the problem stated above for smart proposals. Assuming that there are three entities in state  $\mathbf{x}$  as below:

$$\mathbf{x} : \{\mathbf{E}_1 : \{A A B B\}; \mathbf{E}_2 : \{C C\}; \mathbf{E}_3 : \{C C\}\},$$

a desired split would be splitting  $\mathbf{E}_1$  into two entities as follows:

$$\mathbf{x}'_1 : \{\mathbf{E}_1 : \{A A\}; \mathbf{E}_4 : \{B B\}; \mathbf{E}_2 : \{C C\}; \mathbf{E}_3 : \{C C\}\}.$$

A smart split proposal distribution should propose the state  $\mathbf{x}'_1$  with a quite high probability as illustrated in the left part of Figure 1, where the width of the arrow line indicates the probability value. However, a smart merge proposal, starting from state  $\mathbf{x}'_1$ , would rather have a high probability  $q(\mathbf{x}'_1|\mathbf{x}'_1)$  for proposing the state  $\mathbf{x}'_1$ :

$$\mathbf{x}''_1 : \{\mathbf{E}_1 : \{A A\}; \mathbf{E}_4 : \{B B\}; \mathbf{E}_2 : \{C C C C\}\}.$$

From the point of view of a smart merge, inverting the smart split’s preferred move  $q(\mathbf{x}|\mathbf{x}'_1)$  is highly unlikely, as

represented by the dashed arrow in the figure. Therefore, considering the high value of  $q(\mathbf{x}'_1|\mathbf{x})$ , the proposal ratio becomes extremely low, which leads to a very low acceptance rate for smart split proposals.

Figure 1: Conflicts between smart split and smart merge (red lines for splits and green lines for merges; thick/dashed lines for moves preferred/dispreferred by smart proposals.)

It is a similar situation for smart merge proposals, as illustrated in the right part of Figure 1. A smart merge proposal will give a high probability to generate the state  $\mathbf{x}'_2$ :

$$\mathbf{x}'_2 : \{\mathbf{E}_1 : \{A A B B\}; \mathbf{E}_2 : \{C C C C\}\}.$$

On the other hand, the smart split from the state  $\mathbf{x}'_2$  will be more likely to generate a state such as:

$$\mathbf{x}''_2 : \{\mathbf{E}_1 : \{A A\}; \mathbf{E}_3 : \{B, B\}; \mathbf{E}_2 : \{C C C C\}\},$$

leaving only a tiny probability to propose the state  $\mathbf{x}'_2$  to go back to  $\mathbf{x}$ . The same phenomenon of a low acceptance rate will be engendered.

For the particular case of split and merge, a new entity created by the split proposal changes the parameters of the space, which means, for one split and its inverse merge, there are much more possibilities for splits than those for merges. This neighborhood issue makes the smart merge proposal even harder to be accepted as shown in Formula 4.

## 4.2 Coupling with smart and dumb proposals

Smart proposals are not effective in this case because the entity which we choose to split does not correspond to the entities that we prefer to merge in the reverse direction. However, if we want to distribute a higher probability to the reverse move,  $q(\mathbf{x}|\mathbf{x}'_1)$  for instance, it can be treated as a dumb proposal rather than a smart one. “Dumb” proposals can be considered as distributions that give uniform probability mass over all possible moves.

An important property of MCMC methods is that *detailed balance* can be guaranteed when several different proposals are adopted on condition that each proposal satisfies the Metropolis-Hastings algorithm [Tierney, 1994]. Therefore, there is a solution to combine smart and dumb proposals, namely the *Smart-Dumb Dumb-Smart* proposals (SDDS), as illustrated in Figure 2.

Figure 2: Smart-Dumb Dumb-Smart design for proposals

As a consequence, there are two separate pairs of proposal distributions. For either of them, the dumb proposal gives a uniform distribution over all possible moves. The existence of dumb proposals helps the acceptance of smart proposals. In the context of these two pairs, both smart split and smart merge can produce higher acceptance rates and faster mixing.

## 4.3 An SDDS split–merge algorithm

Inside the SDDS algorithm, we want to propose high-probability states with smart splits and smart merges and to do so efficiently. The algorithm for the smart split proposal with dumb merge and the one for smart merge proposal with dumb split are respectively described in Algorithm 2 and Algorithm 3.

**Smart split/dumb merge proposal** Algorithm 2 begins by choosing randomly between a smart split proposal and a dumb merge proposal. If a smart split is picked, it will first choose one entity  $E_k$  based on a function  $f_{split}(E_k)$ . The function is inversely proportional to the likelihood of the mentions  $\mathbf{m}_{E_k}$  associated with this entity  $E_k$ , which implies that the proposal tends to choose large and mixed entities. The likelihood is given by  $B(\alpha_k + \mathbf{n}_k)/B(\alpha_k)$  where  $\alpha_k$  and  $\mathbf{n}_k$  are respectively the vectors for the Dirichlet prior counts and the observed counts of each token in  $\mathbf{m}_{E_k}$ .

Once the entity  $E_k$  chosen, the smart split procedure will allocate sequentially each mention to one of two newly created entities  $E'_1$  and  $E'_2$ , according to the likelihood of the previously assigned mentions. Given the entity  $E_k : \{AABBCC\}$  for example, the procedure is illustrated in

---

**Algorithm 2** Smart Split and Dumb Merge proposal

Table 1.

Table 1: Splitting one entity into two entities sequentially

| steps  | 0 | 1   | 2   | 3     | 4     | 5   | 6     |
|--------|---|-----|-----|-------|-------|-----|-------|
| $E'_1$ |   | A   | AA  | AA    | AA    | AA  | AA    |
| $E'_2$ |   |     |     | B     | BB    | BBC | BCCC  |
| P      |   | 0.5 | 0.6 | 0.625 | 0.714 | 0.5 | 0.714 |

Two new created entities are empty in the beginning. During each step, the allocation probability for each mention  $m_i$  is calculated by:

$$P(E'_1|m_i) \propto \frac{\alpha_{1,l} + n_{1,l}}{\sum_{l' \in L} (\alpha_{1,l'} + n_{1,l'})}$$
$$P(E'_2|m_i) \propto \frac{\alpha_{2,l} + n_{2,l}}{\sum_{l' \in L} (\alpha_{2,l'} + n_{2,l'})} \quad (5)$$

where  $\alpha_{1,l}$  and  $\alpha_{2,l}$  are the Dirichlet priors for the token  $l$  (the mention  $m_i = l$ , which is A, B or C in this case) being assigned to entity  $E'_1$  and  $E'_2$ ,  $n_{1,l}$  and  $n_{2,l}$  are current observed counts of token  $l$  assigned to  $E'_1$  and  $E'_2$  (counts are updated during each step). The denominator sums up the prior and observed counts for all possible tokens (A, B and C in this case). The probability in each step is given in the table taking all  $\alpha_{1,l}=\alpha_{2,l}=1$  as example (smaller alpha makes this procedure more discriminating). The probability of this allocation procedure is then a product of the probability in each step. This procedure avoids the time-consuming Restricted Gibbs sampling adopted by Jain and Neal [2004]. [Dahl, 2003] proposed a similar sequential procedure but started by creating two new entities with two

random mentions, which causes an initial bias when these two random mentions are supposed to be associated with the same entity.

The reverse dumb merge proposal would rather generate random merges. It picks one entity uniformly from K entities and then picks another from the remaining K-1 entities. The probability of this reverse proposal is then  $2/K(K-1)$  (two orders of choosing these two entities).

If a dumb merge proposal is chosen in the beginning, the choice of two entities will have the probability  $1/K(K-1)$ . Then we need to know the probability of the split proposal that reverses this move, i.e., allocates the mentions exactly into the two given sets. The order of mentions during allocation influences the final probability and the different probabilities from all possible orders are supposed to be summed up, which is not really feasible in practice. Dahl [2003] applied a random permutation on the order of mentions, which may be critical to correctness of MCMC methods since in this way we are obtaining a random probability for the reverse split when merge is proposed and it may not correspond to the exact probability of the inverse move. In our case, we fix a unique order for all mentions so that there is only one way of applying the procedure thus only one possible probability value for the same split results, either the real split procedure or the imaged reverse one. This unique order is chosen in an arbitrary way. The choice of any particular order has no influence on the inference but the same order should be kept all along the experiments.

**Smart merge/dumb split proposal** Algorithm 3 begins from making the random choice between merge and split as well. If smart merge proposal is picked, it will first choose

one entity  $E_i$  randomly from  $K$  entities. The choice of the second entity  $E_j$  is based on how likely it is when merged with  $E_i$ . The entity  $E_j$  is drawn from a distribution given by function  $f_{merge}(E_j|E_i)$ , which is proportional to the likelihood of this resulting merge of  $E_j$  to  $E_i$ . The likelihood of the merge is calculated by:

$$P(\mathbf{m}_{E_i, E_j}, E_j|E_i) = \frac{B(\boldsymbol{\alpha}_i + \mathbf{n}_i + \mathbf{n}_j)}{B(\boldsymbol{\alpha}_i)} \quad (6)$$

where  $\mathbf{m}_{E_i, E_j}$  refers to all mentions assigned to  $E_i$  and  $E_j$ ,  $\boldsymbol{\alpha}_i$  is vector for Dirichlet prior, and  $\mathbf{n}_i + \mathbf{n}_j$  refers to the vector for the observed counts of each term in  $\mathbf{m}_{E_i, E_j}$ .

The reverse dumb split proposal chooses one entity  $E_k$  uniformly from  $K$  entities and allocates each mention randomly into two new created entities, the probability of which is  $1/(K \cdot 2^n)$ , where  $n$  is the number of mention assigned to entity  $E_k$ .

If the dumb split proposal is chosen, it generates a random split with the same probability  $1/(K \cdot 2^n)$ . As for the reverse smart merge proposal, we need to consider the merge in two different orders, namely  $f_{merge}(E_j|E_i)$  and  $f_{merge}(E_i|E_j)$ , where  $f_{merge}(E_i|E_j)$  is proportional to  $P(\mathbf{m}_{E_j, E_i}, E_i|E_j)$  which can be calculated similarly to Formula 6.

## 5 EXPERIMENTS WITH SDDS

### 5.1 Applying SDDS to EMM

We applied the SDDS algorithm to the entity/mention model. During each inference step, the SDDS sampler chooses uniformly from either smart-split/dumb-merge proposal or dumb-split/smart-merge proposal; this is then complemented by one single Gibbs sampling step.<sup>2</sup> It is worth emphasizing again that detailed balance is satisfied when each sub-kernel fulfills the detailed balance condition individually. Three other algorithms are tested for comparison. The first is a random mixing (RM) sampler inspired from [Pasula *et al.*, 2003]. It works by choosing two random entities (which could be the same one) and then distributing corresponding mentions into two new created entities by a randomly chosen split point. The second is the RGSM sampler [Jain and Neal, 2004].<sup>3</sup> The third is a smart-smart (SS) sampler which has the same smart split and merge moves as SDDS but lacks the paired dumb moves.

The simulated data sets use 10 different tokens (A, B, C, etc.). Different configurations were tested, including dif-

<sup>2</sup>The different ways of combining a designed sampler with Gibbs sampler is an issue to be investigated; we adopted this configuration for all tested algorithms for comparison.

<sup>3</sup>The stable version (5, 1, 1) is adopted for comparison, which contains 5 intermediate Restricted Gibbs steps inside one MH step and then one complete Gibbs sampling.

ferent data set sizes ( $N=100, 200, 500$ ) and different initial entity numbers ( $K_0=1, 5, 10, 20$ ). All Dirichlet priors  $\alpha$  are set to 0.001. For the Log-normal prior on the number of entities  $K$ , the location parameter is set to 0.5 (10 entities) and scale parameter is set to 1. Experiments were run for 10K/50K/200K iterations, with a time-out at 10 hours.

We are interested in the posterior distribution of  $K$ , the number of entities, given the available evidence. We illustrate the evolution of the expected value of  $K$  for the various algorithms as a function of the number of iterations, for different values of  $N$  and  $K_0$ . We also give the acceptance rates and time needed for each iteration for comparison.

**Posterior distribution of entity numbers** The posterior distributions of entity numbers are analyzed by the mean of the value  $K$  during iterations. First of all, we fix the initial value  $K_0=5$  to compare results of these four different algorithms for different data sizes, as shown in Figure 3. We can see that for  $N = 100$  and  $N=200$ , all samplers except random mixing sampler can converge to the correct posterior  $K=10$ . However, when a larger data set  $N=500$  is used, the RGSM sampler fails to have successful split or merge therefore the value  $K$  is trapped at initial value. The SS sampler is capable of applying several effective splits whereas the merge proposal does not work well because of the reason we discussed in Section 4.1.

For the data set  $N=500$ , we have also analyzed the sensitivity of the sampler to initial value  $K_0$ , as illustrated in Figure 4. It is easy to observe that RGSM sampler is always trapped in initial  $K_0$  in this case. The SS sampler can generate well-assigned mentions for entities during smart split procedure, whereas it can not converge to the true posterior. It is interesting to see from the results of Random Mixing sampler that it works well when the initial value is twice as large as the true value. In fact, in the RM sampler, the random split procedure encourages the acceptance of merge proposals. However, the random split proposals themselves are not likely to be accepted because they generate very low-probability states. The SDDS sampler outperforms all the others, converging to the true posterior regardless of the initial value.

It is worth mentioning that the inferences start from random allocations, which would generate an ensemble of messed up entities. It is not really useful to merge messed up entities. The acceptance rates for merging messed up entities should be very low as well. It is therefore logical to observe many accepted splits in the beginning of the inference of SDDS algorithm. SDDS algorithm generates more well-formed entities and then yields higher probabilities for merging them.

**Acceptance rates** The relation between the size of data set and the acceptance rates for both split and merge are shown in Figure 5. We can observe that, for the data set

Figure 3: The mean of  $K$  during iteration for different data size, with the initial  $K_0=5$

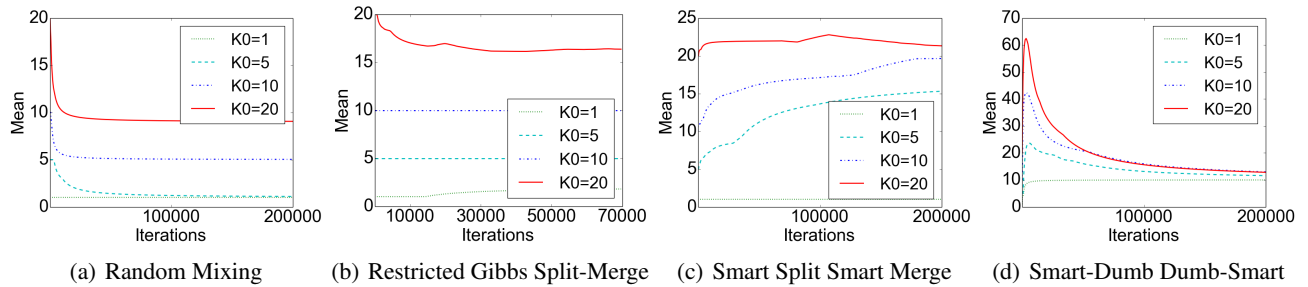

Figure 4: The mean of  $K$  during iteration for different initial  $K_0=1,5,10,20$ , with the data size  $N=500$

$N=100$ , RGSM sampler has high acceptance rates for both split (7.8%) and merge (2.1%). However, when the data size is  $N=200$ , the acceptance rates are decreased largely, only 1.1% for split and 0.08% for merge. When the data size grows to  $N=500$ , almost no effective split or merge is happening. On the contrary, the smart proposals in SDDS algorithm, either smart split or smart merge, maintain satisfying acceptance rates even for the data set  $N=500$ , 1.9% for smart split and 4.8% for smart merge. For the SS sampler, the drop of acceptance rates is similar to RGSM sampler since there is no dumb proposals to support their corresponding smart proposals.

**Time per iteration** As we stated previously, the allocation procedure in our smart split proposal is less time-consuming than the Restricted Gibbs sampling based split proposal. The performance of the running time per iteration is shown for each algorithm in Figure 5. For the RGSM sampler, the time spent per iteration grows quickly with the data size, whereas the time for SDDS algorithm remains stable. In the case of  $N=500$ , RGSM sampler takes 488.63 milliseconds per step while SDDS algorithm takes only 10.02 milliseconds per step. The time per iteration for Random Mixture sampler and that for SS sampler (which are not show in the figure) is in the same scale of SDDS sampler and stays stable for different data sizes.

## 5.2 Applying SDDS to conjugate Dirichlet Process Mixture Model

RGSM algorithm is originally proposed for Dirichlet Process Mixture Model (DPMM). When conjugate priors are used, the Gibbs sampling procedure can be easily constructed for DPMM. A particular Gibbs sampling method is adapted in this context of DPMM model so that the Gibbs sampler can create new components [Neal, 1992]. The proposed SDDS algorithm is also applied to DPMM and is then compared to the Gibbs sampler and RGSM sampler.

The experiments have been done with high dimensional Bernoulli data. Given the independently and identically distributed data set  $\mathbf{y} = (y_1, y_2, \dots, y_N)$ , each observation  $y_i$  has  $m$  Bernoulli attributes,  $(y_{i1}, y_{i2}, \dots, y_{im})$ . Given the component  $c_i$  each item  $y_i$  belongs to, its attributes are independent of each other. The mixture components are considered as the latent class that produces the observed data.

The simulated data for our experiments are generated in the same way as Jain and Neal [2004] did for one high-dimensional data set: 5 components with attribute dimension 15. Experiments are run for different sizes,  $N=100, 1K, \text{ and } 10K$ . The Dirichlet process prior and the Beta prior for attributes are respectively set to 1 and 0.1. (See Jain and Neal [2004] for further details on this model).

Jain and Neal [2004] have demonstrated their results by plotting the traces of the five highest-weight components

Figure 5: The differences of acceptance rates and time per iteration for different data sizes

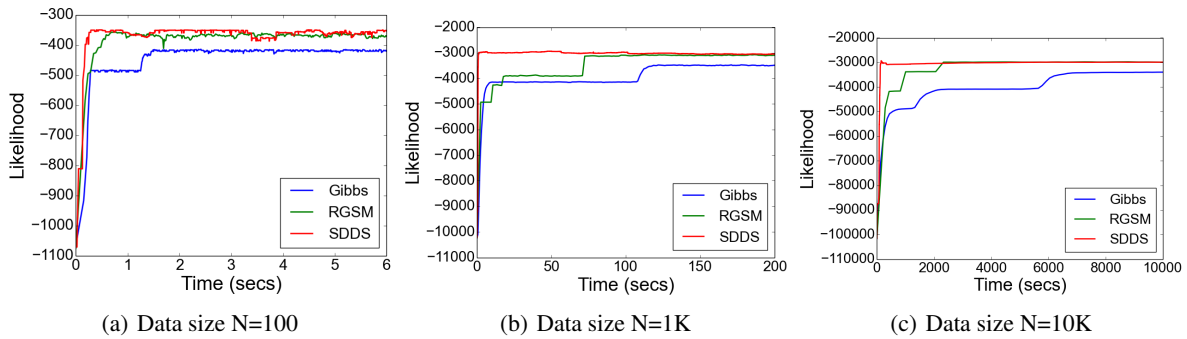

Figure 6: Comparison of the evolution of likelihood during the time for different data sizes

to verify if their algorithms can cover most data and detect five components. We have provided the same plots for the SDDS sampler. We observed the same relative performance for SDDS and RGSM on the DPMM as for the EMM, in terms of time per iteration and acceptance rates (results not shown here). We also compared the evolution of the likelihoods for SDDS, RGSM, and Gibbs as a function of running time (Figure 6). We see that, for  $N=100$ , RGSM arrives at high-probability states about 0.5 second after the SDDS algorithm does. When  $N=1K$ , SDDS gains 70 seconds over RGSM. When  $N=10K$ , SDDS outperforms RGSM by more than 2000 seconds. We conclude from this limited sample of runs that the advantage of SDDS over RGSM increases with data set size.

## 6 CONCLUSION

We have described the SDDS algorithm, which achieves efficient split-merge inference by combining smart and dumb proposals. The idea is illustrated for the entity/mention model. For the smart split proposal, we proposed a fast and exact way of generating splits that are consistent with data. Experiments on the entity/mention model and Dirichlet process mixture models suggest that SDDS algorithm mixes faster than previously known algorithms, and that the advantage increases with data set size.

## Abstract

In many planning domains external factors are hard to model using a compact Markovian state. However, long-term dependencies between consecutive states of an environment might exist, which can be exploited during planning. In this paper we propose a *scenario* representation which enables agents to reason about sequences of future states. We show how weights can be assigned to scenarios, representing the likelihood that scenarios predict future states. Furthermore, we present a model based on a Partially Observable Markov Decision Process (POMDP) to reason about state scenarios during planning. In experiments we show how scenarios and our POMDP model can be used in the context of smart grids and stock markets, and we show that our approach outperforms other methods for decision making in these domains.

## 1 INTRODUCTION

The Markov Decision Process (MDP) formalism is a mathematical framework for modeling agents interacting with their environment (Puterman, 1994). In many real-world planning domains, however, external factors can be difficult to predict, which makes it hard to obtain a Markovian model with the right state features and an appropriate level of detail (Witwicki et al., 2013). In such domains, it is hard to estimate probabilities for the occurrence of uncertain events, and therefore decision making can be a challenging task.

An example of a hard-to-model external factor is renewable energy supply such as generation of wind power. Research has shown that the most severe problems in electricity grids occur during peak-load hours when energy demand is high and wind power generation is interrupted (Moura and De Almeida, 2010), because then the supply of renewable elec-

tricity may not be sufficient to satisfy the demand of consumers. A potential solution is exploiting the flexibility of the loads of consumers, such that they can be supplied during off-peak hours. This solution requires reasoning about future wind speed, but many external factors influencing wind make it hard to define a compact Markovian state for wind. Additionally, methods to predict short-term wind power are affected by errors and may be inaccurate (Giebel et al., 2011).

In order to accommodate planning in domains with events that are difficult to predict and hard to model, we propose a framework that enables agents to reason about future states. This approach is based on the observation that there can be long-term dependencies between states, which can be exploited during planning, rather than explicitly defining a state transition model with appropriate features. In our framework, such long-term dependencies are modeled by scenarios, which are sequences of states. An advantage of using scenarios is illustrated in Figure 1, in which we compare wind predictions generated by a second-order Markov chain and actual wind scenarios that have been observed in practice. The lines in the figure visualize the 5th percentile, mean and 95th percentile of these predictions, and show us that scenarios provide information that is not sufficiently modeled by a second-order Markov chain.

In our work we assign weights to scenarios, corresponding to the likelihood that a scenario predicts future states accurately, and we use the Partially Observable Markov Decision Process framework (Kaelbling et al., 1998) to reason about scenarios during planning. We demonstrate the proposed Scenario-POMDP model in two domains. Besides wind scenarios in smart grids, we show how a Scenario-POMDP can be applied to financial stock markets. This domain has also been subject of study in the artificial intelligence community, since stock price is hard to model and depends on many external factors (Hassan and Nath, 2005). An experimental evaluation shows that our method outperforms other methods for decision making in both domains, indicating that scenarios are a valuable representation to model uncertainty regarding the future.

Figure 1: Comparison between Markov chain wind predictions and realistic wind scenarios starting from 51 km/hr.

The structure of this paper is as follows. Section 2 introduces planning under uncertainty. In Section 3 we introduce scenarios and related concepts. In Sections 4 and 5 we show how planning with scenarios can be applied to smart grids and stock markets. In the remaining sections we discuss related work, conclusions and future work. In the supplementary material we provide problem formulations and additional information regarding the problem domains.

## 2 PLANNING UNDER UNCERTAINTY

Planning under uncertainty involves agents that interact with their environment by executing actions, and observing effects caused by these actions. This is a challenging problem if agents are uncertain about the outcome of their action execution, and if they cannot fully observe the environment they are acting in. The Partially Observable Markov Decision Process (POMDP) formalism provides a framework to plan in such uncertain environments (Kaelbling et al., 1998).

In a POMDP, it is assumed that the environment is in a state  $s \in S$ . After executing an action  $a \in A$  in state  $s$ , the state of the environment transitions to another state  $s' \in S$  according to probability distribution  $P(s'|s, a)$  and a reward  $R(s, a)$  is received from the environment. A state transition from  $s$  to  $s'$  is only conditionally dependent on state  $s$  and action  $a$ , which is called the Markov property. In contrast to MDPs with full observability (Puterman, 1994), the agent does not directly perceive the state of the environment in a POMDP. It receives an observation  $o \in O$  that can be used to reason about the underlying MDP state of the environment, using a probability distribution  $P(o|a, s')$ . Since states are not directly observable in a POMDP, agents maintain a belief state, denoted  $b$ , which represents a probability distribution over states. The resulting belief state  $b_a^o$  after executing action  $a$  and observing  $o$

Figure 2: An agent executing action  $a$ , which causes a state transition to  $m'$ , and the agent receives state observation  $o_t$  from the scenario process at time  $t$  and receives reward  $R$ .

in belief state  $b$  can be determined using Bayes' rule:

$$b_a^o(s') = \frac{P(o|a, s')}{P(o|a, b)} \sum_{s \in S} P(s'|s, a)b(s)$$

where  $P(o|a, b) = \sum_{s' \in S} P(o|a, s') \sum_{s \in S} P(s'|s, a)b(s)$ . The state space  $S$ , action space  $A$  and observation space  $O$  are assumed to be finite in this paper.

To act in a partially observable environment, agents use a policy  $\pi(b)$ , which maps belief states to actions. A policy  $\pi(b)$  is characterized by a value function  $V^\pi(b)$  defining the expected discounted reward collected by the agent when executing policy  $\pi$  from belief state  $b$ . The optimal value function  $V^*(b)$  is defined as:

$$V^*(b) = \max_{a \in A} \left[ \sum_{s \in S} R(s, a)b(s) + \gamma \sum_{o \in O} P(o|a, b)V^*(b_a^o) \right]$$

where  $b_a^o$  is defined by Bayes' rule, and  $\gamma$  is a discount factor satisfying  $0 \leq \gamma < 1$ . Computing exact solutions to POMDPs is known to be intractable (Papadimitriou and Tsitsiklis, 1987), but many approximate methods exist based on point-based value iteration (Pineau et al., 2003; Spaan and Vlassis, 2005). In this paper we use POMCP (Silver and Veness, 2010), an online Monte-Carlo planning algorithm that is capable of dealing with a large number of states. We assume the planning horizon to be finite.

## 3 PLANNING WITH SCENARIOS

In this section we propose a scenario representation for planning under uncertainty. First we introduce the notion of scenarios and we explain how scenarios can be weighted based on previous observations. We also present a general POMDP model to reason about scenarios and future states during planning.

### 3.1 SCENARIOS AND WEIGHTS

We assume that an agent interacts with an environment as shown in Figure 2. The environment consists of a process

**input** : observation sequence  $o_{1,t}$ , scenario set  $X$ ,  
threshold  $\rho$

**output**: weights  $w$

$X' \leftarrow \emptyset$

$d \leftarrow 0$

**while**  $|X'| < \rho$  **do**

$X' \leftarrow \{x \in X : W(x, o_{1,t}) \leq d\}$

$d \leftarrow d + 1$

**end**

**foreach**  $x \in X$  **do**

**if**  $x \in X'$  **then**

$w_x \leftarrow 1 / (\varepsilon + W(x, o_{1,t}))$

**else**

$w_x \leftarrow 0$

**end**

**end**

$w^* \leftarrow \sum_{x \in X} w_x$

**foreach**  $x \in X$  **do**

$w_x \leftarrow w_x / w^*$

**end**

**Algorithm 1: WEIGHTS.**

for which the domain-level state changes to  $m'$  after executing an action. For simplicity, in this paper we assume that the state of this process is observable, but our approach is not limited to this assumption. Additionally, there is another process for which a compact Markovian model does not exist, called the scenario process. We assume that an agent observes a numerical-valued state  $o_t$  of this process at time  $t$ , which we call a state observation, but there is no model available defining the state transitions. The actions executed by the agent do not influence the state transitions of the scenario process. We assume that the rewards received by the agent depend on the state  $m$ , as well as on the state of the scenario process, which means that the agent has to account for future states to optimize the long-term reward.

In order to be able to reason about future states, we propose a scenario representation below. A scenario is a sequence of states of the scenario process, and implicitly models the dependencies between multiple consecutive states.

**Definition 1.** (*Scenario*). A scenario  $x = (x_1, \dots, x_T)$  is a sequence of states of the scenario process for  $T$  consecutive timesteps, where  $x_t$  is the state at time  $t$ . The sequence containing the first  $t$  states of scenario  $x$  is denoted by  $x_{1,t}$ .

States of the scenario process are assumed to be directly observable, represented by a sequence  $o_{1,t} = (o_1, o_2, \dots, o_t)$ , containing state observations from the first  $t$  timesteps. The sequence of state observations can be compared to a scenario, by comparing the individual state observations with states in the scenario. We illustrate this with a small example for the scenario  $x = (x_1, x_2, x_3, x_4) = (8, 5, 3, 2)$ . Suppose that the state observations are defined by the se-

Figure 3: Scenarios and state observations until time  $t$ .

quence  $(o_1, o_2, o_3) = (8, 5, 4)$ , then the first and second state observation are identical to the first two states defined by scenario  $x$ , and the third state observation is different.

Weights can be assigned to scenarios, representing the likelihood that a scenario perfectly predicts the states that will be observed in the future. To reason about future states, we assume that a large scenario set  $X$  is given, containing sequences of states that can be observed in  $T$  consecutive timesteps. If a sequence of states  $o_{1,t}$  is observed until time  $t$ , then the sequence can be used to assign weights to the scenarios in  $X$ . In Sections 4 and 5 we discuss how such a scenario set can be obtained in realistic domains.

An informal visual representation of scenarios is shown in Figure 3. It shows four scenarios, labeled 1 to 4, and the state observation sequence  $o_{1,t}$ . As can be seen in the figure, the state observation sequence does not correspond to any scenario until time  $t$ , but it is very similar to scenario 3. If  $X$  is an accurate set of scenarios, then it is probable that scenario 3 predicts future states. Therefore, the weight assigned to this scenario should be high in comparison to the weights assigned to other scenarios.

The weights assigned to scenarios are inversely proportional to the distance between scenarios and the state observation sequence. The distance between state observation sequence  $o_{1,t} = (o_1, o_2, \dots, o_t)$  and the first  $t$  states of a scenario  $x \in X$  can be measured by computing the sum of squared errors. The function  $W$  below computes this distance for a given scenario  $x \in X$  and state observation sequence  $o_{1,t}$ :

$$W(x, o_{1,t}) = \sum_{i=1}^t (o_i - x_i)^2.$$

We select scenarios up to a certain distance from the state sequence until time  $t$ , and we assign weights to the scenarios such that they sum to 1. The algorithm that we use to assign weights is shown in Algorithm 1. It selects a subset of scenarios  $X'$  containing at least  $\rho$  scenarios similar to  $o_{1,t}$ , based on the sum of squared errors. This step ensures that there is a sufficient number of scenarios with non-zero weight, to prevent that the future is predicted by only one or very few scenarios. A probability distribution is defined over the scenarios in  $X'$ , in which the probabilities are inversely proportional to the computed distance. A nor-

Figure 4: General dynamic Bayesian network of the Scenario-POMDP model.

malization step is performed to ensure that the sum of the probabilities equals 1. The parameter  $\rho$  can be adjusted to lower-bound the number of scenarios with non-zero probability.

### 3.2 SCENARIO-POMDP MODEL

In this section we present a POMDP model, which we can use to model any planning problem with the type of agent-environment interaction outlined in the previous section. The model can be used to reason about future states of a scenario process during planning, such that agents can reason about future states to optimize the long-term reward.

We present a POMDP model with factored states, as shown in the dynamic Bayesian network in Figure 4. Before explaining the Scenario-POMDP model in detail, we formalize it below.

**Definition 2.** (*Scenario-POMDP*). A *Scenario-POMDP* is a POMDP in which each state  $s \in S$  can be factored into a tuple  $s = (m, x, t)$ , where  $m$  is the domain-level state of the environment,  $x \in X$  is a scenario and  $t$  is a time index. A *Scenario-POMDP* has the following properties:

1. The scenario state variable  $x$  is partially observable, and state variables  $t$  and  $m$  are observable<sup>1</sup>. In state  $s = (m, x, t)$ , observation  $x_t$  is observed with probability 1, determined by  $x$  and  $t$ .
2. The transitions of  $m$  are determined by a predefined transition function. State variable  $t$  is always incremented by 1 after executing an action. The scenario state variable  $x$  is fixed.
3. The reward received in state  $s = (m, x, t)$  depends on  $x_t$ , defined by variable  $x$  and variable  $t$ , and depends on domain-level state  $m$  and action  $a$ .

A Scenario-POMDP models problems in which the interaction with the environment is represented by an MDP defining the domain-level actions and states, but the rewards also

<sup>1</sup>The Scenario-POMDP model can also be used if  $m$  is partially observable, which requires factored observations.

**input:** initial domain-level state  $m_0$ , horizon  $T$ , scenario set  $X$ , threshold  $\rho$

```

 $m \leftarrow m_0$ 
for  $t = 1, \dots, T$  do
   $o_t \leftarrow$  state of scenario process
   $o_{1,t} \leftarrow (o_1, \dots, o_t)$ 
   $w \leftarrow$  WEIGHTS( $o_{1,t}, X, \rho$ )
   $a \leftarrow$  POMCP( $m, w, t$ )
  execute action  $a$ 
   $m \leftarrow$  state obtained after executing  $a$  in state  $m$ 
end

```

### Algorithm 2: Scenario-POMCP.

depend on the state of the scenario process. Actions only affect the domain-level state  $m$ , and we assume that they do not influence the state transitions of the scenario process.

The state variable  $m$  represents the domain-level state of the environment, and the actual definition of  $m$  is dependent on the problem domain, as we will show later. The state variable  $x$  represents a scenario, where the scenario is a sequence of states as introduced in Definition 1. A scenario defines the state observations to be made in future timesteps, and therefore the scenario  $x$  is considered to be partially observable. A scenario cannot be fully observable, because this would imply that there is prior knowledge regarding future states of the scenario process. In this paper  $x$  denotes both a scenario and scenario state variable, but this makes the explanations more intuitive and clear. The state variable  $t$  is a variable representing the current timestep, and is fully observable. The Scenario-POMDP model can be considered as a MOMDP, which is a subclass of POMDPs for problems with mixed observability (Ong et al., 2010).

The observations in a Scenario-POMDP are exclusively determined by the factored state variables  $x$  and  $t$ . For scenario variable  $x$  and time variable  $t$ , the observation received by the agent is the observation at time  $t$  in scenario  $x$ . Suppose that the scenario  $x$  is (6, 9, 12) and the time state variable equals 2, then the agent will receive observation 9. This explains how the observations in Figure 4 depend on the scenario variable  $x$  and time variable  $t$ .

An action  $a$ , represented by the square in the figure, only affects the domain-level state  $m$  and does not influence the scenario  $x$ . For each action, the reward  $R$  is dependent on the domain-level state of the environment, as well as the observed state of the scenario process, defined by scenario state variable  $x$  and time variable  $t$ .

### 3.3 PLANNING FOR SCENARIO-POMDPs

We present a general planning algorithm, called Scenario-POMCP, for planning problems that can be formulated as a Scenario-POMDP. The description of the algorithm is

Table 1: Task Scheduling State Variables.

| VARIABLE                  | DESCRIPTION                               |
|---------------------------|---|
| $m_s^i$                   | state of task $i$ , for $i = 1, \dots, n$ |
| $m_a \in \{1, \dots, n\}$ | agent owning the token                    |
| $x \in X$                 | scenario                                  |
| $t \in \{1, \dots, T\}$   | time                                      |

shown in Algorithm 2. The initial domain-level state  $m_0$ , time horizon  $T$ , scenario set  $X$  and threshold  $\rho$  are given as input. The state observations  $o_t$  are used to define  $o_{1,t}$  and Algorithm 1 is used as a subroutine to assign weights to scenarios in  $X$ . The POMCP algorithm (Silver and Veness, 2010) is used as planning algorithm, which is an online planning algorithm for POMDPs based on Monte-Carlo tree search. This algorithm receives  $m$ ,  $w$  and  $t$  as input, and samples scenarios from  $X$  with a probability proportional to their weight in the vector  $w$ . We use POMCP because this algorithm can be adapted to sample scenarios based on weights, rather than sampling states from a belief state, and the algorithm is able to deal with a large number of states. The latter is relevant since the number of states of a Scenario-POMDP may grow very large. Eventually our algorithm executes the resulting action  $a$  before proceeding to the next timestep. At any timestep a new POMCP search tree is created, because there is no explicit link between the weights of consecutive timesteps. More implementation details are provided in the supplementary material.

## 4 SCENARIOS IN SMART GRIDS

In this section we formulate matching of demand with renewable supply in smart grids as a Scenario-POMDP, and we run simulations to compare the performance with other methods.

### 4.1 BACKGROUND

We consider  $n$  power demanding tasks, denoted by  $J = \{j_1, \dots, j_n\}$ , where each task  $j_i$  is parameterized by a duration  $l_i$ , release time  $r_i$ , deadline  $d_i$  and power demand  $p_i$ . Hence, we define each task  $j_i$  as a tuple  $j_i = (l_i, r_i, d_i, p_i)$ . A task is not allowed to start before its release time, must be finished by the deadline and cannot be preempted. The power demand  $p_i$  of task  $j_i$  represents the demand per timestep, which means that the total power consumption of task  $j_i$  equals  $l_i \cdot p_i$ .

There are two electricity sources: renewable energy derived from wind and conventional generation from the electricity grid. The available supply of conventional generation is assumed infinite and there is a cost function  $c(u)$  defining the

Figure 5: Dynamic Bayesian network of the Scenario-POMDP for task scheduling.

cost of consuming  $u$  units from the grid. We assume that renewable energy supply per timestep is finite, has zero cost and cannot be stored to be used in subsequent timesteps. The amount of renewable supply generated by wind is represented by a scenario  $x = (x_1, x_2, \dots, x_T)$  defining the number of units available at each timestep, where  $T$  is the time horizon.

A schedule  $S = (h_1, \dots, h_n)$  defines for each task  $j_i$  a starting time  $h_i$  satisfying the following conditions:

$$h_i \geq r_i, \quad h_i + l_i - 1 \leq d_i, \quad (i = 1, \dots, n).$$

The first condition states that task  $j_i$  cannot start before its release time  $r_i$  and the second condition defines that task  $j_i$  cannot run after the deadline  $d_i$ . The total demand  $D(S, t)$  of a schedule  $S = (h_1, \dots, h_n)$  at time  $t$  is defined as  $D(S, t) = \sum_{i=1}^n I_S(i, t) \cdot p_i$ , where  $I_S(i, t)$  is an indicator function that equals 1 if task  $j_i$  runs at time  $t$  in schedule  $S$ , and equals 0 otherwise. The number of required grid units  $U_{S,x}$  for schedule  $S$  and fixed scenario  $x = (x_1, x_2, \dots, x_T)$  can be computed as follows:

$$U_{S,x} = \sum_{t=1}^T \max(D(S, t) - x_t, 0).$$

The cost function  $c(U_{S,x})$  is used as an objective function to be minimized, in order to match demand and the renewable supply defined by the scenario.

### 4.2 SCENARIO-POMDP FORMULATION

We formulate the problem to start and defer tasks as a planning problem, in which we assume that an agent is associated with each task. A scenario  $x = (x_1, \dots, x_{24})$  is a sequence of wind state observations, where each  $x_i$  corresponds to the wind speed measured during hour  $i$ . The time

horizon  $T$  is equal to 24. Available renewable supply generated by wind is observed during the day, and the cost of running a task depends on the supply from wind and the decisions made for other tasks.

The problem is formulated as a Scenario-POMDP, using the factored state variables in Table 1. The state variables  $m_{s,1}, \dots, m_{s,n}$  define the states of the individual tasks, which encode properties such as release time, duration and deadline. The state variable  $m_a$  represents which agent is allowed to make a decision, which is used to reduce the size of the action space. More details are provided in the supplement. The factored state description is also visualized as a dynamic Bayesian network in Figure 5, which shows the correspondence with the Scenario-POMDP model in Figure 4.

An agent is able to execute two different actions: RUN and IDLE, corresponding to either running a task at a certain timeslot or doing nothing. The rewards are equal to the cost of running a task, multiplied by  $-1$ , which leads to a higher penalty if costly conventional generation is used. The observations automatically follow from the Scenario-POMDP model, as explained in Section 3.

### 4.3 EXPERIMENTS

In the experiments we run simulations to compare the proposed Scenario-POMDP formulation with other methods. We obtained historical hourly wind data from the Sotavento wind farm located in Galicia, Spain for 1708 days in the period from October 2008 until May 2013.<sup>2</sup> We consider the dataset as a long vector defining wind for 1708 consecutive days of 24 hours each, in which wind is measured in km/hr. For each subsequence of 24 hours, we define a scenario  $x = (x_1, \dots, x_{24})$ , which yields 40969 scenarios in total. In order to discretize the observation space, we round wind speed values to the nearest integer. The generated power  $Z(x, t)$  at time  $t$  in scenario  $x$  can be derived using a sigmoid power curve:

$$Z(x, t) = C \cdot (1 + e^{6 - \frac{2}{3}x_t})^{-1}$$

where  $C$  is a variable to define the capacity of the generator (Robu et al., 2012). For each task scheduling instance, we choose a scalar  $C$  such that  $Z(x, t) = \sum_{i=1}^n l_i \cdot p_i$ , which ensures that the total demand equals the available renewable supply.

We evaluate our planning algorithm on 200 task scheduling instances. Each instance consists of a set containing 6 tasks:  $J = \{j_1, j_2, \dots, j_6\}$ . We assign a duration between 3 and 7 to each task  $j_i$ , and a release time between 8 and 12, both sampled uniformly at random. The release times represent that tasks are released between 8AM and noon. The deadline  $d_i$  is set after 24 hours, to ensure that tasks

<sup>2</sup>Consult [www.sotaventogalicia.com](http://www.sotaventogalicia.com) for details.

Figure 6: Performance comparison between planning with scenarios and other methods, without outliers.

Table 2: Statistics for Smart Grids Experiment 1.

|      | CONS. | MDP  | POMCP 1 | POMCP 2 |
|------|-------|------|---------|---------|
| Mean | 1.33  | 1.15 | 1.05    | 1.23    |
| Std  | 0.44  | 0.21 | 0.12    | 0.25    |
| Max  | 4.22  | 2.55 | 2.07    | 2.84    |

have finished by the end of the day. The power demand  $p_i$  equals 10 for each task, such that running tasks require 10 units at each timestep. The cost of consuming one unit from the grid is assumed to be 1. To define the renewable supply that is available during the day in each experiment, we sample an observation sequence from the scenario set. Days in which the renewable supply is relatively flat contain limited uncertainty. Therefore, we select scenarios where the renewable supply from time 1 to 6 and from time 13 to 18 is higher than the supply during the remaining hours. This guarantees that the renewable supply is unstable and varies during the day.

In our experiments we aim to compare the performance of Scenario-POMCP with the cost of optimal omniscient schedules. These assume that the supply throughout the day is known, which is a lower bound on the performance. We use mixed-integer programming with a 1 percent MIP gap to compute this for each instance. The scenario-based POMCP planner runs 200 iterations with an  $\epsilon$ -greedy exploration strategy, in which the probability to select random actions decreases linearly from 1 to 0, and threshold  $\rho$  in the weight computation equals 10. Additionally, we run an MDP planner that is based on Monte-Carlo tree search, and we also compare with a consensus task scheduling algorithm (Ströhle et al., 2014). More implementation details, and additional information regarding the consensus algorithm, are provided in the supplement.

The results of our comparison are shown in Figure 6, in which we show the performance relative to the cost of the optimal omniscient schedules. The cost of the optimal omniscient schedules is represented by 1, and the distributions show the performance relative to this cost. For example, if the cost is 1.2, this means that the cost is 20 percent higher than the cost of an optimal omniscient schedule. For readability reasons outliers have been omitted in the figure, and therefore additional statistics are provided in Table 2.

Figure 7: Cost increase for increasing probability to exclude the state observation sequence from  $X$ .

Table 3: Statistics for Smart Grids Experiment 2.

|      | 0.0  | 0.2  | 0.4  | 0.6  | 0.8  | 1.0  |
|------|------|------|------|------|------|------|
| Mean | 1.05 | 1.10 | 1.17 | 1.20 | 1.27 | 1.23 |
| Std  | 0.12 | 0.21 | 0.35 | 0.37 | 0.38 | 0.25 |
| Max  | 2.07 | 2.77 | 4.19 | 4.19 | 4.19 | 2.84 |

From the results we can conclude that the MDP planner performs slightly better than the consensus planner. For Scenario-POMCP we ran the algorithm with two different configurations. The column labeled POMCP 1 represents the case in which the observed state scenario is already present in the scenario set  $X$ , and then it performs much better than other methods. The column labeled POMCP 2 shows the results for the experiment in which the observed state scenario is never present in the set  $X$ . In those cases the performance is slightly worse, but still competitive with other methods.

In practice it can be expected that accurate scenario sets can be obtained from large historical datasets, and it is unlikely that the observed state scenario is never present in  $X$ . Therefore, we did an additional experiment in which the observed state scenario is excluded from  $X$  with a certain probability. This means that the algorithm sometimes encounters known scenarios, and in other cases the observed scenario is new. The results are shown in Figure 7 and Table 3, from which we can conclude that the performance of Scenario-POMCP is better if it is more likely that the observed state sequence is already part of the set. Therefore, better performance can be obtained by having a scenario set that covers all possible sequences of states accurately.

Our experiments make clear that the Scenario-POMDP model can be used for matching demand and uncertain supply in the smart grids domain. Additional results can be found in previous work (Walraven and Spaan, 2015).

## 5 SCENARIOS IN OPTION TRADING

In this section we show how scenarios can be used in financial stock markets.

### 5.1 BACKGROUND

A popular type of financial option is the European call option. This option gives the holder the right, but not the obligation, to buy a share at a prescribed point in time for a prescribed price regardless of the stock price. A European call option is parameterized by a strike price  $E$  and expiry date  $H$ , giving the holder the right to pay  $E$  for a share at time  $H$ . The value of the European call option at time  $H$  is  $\max(S(H) - E, 0)$ , where  $S(H)$  denotes the stock price at time  $H$ . If the strike price is lower than the stock price at expiry, the option holder can earn money by buying a share and selling it immediately on the market. If the strike price is higher, then the trader cannot gain anything. The value of a European call option can be determined using the Black-Scholes equation (Black and Scholes, 1973), for which a description is provided in the supplement. Reasoning about the future is necessary during trading, because if the stock price drops an option may become worthless.

### 5.2 SCENARIO-POMDP FORMULATION

We formulate buying and selling call options as a single-agent planning problem. A scenario  $x = (x_1, \dots, x_t)$  is defined as a sequence of stock price values, where  $x_i$  is the stock price observed at time  $i$ . We assume that there is an agent observing the market, and depending on the stock price it may decide to buy a call option, and if it owns a call option the agent may decide to sell the option to make profit. There is one type of call options the agent can buy. If the current stock price is  $j$ , the agent can buy a call option that expires after 10 days, with strike  $j$ .

The planning problem can be defined as a Scenario-POMDP, and we formulate the problem using the factored state variables in Table 4. The scenario variable  $x$  and time variable  $t$  are identical to the state variables  $x$  and  $t$  in a Scenario-POMDP, and they define the observations. The state variables  $m_o$ ,  $m_e$  and  $m_t$  represent the current state of the option portfolio of the agent. The variable  $m_o$  can be either true (T) or false (F), representing whether the agent currently owns a call option or not. If the agent owns a call option, the strike price of the option is represented by state variable  $m_e$ , and state variable  $m_t$  represents the number of days until expiry. The factored variables  $m_o$ ,  $m_e$  and  $m_t$  together define the state  $m$  of the option portfolio. The factored state description is also visualized as a dynamic Bayesian network in Figure 8, which shows the correspondence with the Scenario-POMDP model in Figure 4.

The agent can execute three different actions: BUY, SELL and NOOP. The action NOOP represents doing nothing, and the actions BUY and SELL correspond to buying and selling an option. The agent must sell once the option has expired. The rewards correspond to either paying a certain amount of money, or receiving a certain amount of money. The agent always pays the Black-Scholes value of the op-

Table 4: Option Trading State Variables.

| VARIABLE                  | DESCRIPTION                          |
|---------------------------|--------------------------------------|
| $m_o \in \{T, F\}$        | represents whether agent owns a call |
| $m_e \in \mathbb{N}$      | strike price of the call             |
| $m_t \in \{0, \dots, 9\}$ | time to expiry                       |
| $x \in X$                 | scenario                             |
| $t \in \{1, \dots, T\}$   | time                                 |

Figure 8: Dynamic Bayesian network of the Scenario-POMDP for option trading.

tion when buying an option, and receives the Black-Scholes value of the option when selling the option. The observations automatically follow from the Scenario-POMDP model, as explained in Section 3. A full description of the state transitions and rewards can be found in the supplement.

### 5.3 EXPERIMENTS

We did several experiments to evaluate the performance of the option trading agent on realistic data. To be able to reason about the stock price in the future, we obtained the historical daily close price values to build realistic scenario sets for shares in companies A and B. For company A, we use the data from January 2, 2001 to December 8, 2010, and for company B we use the data from September 27, 2000 to September 12, 2008. The stock price values are discretized, such that each price is a natural number. We enumerated subsequences of length 40 from the datasets to create a scenario set for each company.

To evaluate the performance, we simulate the stock market for each company for a period of at least 1000 days, with historical data that is more recent than the datasets we used to create the scenario set, which ensures that both datasets are distinct. For company A we simulate the stock

Figure 9: Account balance during simulations for company A (top) and company B (bottom).

price from December 9, 2010 to December 1, 2014. For company B we simulate the stock price from September 15, 2008 to February 20, 2015. We measured the average historical volatility using an Exponential Weighted Moving Average approach (Higham, 2008), and based on that we assume that the volatility of the market equals 0.4. The annual interest rate is assumed to be 0.03.

Our scenario-based agent uses Scenario-POMCP to select actions, which is implemented with a rolling time horizon. In our experiment the number of POMCP search iterations is set to 200, and the parameter  $\rho$  is equal to 10. POMCP uses UCB (Auer et al., 2002) as action selection heuristic with parameter 100 for company A and parameter 40 for company B.

In our experiments we aim to show that our method based on scenarios trades better than other methods. We can do this by keeping track of the account balance during the simulations, and we expect that an agent using the scenario planner earns more money than other methods. We also implemented an agent that is trading randomly, and an agent using an MDP formulation of the problem, which models the stock price as a Markov chain. The MDP-based agent uses Monte-Carlo tree search to select actions.

To compare the performance of the methods involved, we compare the trajectories defining the account balance during the simulations, as shown in Figure 9. For each method it shows the balance of the bank account for either 1000 or 1600 days. For each company, the scenario-based agent earns consistently more money in comparison to the other methods and, as expected, the random agent performs poorly. Based on our experiments we conclude that planning with scenarios has shown to perform well in this domain.

## 6 RELATED WORK

Ströhle et al. (2014) present a method to schedule tasks, where the uncertainty is also represented by weighted scenarios. Their method solves the problem for each scenario to reach consensus. A similarity with our work is that the method can be used to balance demand and supply, but our Scenario-POMDP formulation has been shown to outperform the consensus algorithm in case of high uncertainty. An important difference between the work by Ströhle et al. and this paper is that we define scheduling of tasks as a planning problem.

The problem to assign weights to expert opinions regarding the future is studied by Carvalho and Larson (2013). The method proposed is similar to our work because the similarity between opinions is measured by a distance function based on squared errors, which we also use to assign weights to scenarios, and our scenarios can also be considered as opinions regarding uncertain future events. In our work we always recompute weights associated with scenarios, whereas the work on opinion pools allows experts to update weights when new opinions become available.

Optimization using scenarios has been studied in the context of stochastic programming. Multi-stage stochastic programming problems can be considered as a subclass of Markov Decision Processes with a finite horizon (Defourny et al., 2011), and in this formalism the uncertainty is also represented by future scenarios, which is similar to our representation of state scenarios.

Exploiting factored structures in the POMCP algorithm has been studied by Amato and Oliehoek (2015). They propose a variant of POMCP that does not assume a factored model, but it uses factored value functions, which reduces the number of joint actions and joint histories in the multi-agent setting. A similarity is that we use a factored representation in each node of the POMCP search tree, which we can exploit to sample scenarios rather than states, but factored value functions have not been considered in our work.

## 7 CONCLUSIONS

In this paper we proposed a scenario-based approach to predict external factors that are difficult to model using a compact Markovian state. Scenarios represent sequences of states, and we have shown how a scenario can be weighted based on a sequence of states that occurred in the past, corresponding to the likelihood that a scenario perfectly predicts future states. In order to use the scenario representation in planning problems, we proposed a model called Scenario-POMDP, which enables agents to reason about future states during planning. To demonstrate the proposed model, we formulated matching of demand with renewable supply in smart grids as a Scenario-POMDP, and we have shown that our model can also be used to automati-

cally trade financial options. In both cases our Scenario-POMDP model performs better than other methods for decision making in these domains.

In future work we aim to study metrics for computing the distance between scenarios in which states are not represented by a single numerical value. Another direction for further research is defining a belief update for scenarios based on Bayes' rule, to replace the Monte-Carlo backups in our planner. Moreover, in our current work we assume that the domain-level state of the environment is observable, but we also want to study planning with scenarios for problems in which this part of the environment is partially observable, which requires factored observations.

## Abstract

Transfer learning (sometimes also referred to as domain-adaptation) algorithms are often used when one tries to apply a model learned from a fully labeled source domain, to an unlabeled target domain, that is similar but not identical to the source. Previous work on covariate shift focuses on matching the marginal distributions on observations  $X$  across domains while assuming the conditional distribution  $P(Y|X)$  stays the same. Relevant theory focusing on covariate shift has also been developed. Recent work on transfer learning under model shift deals with different conditional distributions  $P(Y|X)$  across domains with a few target labels, while assuming the changes are smooth. However, no analysis has been provided to say when these algorithms work. In this paper, we analyze transfer learning algorithms under the model shift assumption. Our analysis shows that when the conditional distribution changes, we are able to obtain a generalization error bound of  $O(\frac{1}{\lambda_*\sqrt{n_t}})$  with respect to the labeled target sample size  $n_t$ , modified by the smoothness of the change ( $\lambda_*$ ) across domains. Our analysis also sheds light on conditions when transfer learning works better than no-transfer learning (learning by labeled target data only). Furthermore, we extend the transfer learning algorithm from a single source to multiple sources.

## 1 INTRODUCTION

In a classical transfer learning setting (see Fig. 1), we have a source domain with sufficient fully labeled data, and a target domain with data that has little or no labels. These two domains are related but not identical, and the usual assumption is that there is some knowledge that can be transferred from the source domain to the target domain. Examples of transfer learning applied in the real-world include, adapting

classification models for different products, and transferring across diseases on medical data (Pan et al. (2009)). A number of different transfer learning techniques have been introduced in the past, e.g., algorithms dealing with covariate shift (Shimodaira (2000), Huang et al. (2007), Gretton et al. (2007)). Related theoretical analyses on covariate shift have also been developed, e.g., for sample size  $m$  in the source domain and sample size  $n$  in the target domain, the analysis of Mansour et al. (2009) achieves a rate of  $O(m^{-1/2} + n^{-1/2})$ , and convergence of reweighted means in feature space achieves rate  $O((1/m + 1/n)^{1/2})$  (Huang et al. (2007)).

Figure 1: Transfer learning example:  $m$  source data points  $\{X^s, Y^s\}$  (red),  $n$  target data points  $\{X^t, Y^t\}$  (blue), and  $n_t$  labeled target points (solid blue circles). Here  $X$  denotes the input features and  $Y$  denotes the output labels.

However, not much work on transfer learning has considered the case when a few labels in the target domain are available. Also little work has been done when conditional distributions are allowed to change (defined as **model shift**). Recently, algorithms dealing with transfer learning under model shift have been proposed, where the changes on conditional distributions are assumed to be smooth (Wang et al. (2014)). However, no theoretical analysis has been provided for these approaches.

In this paper, we develop theoretical analysis for transfer learning algorithms under the model shift assumption. Our analysis shows that even when the conditional distributions are allowed to change across domains, we are still able to obtain a generalization bound of  $O(\frac{1}{\lambda_*\sqrt{n_t}})$  with respect to

the labeled target sample size  $n_t$ , modified by the smoothness of the transformation parameters ( $\lambda_*$ ) across domains. Our analysis also sheds light on conditions when transfer learning works better than no-transfer learning. We show that under certain smoothness assumptions it is possible to obtain a favorable convergence rate with transfer learning compared to no transfer at all. Furthermore, using the generalization bounds we derived in this paper, we are able to extend the transfer learning algorithm from a single source to multiple sources, where each source is assigned a weight that indicates how helpful it is for transferring to the target.

We illustrate our theoretical results by empirical comparisons on both synthetic data and real-world data. Our results demonstrate cases where we obtain the same rate as no-transfer learning, and cases where we obtain a favorable rate with transfer learning under certain smoothness assumptions, which coincide with our theoretical analysis. In addition, experiments on the real data show that our algorithm for reweighting multiple sources yields better results than existing state-of-the-art algorithms.

## 2 RELATED WORK

Traditional methods for transfer learning use relatively restrictive assumptions, where specific parts of the learning model are assumed to be carried over between tasks. For example, Mihalkova et al. (2007) transfers relational knowledge across domains using Markov logic networks. Niculescu-Mizil & Caruana (2007) learns Bayes Net structures by biasing learning toward similar structures for each task. Do & Ng (2005) and Raina et al. (2006) assume that models for related tasks share same parameters or prior distributions of hyperparameters.

A large part of transfer learning work is devoted to the problem of covariate shift (Shimodaira (2000), Huang et al. (2007), Gretton et al. (2007)), where the assumption is that only the marginal distribution  $P(X)$  differs across domains but the conditional distribution  $P(Y|X)$  stays the same. The kernel mean matching (KMM) method (Huang et al. (2007), Gretton et al. (2007)), is one of the algorithms that deal with covariate shift. Huang et al. (2007) proved the convergence of reweighted means in the feature space, and showed that their method results in almost unbiased risk estimates. More recent research (Zhang et al. (2013)) focused on modeling target shift ( $P(Y)$  changes), conditional shift ( $P(X|Y)$  changes), and a combination of both. The assumption for target shift is that  $X$  depends causally on  $Y$ , thus  $P(Y)$  can be re-weighted to match the distributions on  $X$  across domains. The authors also provided some theoretical analysis of the conditions when  $P(X|Y)$  is identifiable. Both covariate shift and target/conditional shift make no use of target labels  $Y^t$ , even if some are available. For transfer learning under model shift, there could be a difference in  $P(Y|X)$  that can not simply be captured by

the differences in  $P(X)$ , hence neither covariate shift nor target/conditional shift will work well under the model shift assumption.

A number of theoretical analyses on domain adaptation have also been developed. Ben-David et al. (2006) presented VC-dimension-based generalization bounds for adaptation in classification tasks. Later Blitzer et al. (2007) extended the work with a bound on the error rate under a weighted combination of the source data. Mansour et al. (2009) introduced a discrepancy distance suitable for arbitrary loss functions and derived new generalization bounds for domain adaptation for a wide family of loss functions. However, most of the work mentioned above deals with domain adaptation under the covariate shift assumption, which means they still assume the conditional distribution stays the same across domains, or the labeling functions in the two domains share strong proximity in order for adaptation to be possible. For example, one of the bounds derived in Mansour et al. (2009) has a term  $\mathcal{L}(h_Q^*, h_P^*)$  related to the average loss between the minimizer  $h_Q^*$  in the source domain and the minimizer  $h_P^*$  in the target domain, which could be fairly large when there exists a constant offset between the two labeling functions.

In Wang et al. (2014), the authors proposed a transfer learning algorithm to handle the general case where  $P(Y|X)$  changes smoothly across domains. However, the authors fail to make explicit connections between the smoothness assumption and the generalization bounds for transfer learning. They do not show whether the performance will degrade when the smoothness assumption is relaxed, and whether the smoothness assumption yields a lower generalization error for transfer learning than no-transfer learning.

Similarly, most work in transfer learning with multiple sources focuses only on  $P(X)$ . For example, Mansour et al. (2008) proposed a distribution weighted combining rule of source hypotheses using the input distribution  $P(X)$  for both source and target. This approach requires estimating the distribution  $D_i(x)$  of source  $i$  on a target point  $x$  from large amounts of unlabeled points typically available from the source, which might be difficult in real applications with high-dimensional features. Other existing work focuses on finding the set of sources that are closely related to the target (Crammer et al. (2008)), or a reweighting of sources based on prediction errors (Yao and Doretto, (2010)). Chattopadhyay et al. (2011) proposed a conditional probability based weighting scheme under a joint optimization framework, which leads to a reweighting of sources that prefers more consistent predictions on the target. However, these existing approaches do not consider the problem that there might exist shifts in the conditional distribution from source to the target, and how the smoothness of this shift can help in learning the target, which is the main issue addressed in this paper.

### 3 TRANSFER LEARNING UNDER MODEL SHIFT: A REVIEW OF THE ALGORITHMS

**Notation:** Let  $\mathcal{X} \in \mathcal{R}^d$  and  $\mathcal{Y} \in \mathcal{R}$  be the input and output space for both the source and the target domain. We are given a set of  $m$  labeled data points,  $(x_i^s, y_i^s) \in (X^s, Y^s)$ ,  $i = 1, \dots, m$ , from the source domain. We are also given a set of  $n$  target data points,  $X^t$ , from the target domain. Among these we have  $n_l$  labeled target data points, denoted as  $(X^{tL}, Y^{tL})$ . The unlabeled part of  $X^t$  is denoted as  $X^{tU}$ , with unknown labels  $Y^{tU}$ . For simplicity let  $z \in \mathcal{Z} = \mathcal{X} \times \mathcal{Y}$  denote the pair of  $(x, y)$ , and we use  $z^s, z^t, z^{tL}$  for the source, target, and labeled target, correspondingly. We assume  $X^s, X^t$  are drawn from the same  $P(X)$  throughout the paper since we focus more on  $P(Y|X)$ <sup>1</sup>. If necessary  $P(X)$  can be easily matched by various methods dealing with covariate shift (e.g. Kernel Mean Matching) without the use of  $Y$ .

Let  $\mathcal{H}$  be a reproducing kernel Hilbert space with kernel  $K$  such that  $K(x, x) \leq \kappa^2 < \infty$  for all  $x \in X$ . Let  $\|\cdot\|_k$  denote the corresponding RKHS norm. Let  $\phi$  denote the feature mapping on  $x$  associated with kernel  $K$ , and  $\Phi(X)$  denote the matrix where the  $i$ -th column is  $\phi(x_i)$ . Denote  $K_{XX'}$  as the kernel computed between matrix  $X$  and  $X'$ , i.e.,  $K_{ij} = k(x_i, x'_j)$ . When necessary, we use  $\psi$  to denote the feature map on  $y$ , and the corresponding matrix as  $\Psi(Y)$ . For a hypothesis  $h \in \mathcal{H}$ , assume that  $|h(x)| \leq M$  for some  $M > 0$ . Also assume bounded label set  $|y| \leq M$ . We use  $\ell_2$  loss as the loss function  $l(h(x), y)$  throughout this paper, which is  $\sigma$ -admissible, i.e.,

$$\forall x, y, \forall h, h', |l(h(x), y) - l(h'(x), y)| \leq \sigma |h(x) - h'(x)|. \quad (1)$$

It is easy to see that  $\sigma = 4M$  for bounded  $h(x)$  and  $y$ . Note the loss function is also bounded,  $l(h(x), y) \leq 4M^2$ .

Next we will briefly review two algorithms introduced in Wang et al. (2014) that handle transfer learning under model shift: the first is conditional distribution matching, and the second is two-stage offset estimation.

#### (1) Conditional Distribution Matching (CDM).

The basic idea of CDM is to match the conditional distributions  $P(Y|X)$  for the source and the target domain. Since there is a difference in  $P(Y|X)$  across domains, these two conditional distributions cannot be matched directly. Therefore, the authors propose to make a parameterized-location-scale transform on the source labels  $Y^s$ :

$$Y^{new} = Y^s \odot \mathbf{w}(X^s) + \mathbf{b}(X^s),$$

where  $\mathbf{w}$  denotes the scale transform,  $\mathbf{b}$  denotes the location transform, and  $\odot$  denotes the Hadamard (elementwise)

<sup>1</sup>This assumption is only required in our analysis for simplicity. It can be relaxed when applying the algorithms.

Figure 2: Illustration of the conditional distribution matching algorithm: red (source), blue (target).

product.  $\mathbf{w}$  and  $\mathbf{b}$  are non-linear functions of  $X$  which allows a non-linear transform from  $Y^s$  to  $Y^{new}$ .

The objective is to use the transformed conditional distribution in the source domain  $P(Y^{new}|X^s)$ , to match the conditional distribution in the target domain,  $P(Y^{tL}|X^{tL})$ , such that the transformation parameter  $\mathbf{w}$  and  $\mathbf{b}$  can be learned through optimization. The matching on  $P(Y|X)$  is achieved by minimizing the discrepancy of the mean embedding of  $P(Y|X)$  with a regularization term:

$$\min_{\mathbf{w}, \mathbf{b}} L + L_{reg}, \text{ where} \quad (2)$$

$$L = \|\hat{\mathcal{U}}[P_{Y^{new}|X^s}] - \hat{\mathcal{U}}[P_{Y^{tL}|X^{tL}}]\|_k^2,$$

$$L_{reg} = \lambda_{reg} (\|\mathbf{w} - \mathbf{1}\|^2 + \|\mathbf{b}\|^2),$$

where  $\mathcal{U}[P_{Y|X}]$  is the mean embedding of the conditional distribution  $P(Y|X)$  (Song et al. (2009)), and  $\hat{\mathcal{U}}[P_{Y|X}]$  is the empirical estimation of  $\mathcal{U}[P_{Y|X}]$  based on samples  $X, Y$ . Further the authors make a smoothness assumption on the transformation, i.e.,  $\mathbf{w}, \mathbf{b}$  are parameterized using:  $\mathbf{w} = R\mathbf{g}, \mathbf{b} = R\mathbf{h}$ , where  $R = K_{X^s X^s} (K_{X^s X^s} + \lambda_R I)^{-1}$ , and  $\mathbf{g}, \mathbf{h} \in \mathbb{R}^{m \times 1}$  are the new parameters to optimize in the objective. After obtaining  $\mathbf{g}, \mathbf{h}$  (or equivalently  $\mathbf{w}, \mathbf{b}$ ),  $Y^{new}$  is computed based on the transformation. Finally the prediction on  $X^{tU}$  is based on the merged data:  $(X^s, Y^{new}) \cup (X^{tL}, Y^{tL})$ .

Fig 2 shows an illustration of the conditional distribution matching algorithm. As we can see from the figure,  $Y^s$  is transformed to  $Y^{new}$  such that  $P(Y^{new}|X^s)$  and  $P(Y^{tL}|X^{tL})$  can be approximately matched together.

**Remark.** Here we analyze what happens when the smoothness assumption is relaxed. It is easy to derive that, when setting  $\mathbf{w} = \mathbf{1}, \mathbf{b} = \mathbf{0}$ , we can directly solve for  $Y^{new}$  by taking the derivative of  $L$  with respect to  $Y^{new}$ , and we get:

$$K_{X^s X^s} (K_{X^s X^s} + \lambda I)^{-1} Y^{new} = K_{X^s X^{tL}} (K_{X^{tL} X^{tL}} + \lambda I)^{-1} Y^{tL}, \quad (3)$$

where  $\lambda$  is some regularization parameter to make sure the kernel matrix is invertible. In other words, the smoothed  $Y^{new}$  is given by the prediction on the source using only labeled target data. Hence  $Y^{new}$  provides no extra information for prediction on the target, compared with using the labeled target data alone.

## (2) Two-stage Offset Estimation (Offset).

The idea of Offset is to model the target function  $f^t$  using the source function  $f^s$  and an offset,  $f^o = f^t - f^s$ , while assuming that the offset function is smoother than the target function. Specifically, using kernel ridge regression (KRR) to estimate all three functions, the algorithm works as follows:

- (1) Model the source function using the source data, i.e.,  $f^s(x) = K_{xX^s}(K_{X^sX^s} + \lambda I)^{-1}Y^s$ .
- (2) Model the offset function by the difference between the true target labels and the predicted target labels, i.e.,  $f^o(X^{tL}) = Y^{tL} - f^s(X^{tL})$ .
- (3) Transform  $Y^s$  to  $Y^{new}$  by adding the offset, i.e.,  $Y^{new} = Y^s + f^o(X^s)$ , where  $f^o(X^s) = K_{X^sX^{tL}}(K_{X^{tL}X^{tL}} + \lambda I)^{-1}f^o(X^{tL})$ .
- (4) Train a model on  $\{X^s, Y^{new}\} \cup \{X^{tL}, Y^{tL}\}$ , and use the model to make predictions on  $X^{tU}$ .

We would like to answer: under what conditions these transfer learning algorithms will work better than no-transfer learning, and how the smoothness assumption affects the generalization bounds for these algorithms.

## 4 ANALYSIS OF CONDITIONAL DISTRIBUTION MATCHING

In this section, we analyze the generalization bound for the conditional distribution matching (CDM) approach.

### 4.1 RISK ESTIMATES FOR CDM

We use stability analysis on the algorithm to estimate the generalization error. First we have:

**Theorem 1.** (Bousquet & Elisseeff (2002), Theorem 12 and Example 3) Consider a training set  $S = \{z_1 = (x_1, y_1), \dots, z_m = (x_m, y_m)\}$  drawn i.i.d. from an unknown distribution  $D$ . Let  $l$  be the  $\ell_2$  loss function which is  $\sigma$ -admissible with respect to  $\mathcal{H}$ , and  $l \leq 4M^2$ . The Kernel Ridge Regression algorithm defined by:

$$A_S = \arg \min_{h \in \mathcal{H}} \frac{1}{m} \sum_{i=1}^m l(h, z_i) + \lambda \|h\|_k^2$$

has uniform stability  $\beta$  with respect to  $l$  with  $\beta \leq \frac{\sigma^2 \kappa^2}{2\lambda m}$ .

In addition, let  $R = \mathbb{E}_z[l(A_S, z)]$  be the generalization error, and  $R_{emp} = \frac{1}{m} \sum_{i=1}^m l(A_S, z_i)$  be the empirical error, then the following holds with probability at least  $1 - \delta$ ,

$$R \leq R_{emp} + \frac{\sigma^2 \kappa^2}{\lambda m} + \left(\frac{2\sigma^2 \kappa^2}{\lambda} + 4M^2\right) \sqrt{\frac{\ln(1/\delta)}{2m}}.$$

In CDM, the prediction on the unlabeled target data points is given by merging the transformed source data and the labeled target data, i.e.,  $(X^s, Y^{new}) \cup (X^{tL}, Y^{tL})$ . Hence

we need to bound the difference between the empirical error on the merged data and the generalization error (risk) in the target domain.

Denote  $\tilde{z}_i = (\tilde{x}_i, \tilde{y}_i) \in (\tilde{X}, \tilde{Y})$ , where  $\tilde{X}, \tilde{Y}$  represents the merged data:  $\tilde{X} = X^s \cup X^{tL}, \tilde{Y} = Y^{new} \cup Y^{tL}$ . Let  $h^* \in \mathcal{H}$  be the minimizer on the merged data, i.e.,

$$h^* = \arg \min_{h \in \mathcal{H}} \frac{1}{m + n_l} \sum_{i=1}^{m+n_l} l(h, \tilde{z}_i) + \lambda \|h\|_k^2.$$

Then the following theorem holds:

**Theorem 2.** Assume the conditions in Theorem 1 hold. Also assume  $\|\hat{\mathcal{U}}[P_{Y^{new}|X^s}] - \hat{\mathcal{U}}[P_{Y^{tL}|X^{tL}}]\|_k \leq \epsilon$  after we optimize objective Eq. 2. The following holds with probability at least  $1 - \delta$ :

$$\begin{aligned} & \left| \frac{1}{m + n_l} \sum_{i=1}^{m+n_l} l(h^*, \tilde{z}_i) - E_{z^t}[l(h^*, z^t)] \right| \\ & \leq 4M(\epsilon \kappa + C(\lambda_c^{1/2} + (n_l \lambda_c)^{-1/2})) + \\ & \quad \frac{\sigma^2 \kappa^2}{\lambda_t(m + n_l)} + \left(\frac{2\sigma^2 \kappa^2}{\lambda_t} + 4M^2\right) \sqrt{\frac{\ln(1/\delta)}{2(m + n_l)}}, \end{aligned}$$

where  $\lambda_c$  is the regularization parameter used in estimating  $\hat{\mathcal{U}}[P_{Y^{tL}|X^{tL}}] = \Psi(Y^{tL})(K_{X^{tL}X^{tL}} + \lambda_c n_l I)^{-1} \Phi^\top(X^{tL})$ , and  $\lambda_t$  is the regularization parameter when estimating the target function.  $C > 0$  is some constant.

*Proof.* Let  $\bar{z}_i = (\bar{x}_i, \bar{y}_i) \in (\bar{X}, \bar{Y})$ , where  $\bar{X}, \bar{Y}$  are the auxiliary samples with  $\bar{X} = X^s \cup X^{tL}, \bar{Y} = \bar{Y}_s^t \cup Y^{tL}$ , where  $\bar{Y}_s^t$  are pseudo labels in the target domain for the source data points  $X^s$ . Using triangle inequality we can decompose the LHS by:

$$\begin{aligned} & \left| \frac{1}{m + n_l} \sum_{i=1}^{m+n_l} l(h^*, \tilde{z}_i) - E_{z^t}[l(h^*, z^t)] \right| \\ & \leq \left| \frac{1}{m + n_l} \sum_{i=1}^{m+n_l} l(h^*, \tilde{z}_i) - \frac{1}{m + n_l} \sum_{i=1}^{m+n_l} l(h^*, \bar{z}_i) \right| \\ & \quad + \left| \frac{1}{m + n_l} \sum_{i=1}^{m+n_l} l(h^*, \bar{z}_i) - E_{z^t}[l(h^*, z^t)] \right| \end{aligned}$$

The second term is easy to bound since it is simply the difference between the empirical error and the generalization error in the target domain with effective sample size  $n_l + m$ , thus using Theorem 1, we have

$$\begin{aligned} & \left| \frac{1}{m + n_l} \sum_{i=1}^{m+n_l} l(h^*, \bar{z}_i) - E_{z^t}[l(h^*, z^t)] \right| \\ & \leq \frac{\sigma^2 \kappa^2}{\lambda_t(m + n_l)} + \left(\frac{2\sigma^2 \kappa^2}{\lambda_t} + 4M^2\right) \sqrt{\frac{\ln(1/\delta)}{2(m + n_l)}}. \end{aligned} \quad (4)$$

To bound the first term, we have

$$\begin{aligned}
& \left| \frac{1}{m+n_l} \sum_{i=1}^{m+n_l} l(h^*, \tilde{z}_i) - \frac{1}{m+n_l} \sum_{i=1}^{m+n_l} l(h^*, \bar{z}_i) \right| \\
& \leq \frac{1}{m+n_l} \sum_{i=1}^{m+n_l} |l(h^*, \tilde{z}_i) - l(h^*, \bar{z}_i)| \\
& \leq \frac{1}{m+n_l} \sum_{i=1}^m 4M |y_i^{new} - \mathcal{U}[P_{Y^t|X^t}] \phi(x_i^s)| \\
& \leq \frac{4M}{m+n_l} \sum_{i=1}^m (|\hat{\mathcal{U}}[P_{Y^{new}|X^s}] \phi(x_i^s) - \hat{\mathcal{U}}[P_{Y^{tL}|X^{tL}}] \phi(x_i^s)| \\
& \quad + |\hat{\mathcal{U}}[P_{Y^{tL}|X^{tL}}] \phi(x_i^s) - \mathcal{U}[P_{Y^t|X^t}] \phi(x_i^s)|) \\
& \leq \frac{4M}{m+n_l} \sum_{i=1}^m (|\hat{\mathcal{U}}[P_{Y^{new}|X^s}] - \hat{\mathcal{U}}[P_{Y^{tL}|X^{tL}}]|_k \sqrt{k(x, x)} \\
& \quad + |\hat{\mathcal{U}}[P_{Y^{tL}|X^{tL}}] \phi(x_i^s) - \mathcal{U}[P_{Y^t|X^t}] \phi(x_i^s)|) \\
& \leq 4M(\epsilon\kappa + C(\lambda_c^{1/2} + (n_l\lambda_c)^{-1/2})), \tag{5}
\end{aligned}$$

where in the last inequality, the second term is bounded using Theorem 6, Song et al. (2009).

Now combining Eq. 5 and Eq. 4 concludes the proof.  $\square$

## 4.2 TIGHTER BOUNDS UNDER SMOOTH PARAMETERIZATION

Theorem 2 suggests that using CDM, the empirical risk converges to the expected risk at a rate of

$$O(\lambda_c^{1/2} + (n_l\lambda_c)^{-1/2} + \lambda_t^{-1}(m+n_l)^{-1/2}). \tag{6}$$

In the following, we show how the smoothness parameterization in CDM helps us obtain faster convergence rates.

Under the smoothness assumption on the transformation,  $\mathbf{w}$ ,  $\mathbf{b}$  are parameterized using:  $\mathbf{w} = R\mathbf{g}$ ,  $\mathbf{b} = R\mathbf{h}$ , where  $R = K_{X^s X^s}(K_{X^s X^s} + \lambda_R I)^{-1}$ . For simplicity we assume the same  $\lambda_R$  for both  $\mathbf{w}$  and  $\mathbf{b}$ . Similar to the derivation in Eq. 5, we have

$$\begin{aligned}
& |y_i^{new} - \mathcal{U}[P_{Y^t|X^t}] \phi(x_i^s)| \\
& = |\hat{\mathcal{U}}[P_{Y^{new}|X^s}] \phi(x_i^s) - \hat{\mathcal{U}}[P_{Y^{tL}|X^{tL}}] \phi(x_i^s)| \\
& \quad + |\hat{\mathcal{U}}[P_{Y^{tL}|X^{tL}}] \phi(x_i^s) - \mathcal{U}[P_{Y^t|X^t}] \phi(x_i^s)| \\
& \leq \epsilon\kappa + |\hat{\mathcal{U}}[P_{w^{tL}|X^{tL}}] \phi(x_i^s) - \mathcal{U}[P_{w^t|X^t}] \phi(x_i^s)| \cdot |y_i^s| \\
& \quad + |\hat{\mathcal{U}}[P_{b^{tL}|X^{tL}}] \phi(x_i^s) - \mathcal{U}[P_{b^t|X^t}] \phi(x_i^s)| \\
& \leq \epsilon\kappa + C_1(\lambda_R^{1/2} + (n_l\lambda_R)^{-1/2})M + C_2(\lambda_R^{1/2} + (n_l\lambda_R)^{-1/2})|y_i^s| \\
& \leq \epsilon\kappa + C'(\lambda_R^{1/2} + (n_l\lambda_R)^{-1/2}). \tag{7}
\end{aligned}$$

Hence we can update the bound in Eq. 5 by:

$$\begin{aligned}
& \left| \frac{1}{m+n_l} \sum_{i=1}^{m+n_l} l(h^*, \tilde{z}_i) - \frac{1}{m+n_l} \sum_{i=1}^{m+n_l} l(h^*, \bar{z}_i) \right| \\
& \leq 4M(\epsilon\kappa + C'(\lambda_R^{1/2} + (n_l\lambda_R)^{-1/2})). \tag{8}
\end{aligned}$$

It is easy to see that Eq. 4 remains the same. Hence, the rate for CDM under the smooth parametrization is:

$$O(\lambda_R^{1/2} + (n_l\lambda_R)^{-1/2} + \lambda_t^{-1}(m+n_l)^{-1/2}). \tag{9}$$

In transfer learning we usually assume the number of source data is sufficient, i.e.,  $m \rightarrow \infty$ . Comparing Eq. 9 with Eq. 6 we can see that, when the number of labeled points  $n_l$  is small, the term  $(n_l\lambda_c)^{-1/2}$  in Eq. 6 and the term  $(n_l\lambda_R)^{-1/2}$  in Eq. 9 take over. If we further assume that the transformation  $\mathbf{w}$  and  $\mathbf{b}$  are smoother functions with respect to  $X$  than the target function with respect to  $X$ , i.e.,  $\lambda_R > \lambda_c$ , then Eq. 9 is more favorable. On the other hand, when the number of labeled target points  $n_l$  is large enough for the first term  $\lambda_c^{1/2}$  in Eq. 6 and the first term  $\lambda_R^{1/2}$  in Eq. 9 to take over, then it is reasonable to use a  $\lambda_R$  closer to  $\lambda_c$  to get a similar convergence rate as in Eq. 6. Intuitively, when the number of labeled target points is large enough, it is not very helpful to transfer from the source for target prediction.

**Remark.** Note that in Eq. 6 and Eq. 9, an ideal choice of  $\lambda$  close to  $1/\sqrt{n_l}$  can minimize  $\lambda^{1/2} + (n_l\lambda)^{-1/2}$ . However, note that the generalization bound is the difference between the expected risk  $R$  and the empirical risk  $R_{emp}$ , and a  $\lambda$  that minimizes the generalization bound does not necessarily minimize the expected risk  $R$ , since the empirical risk  $R_{emp}$  (which is also affected by  $\lambda$ ) can still be large. To obtain a relatively small empirical risk,  $\lambda$  should be determined by the smoothness of the offset/target function, since it is the regularization parameter when estimating the offset/target. In practice  $\lambda$  is chosen by cross validation on the labeled data, and is not necessarily close to  $1/\sqrt{n_l}$ . For example, on real data we find that  $\lambda$  is usually chosen to be in the range of  $1e-2$  to  $1e-4$  to accommodate a fairly wide range of functions, which makes the second term  $1/\sqrt{n_l\lambda}$  dominate the risk if  $n_l$  is much smaller than  $1e4$ .

### 4.2.1 Connection with Domain Adaptation Learning Bounds

In Mansour et al. (2009), the authors provided several bounds on the pointwise difference of the loss for two different hypothesis (Theorem 11, 12 and 13). It is worth noting that in order to bound the pointwise loss, the authors make the following assumptions when the labeling function  $f_S$  (source) and  $f_T$  (target) are potentially different:

$$\delta^2 = L_{\hat{S}}(f_S(x), f_T(x)) \ll 1,$$

where  $L_{\hat{S}}(f_S(x), f_T(x)) = \mathbb{E}_{\hat{S}(x)} l(f_S(x), f_T(x))$ . This condition is easily violated under the model shift assumption, where the two labeling functions can differ by a large margin. However, with our transformation from  $Y^s$  to  $Y^{new}$ , we can translate the above assumption to the following equivalent condition:

$$\delta^2 = L_{\hat{S}}(Y^{new}, f_T(x)) = \frac{1}{m} \sum_{i=1}^m (y_i^{new} - \mathcal{U}[P_{Y^t|X^t}] \phi(x_i^s))^2$$

$$\leq (\epsilon\kappa + C'(\lambda_R^{1/2} + (n_l\lambda_R)^{-1/2}))^2,$$

using the results in Eq. 7. Hence we can bound  $\delta^2$  to be small under reasonable assumptions on  $n_l$  and  $\lambda_R$ .

#### 4.2.2 Comparing with No-transfer Learning

Without transfer, which means we predict on the unlabeled target set based merely on the labeled target set, the generalization error bound is simply:  $|\frac{1}{n_l} \sum_{i=1}^{n_l} l(h^{tL}, z_i^{tL}) - E_{z^t}[l(h^{tL}, z^t)]| \leq \frac{\sigma^2\kappa^2}{\lambda_t n_l} + (\frac{2\sigma^2\kappa^2}{\lambda_t} + 4M^2) \sqrt{\frac{\ln(1/\delta)}{2n_l}}$ , where  $h^{tL}$  is the KRR minimizer on  $\{X^{tL}, Y^{tL}\}$ . Then

$$E_{z^t}[l(h^{tL}, z^t)] - \frac{1}{n_l} \sum_{i=1}^{n_l} l(h^{tL}, z_i^{tL}) = O(\frac{1}{\lambda_t \sqrt{n_l}}). \quad (10)$$

We can see that with transfer learning, first we obtain a faster rate  $O(\lambda_t^{-1}(m + n_l)^{-1/2})$  in Eq. 9 with effective sample size  $n_l + m$  than  $O(\lambda_t^{-1}n_l^{-1/2})$  in Eq. 10 with effective sample size  $n_l$ . However, the transfer-rate Eq. 9 comes with a penalty term  $O(\lambda_R^{1/2} + (n_l\lambda_R)^{-1/2})$  which captures the estimation error between the transformed labels and the true target labels. Again, in transfer learning usually we assume  $m \rightarrow \infty$ , and  $n_l$  is relatively small, then the transfer-rate becomes  $O((n_l\lambda_R)^{-1/2})$ . Further if we assume that the smoothness parameter  $\lambda_R$  for the transformation is larger than the smoothness parameter  $\lambda_t$  for the target function ( $\lambda_R > \lambda_t$  will be sufficient if  $\lambda_R < 1$ , otherwise we need to set  $\lambda_R > \lambda_t^2$  if  $\lambda_R \geq 1$ ), then we obtain a faster convergence rate with transfer than no-transfer. We will further illustrate the results by empirical comparisons on synthetic and real data in the experimental section.

## 5 ANALYSIS ON THE OFFSET METHOD

In this section, we analyze the generalization error on the two-stage offset estimation (**Offset**) approach. Interestingly, our analysis shows that the generalization bounds for offset and CDM have the same dependency on  $n_l$ .

### 5.1 RISK ESTIMATES FOR OFFSET

(1) First, we learn a model from the source domain by minimizing the squared loss on the source data, i.e.,

$$h^s = \arg \min_{h \in \mathcal{H}} \frac{1}{m} \sum_{i=1}^m l(h, z_i^s) + \lambda_s \|h\|_k^2.$$

Using Theorem 1, we have with probability at least  $1 - \delta$ ,

$$R^s \leq R_{emp}^s + \frac{\sigma^2\kappa^2}{\lambda_s m} + (\frac{2\sigma^2\kappa^2}{\lambda_s} + 4M^2) \sqrt{\frac{\ln(1/\delta)}{2m}},$$

where  $R^s = E_{z^s}[l(h^s, z^s)]$ ,  $R_{emp}^s = \frac{1}{m} \sum_{i=1}^m l(h^s, z_i^s)$ . Hence

$$R^s - R_{emp}^s = O(\frac{1}{\lambda_s \sqrt{m}}), \quad (11)$$

(2) Second, we learn the offset by KRR on  $\{X^{tL}, \hat{y}^o\}$ , where  $\hat{y}^o = Y^{tL} - f^s(X^{tL})$ , i.e.,  $\hat{y}^o$  is the estimated offset on labeled target points  $X^{tL}$ , and  $f^s(X^{tL})$  is the prediction on  $X^{tL}$  using source data.

Denote  $\hat{h}^o$  as the minimizer on  $\hat{z}^o = \{X^{tL}, \hat{y}^o\}$ , i.e.,

$$\hat{h}^o = \arg \min_{h \in \mathcal{H}} \frac{1}{n_l} \sum_{i=1}^{n_l} l(h, \hat{z}_i^o) + \lambda_o \|h\|_k^2$$

$$= \arg \min_{h \in \mathcal{H}} R(h) + N(h). \quad (12)$$

Denote  $h^o$  as the minimizer on  $z^o = \{X^{tL}, y^o\}$ , where  $y^o$  is the unknown true offset:

$$h^o = \arg \min_{h \in \mathcal{H}} \frac{1}{n_l} \sum_{i=1}^{n_l} l(h, z_i^o) + \lambda_o \|h\|_k^2$$

$$= \arg \min_{h \in \mathcal{H}} R'(h) + N(h), \quad (13)$$

Using Theorem 1, we have with probability at least  $1 - \delta$ ,

$$R^o \leq R_{emp}^o + \frac{\sigma^2\kappa^2}{\lambda_o n_l} + (\frac{2\sigma^2\kappa^2}{\lambda_o} + 4M^2) \sqrt{\frac{\ln(1/\delta)}{2n_l}} \quad (14)$$

where  $R^o = E_{z^o}[l(h^o, z^o)]$ ,  $R_{emp}^o = \frac{1}{n_l} \sum_{i=1}^{n_l} l(h^o, z_i^o)$ . In our estimation we use  $\hat{y}^o$  instead of  $y^o$ , hence we need to account for this estimation error.

**Lemma 1.** *The generalization error  $R^o$  is bounded by:*

$$R^o = \bar{R}_{emp}^o + O(\frac{1}{\lambda_o \sqrt{n_l}}), \quad (15)$$

as  $m \rightarrow \infty$ . Here  $\bar{R}_{emp}^o = \frac{1}{n_l} \sum_{i=1}^{n_l} l(\hat{h}^o, \hat{z}_i^o)$  is the empirical error of our estimator  $\hat{h}^o$  on  $\{X^{tL}, \hat{y}^o\}$ .

*Proof.* Define the Bregman Divergence associated to  $F$  of  $f$  to  $g$  by  $B_F(f||g) = F(f) - F(g) - \langle f - g, \nabla F(g) \rangle$ . Let  $F(h) = R(h) + N(h)$ ,  $F'(h) = R'(h) + N(h)$ . Since  $h^o, \hat{h}^o$  are the minimizers, we have  $B_{F'}(\hat{h}^o||h^o) + B_F(h^o||\hat{h}^o) = F'(\hat{h}^o) - F'(h^o) + F(h^o) - F(\hat{h}^o) = R'(\hat{h}^o) - R'(h^o) + R(h^o) - R(\hat{h}^o)$ . In addition, using the nonnegativity of  $B$  and  $B_F = B_R + B_N$ ,  $B_{F'} = B_{R'} + B_N$ , we have  $B_N(\hat{h}^o||h^o) + B_N(h^o||\hat{h}^o) \leq B_F(h^o||\hat{h}^o) + B_{F'}(\hat{h}^o||h^o)$ . Combining the two we have  $B_N(\hat{h}^o||h^o) + B_N(h^o||\hat{h}^o) \leq R'(\hat{h}^o) - R'(h^o) +$

$$R(h^o) - R(\hat{h}^o) = \frac{1}{n_l} \sum_{i=1}^{n_l} l(\hat{h}^o, z_i^o) - \frac{1}{n_l} \sum_{i=1}^{n_l} l(h^o, z_i^o) + \frac{1}{n_l} \sum_{i=1}^{n_l} l(h^o, \hat{z}_i^o) - \frac{1}{n_l} \sum_{i=1}^{n_l} l(\hat{h}^o, \hat{z}_i^o) \leq \frac{2}{n_l} \sum_{i=1}^{n_l} \sigma |y_i^o - \hat{y}_i^o|, \text{ using } |l(\hat{h}^o, z_i^o) - l(\hat{h}^o, \hat{z}_i^o)| \leq |2\hat{h}^o(x_i) - y_i^o - \hat{y}_i^o| \cdot |y_i^o - \hat{y}_i^o| \leq \sigma |y_i^o - \hat{y}_i^o|, \sigma = 4M.$$

Since for RKHS norm  $B_N(f||g) = \|f - g\|_k^2$ , we have  $B_N(\hat{h}^o||h^o) + B_N(h^o||\hat{h}^o) = 2\|h^o - \hat{h}^o\|_k^2$ . Combined with the above inequality, we have  $2\|h^o - \hat{h}^o\|_k^2 \leq \frac{2}{n_l} \sum_{i=1}^{n_l} \sigma |y_i^o - \hat{y}_i^o|$ . Then we have  $|l(h^o, z_i^o) - l(\hat{h}^o, z_i^o)| \leq \sigma |h^o(x_i) - \hat{h}^o(x_i)| \leq \sigma \|h^o - \hat{h}^o\|_k \kappa \leq \sigma \kappa \sqrt{\frac{1}{n_l} \sum_{i=1}^{n_l} \sigma |y_i^o - \hat{y}_i^o|}$ . Hence  $|\frac{1}{n_l} \sum_{i=1}^{n_l} l(h^o, z_i^o) - \frac{1}{n_l} \sum_{i=1}^{n_l} l(\hat{h}^o, \hat{z}_i^o)| \leq \frac{1}{n_l} \sum_{i=1}^{n_l} [|l(h^o, z_i^o) - l(\hat{h}^o, z_i^o)| + |l(\hat{h}^o, z_i^o) - l(\hat{h}^o, \hat{z}_i^o)|] \leq \sigma \kappa \sqrt{\frac{1}{n_l} \sum_{i=1}^{n_l} \sigma |y_i^o - \hat{y}_i^o|} + \frac{1}{n_l} \sum_{i=1}^{n_l} \sigma |y_i^o - \hat{y}_i^o|$ . Now we can conclude that

$$R_{emp}^o = \frac{1}{n_l} \sum_{i=1}^{n_l} l(h^o, z_i^o) \leq \bar{R}_{emp}^o + P, \quad (16)$$

where  $\bar{R}_{emp}^o = \frac{1}{n_l} \sum_{i=1}^{n_l} l(\hat{h}^o, \hat{z}_i^o)$ , and  $P = \sigma \kappa \sqrt{\frac{1}{n_l} \sum_{i=1}^{n_l} \sigma |y_i^o - \hat{y}_i^o|} + \frac{1}{n_l} \sum_{i=1}^{n_l} \sigma |y_i^o - \hat{y}_i^o|$ . To bound  $P$ , first we have  $\frac{1}{n_l} \sum_{i=1}^{n_l} |y_i^o - \hat{y}_i^o| = \frac{1}{n_l} \sum_{i=1}^{n_l} |(y_i^{tL} - y_i^s) - (y_i^{tL} - \hat{y}_i^s)| = \frac{1}{n_l} \sum_{i=1}^{n_l} |y_i^s - \hat{y}_i^s| \leq \sqrt{\frac{1}{n_l} \sum_{i=1}^{n_l} (y_i^s - \hat{y}_i^s)^2}$ . Using Eq. 11,  $\frac{1}{n_l} \sum_{i=1}^{n_l} (y_i^s - \hat{y}_i^s)^2$  is bounded by  $R_{emp}^s + O(\frac{1}{\lambda_s \sqrt{m}})$ . We can see that the penalty term  $P$  diminishes as  $m \rightarrow \infty$ . Plugging Eq. 16 into Eq. 14 concludes the proof.  $\square$

(3) Now we analyze the generalization error in the target domain. Using the assumption that the target labels  $y^t$  can also be decomposed by  $y^o + y^s$ , we have:

$$\begin{aligned} \mathbb{E}_{z^t} [l(h, z^t)] &= \mathbb{E}_{z^t} [(h(x^t) - y^t)^2] \\ &= \mathbb{E}[(h^o(x^t) + h^s(x^t) - y^o - y^s)^2] \\ &\leq 2\mathbb{E}(h^o(x^t) - y^o)^2 + 2\mathbb{E}(h^s(x^t) - y^s)^2. \end{aligned} \quad (17)$$

Plugging in Eq. 11 and Eq. 15, we have

$$R^t = \mathbb{E}_{z^t} [l(h, z^t)] = 2R_{emp}^s + 2\bar{R}_{emp}^o + O\left(\frac{1}{\lambda_o \sqrt{n_l}} + \frac{1}{\lambda_s \sqrt{m}}\right)$$

In transfer learning usually we assume that the number of source data is sufficient, i.e.,  $m \rightarrow \infty$ , hence

$$R^t - 2(R_{emp}^s + \bar{R}_{emp}^o) = O\left(\frac{1}{\lambda_o \sqrt{n_l}}\right). \quad (18)$$

### 5.1.1 Comparing with No-transfer Learning

As with the no-transfer-rate in Sec. 4.2.2, we have

$$R^t - R_{emp}^{tL} = O\left(\frac{1}{\lambda_t \sqrt{n_l}}\right), \quad (19)$$

where  $\lambda_t$  is the regularization parameter when estimating the target function. Comparing this rate with Eq. 18, and using our assumption that we have a smoother offset than the target function, i.e.,  $\lambda_o > \lambda_t$ , we can see that we obtain a faster convergence rate with transfer than no-transfer.

## 6 MULTI-SOURCE TRANSFER LEARNING

In this section, we show that we can easily adapt the transfer learning algorithm from a single source to transfer learning with multiple-sources, by utilizing the generalization bounds we derived in earlier sections. Transfer learning with multiple sources is similar to multi-task learning, where we learn the target and multiple sources jointly.

A closer look at Eq. 9 for CDM, and Eq. 18 for Offset reveals that, when  $n_l$  is small and  $m \rightarrow \infty$ , we have a convergence rate of  $O(\frac{1}{\lambda_* \sqrt{n_l}})$  for both algorithms, where  $\lambda_*$  is some parameter that controls the smoothness of the source-to-target transfer (for Eq. 9 we can set  $\lambda_R = \lambda_*^2$ ). This observation motivates our reweighting scheme on the source hypotheses to achieve transfer learning under multiple sources, described as the following.

Assume we have  $S$  sources and a target. First, we apply the transfer learning algorithm from a single source to obtain a model  $M_s$  from each source  $s$  to target  $t$ , where the parameter  $\lambda_*^s$  is determined by cross-validation,  $s = 1, \dots, S$ . Second, we compute the weight for each source  $s$  by:

$$\begin{aligned} w_s &= p(D|M_s)p(M_s), \text{ where} \\ p(D|M_s) &= \exp\left\{-\sum_{i=1}^{m_s} (y_i^{tL} - \hat{f}^s(x_i^{tL}))^2\right\}, \\ p(M_s) &\propto \exp\left\{-\alpha \frac{1}{\lambda_*^s}\right\}, \end{aligned}$$

where  $\hat{f}^s(x_i^{tL})$  is the prediction given by  $M_s$ .

The idea is similar to Bayesian Model Averaging (Hoeting et al. (1999)), where the first term  $p(D|M_s)$  serves as the data likelihood of the predictive model  $M_s$  from source  $s$ , and the second term  $p(M_s)$  is the prior probability on model  $M_s$ . In our case,  $p(M_s)$  is chosen to indicate how similar each source to the target is, where the similarity is measured by how smooth the change is from source  $s$  to target  $t$ . It is easy to see that, the weights coincide with our analysis of the generalization bounds for transfer learning, and the choice of  $\alpha$  should be in the order of  $O(1/\sqrt{n_l})$ . Intuitively, when the number of labeled target points  $n_l$  is small,  $p(M_s)$  has a larger effect on  $w_s$ , which means we prefer the source that has a smoother change (larger  $\lambda_*^s$ ) for the transfer. On the other hand, when  $n_l$  is large, then  $p(D|M_s)$  takes over, i.e., we prefer the source that results in a larger data likelihood (smaller prediction errors). Fi-

nally, we combine the predictions by:

$$\hat{f}(x_i^{tU}) = \sum_{s=1}^S \frac{w_s}{\sum_{s=1}^S w_s} \hat{f}^s(x_i^{tU})$$

This weighted combination of source hypotheses gives us the following generalization bound in the target domain:

$$\begin{aligned} \mathbb{E}_{z^t} [l(h, z^t)] &= \mathbb{E}_{z^t} \left[ \left( \sum_s \frac{w_s}{\sum_{s=1}^S w_s} h_s(x^t) - y^t \right)^2 \right] \\ &= \mathbb{E}_{z^t} \left[ \left( \sum_s \frac{w_s}{\sum_{s=1}^S w_s} (h_s(x^t) - y^t) \right)^2 \right] \\ &\leq \sum_s \frac{w_s}{\sum_{s=1}^S w_s} \mathbb{E}_{z^t} [(h_s(x^t) - y^t)^2] \\ &= \sum_s \frac{w_s}{\sum_{s=1}^S w_s} [\tilde{R}_{emp}^s + O(\frac{1}{\lambda_s \sqrt{n_t}})], \end{aligned}$$

where the third inequality uses Jensen’s inequality, and the last equality uses the bounds we derived. Here  $\tilde{R}_{emp}^s$  refers to the empirical error for source  $s$  when transferring from  $s$  to  $t$  (Thm. 2 for CDM and Eq. 18 for Offset).

## 7 EXPERIMENTS

### 7.1 SYNTHETIC EXPERIMENTS

In this section, we empirically compare the generalization error of transfer learning algorithms to that of no-transfer learning (learning by labeled target data only), on synthetic datasets simulating different conditions.

We generate the synthetic dataset in this way:  $X^s, X^t$  are drawn uniformly at random from  $[0, 4]$ ,  $Y^s = \sin(2X^s) + \sin(3X^s)$  with additive Gaussian noise.  $Y^t$  is the same function with a smoother location-scale transformation/offset. In each of the following comparisons, we plot the mean squared error (MSE) on the unlabeled target points (as an estimation of the generalization error) with respect to different number of labeled target points. The labeled target points are chosen uniformly at random, and we average the error over 10 experiments. The parameters are chosen using cross validation.

In Fig. 3, we compare transfer learning using CDM with no-transfer learning. The results show that with the additional smoothness assumption, we are able to achieve a much lower generalization error for transfer learning than no-transfer learning. In Fig. 4 and 5, we compare transfer learning using the Offset approach with no-transfer learning. The two figures show different generalization error curves when the smoothness of the offset is different. We can see that with a smoother offset (Fig. 4) we are able to achieve a much lower generalization error than no-transfer learning. With a less smooth offset (Fig. 5) we can still achieve a lower generalization error than no-transfer learning, but the rate is slower compared to Fig. 4. Further we

analyze the case when the smoothness assumption does not hold, by setting the source function to be  $\sin(X^s) + \epsilon$  such that the target changes faster than the source. In this case, transfer learning with CDM/Offset yield almost the same generalization error as no-transfer learning (Fig. 6), i.e., the source data does not help in learning the target.

Figure 3: No-transfer learning vs. transfer learning (CDM)

Figure 4: No-transfer learning vs. transfer learning using the Offset approach (smoother offset,  $\lambda_R = 0.1$ )

Figure 5: No-transfer learning vs. transfer learning using the Offset approach (less smooth offset,  $\lambda_R = 0.001$ )

Figure 6: No-transfer learning vs. transfer learning, when the smoothness assumption does not hold

### 7.2 EXPERIMENTS ON THE REAL DATA

#### 7.2.1 Comparing Transfer Learning to No-transfer Learning, Using Different Sources

The real-world dataset is an Air Quality Index (AQI) dataset (Mei et al. (2014)) during a 31-day period from Chinese cities. For each city, the input feature  $x_i$  is a bag-of-words vector extracted from Weibo posts of each day, with 100,395 dimensions as the dictionary size. The output label  $y_i$  is a real number which is the AQI of that day.

Fig. 7 shows a comparison of MSE on the unlabeled target points, with respect to different number of labeled target

points, when transferring from a nearby city (Ningbo) and a faraway city (Xi'an), to a target city (Hangzhou). The data is shown in the left figure of Fig. 7, where the x-axis is each day. The results are averaged over 20 experiments with uniformly randomly chosen labeled target points. First we observe that we obtain a lower generalization error by transferring from other cities than learning by the target city data alone (no-transfer). In addition, the generalization error are much lower if we transfer from nearby cities where the difference between source and target is smoother.

Figure 7: Comparison of MSE on unlabeled target points

### 7.2.2 Transfer Learning with Multiple Sources

The results in Sec. 7.2.1 indicate that, when transferring from multiple sources to a target, it is important to choose which source to transfer, in order to obtain a larger gain. In this section, we show the results on the same air quality index data by reweighting different sources (Sec. 6).

Fig. 8 shows a comparison of MSE on the unlabeled target data (data shown in the left figure) with respect to different number of labeled target points ( $n_l \in \{2, 5, 10, 15, 20\}$ ), where the prediction is based on each source independently (labeled as **source**  $i$ ,  $i \in \{1, 2, 3\}$ ), and based on multiple sources (labeled as **posterior**). Since CDM and Offset give similar bounds, we use two-stage offset estimation as the prediction algorithm from each source  $s$  to target  $t$ . The weighting on the sources is as described in Sec. 6. As can be seen from the results, using posterior reweighting on different sources, we obtain results that are very close to the results using the best source.

Figure 8: Comparison of MSE on unlabeled target points, with multiple sources

Further in Figure. 9, we show a comparison of MSE on the unlabeled target data between the proposed approach and two baselines, with respect to different number of la-

beled target points. The results are averaged over 20 experiments. The first baseline **wDA** is a weighted multi-source domain adaptation approach proposed in Mansour et al. (2008), where the distribution  $D_i(x)$  for source  $i$  on a target point  $x$  is estimated using kernel density estimation with a Gaussian kernel. Note that the original algorithm proposed in Mansour et al. (2008) does not assume the existence of a few labeled target points, thus the hypothesis  $h_i(x)$  from each source  $i$  is computed by using the source data only. To ensure a fair comparison, we augment  $h_i(x)$  by using the prediction of the Offset approach given  $n_l$  labeled target points. The second baseline **optDA** is a multi-source domain adaptation algorithm under an optimization framework, as proposed in Chattopadhyay et al. (2011), where the parameters  $\gamma_A, \gamma_I$  are set as described in the paper, and  $\theta$  is chosen using cross-validation on the set  $\{0.1, 0.2, \dots, 0.9\}$  (the final choice of  $\theta$  is 0.1). Note that our proposed algorithm gives the best performance. In addition, our algorithm does not require density estimation as in **wDA**, which can be difficult in real-world applications with high-dimensional features. Further note **posterior** considers the change in  $P(Y|X)$  while **wDA** focuses on the change of  $P(X)$ . A potential improvement can be achieved by combining these two in the reweighting scheme, which should be an interesting future direction.

## 8 CONCLUSION

In this paper, we provide theoretical analysis for algorithms proposed for transfer learning under the model shift assumption. Unlike previous work on covariate shift, the model shift poses a harder problem for transfer learning, and our analysis shows that we are still able to achieve a similar rate as in covariate shift/domain adaptation, modified by the smoothness of the transformation parameters. We also show conditions when transfer learning works better than no-transfer learning. Finally we extend the algorithms to transfer learning with multiple sources.

## Abstract

Many machine learning and signal processing tasks involve computing sparse representations using an overcomplete set of features or basis vectors, with compressive sensing-based applications a notable example. While traditionally such problems have been solved individually for different tasks, this strategy ignores strong correlations that may be present in real world data. Consequently there has been a push to exploit these statistical dependencies by jointly solving a series of sparse linear inverse problems. In the majority of the resulting algorithms however, we must a priori decide which tasks can most judiciously be grouped together. In contrast, this paper proposes an integrated Bayesian framework for both clustering tasks together and subsequently learning optimally sparse representations within each cluster. While probabilistic models have been applied previously to solve these types of problems, they typically involve a complex hierarchical Bayesian generative model merged with some type of approximate inference, the combination of which renders rigorous analysis of the underlying behavior virtually impossible. On the other hand, our model subscribes to concrete motivating principles that we carefully evaluate both theoretically and empirically. Importantly, our analyses take into account all approximations that are involved in arriving at the actual cost function to be optimized. Results on synthetic data as well as image recovery from compressive measurements show improved performance over existing methods.

## 1 INTRODUCTION

Solving sparse linear inverse problems is a fundamental building block in numerous machine learning, computer vision, and signal processing applications related to compressive sensing and beyond (Elhamifar & Vidal 2013; Soltanolkotabi & Candes, 2012; Zhang & Rao, 2011; Hu et al., 2013). In its most basic form, sparse estimation algorithms are built upon the observation model

$$\mathbf{y} = \Phi \mathbf{x} + \epsilon, \quad (1)$$

where  $\Phi \in \mathbb{R}^{N \times M}$  is a dictionary of basis vectors that we assume to have unit  $\ell_2$  norm,  $\mathbf{x} \in \mathbb{R}^M$  is a vector of unknown coefficients we would like to estimate,  $\mathbf{y} \in \mathbb{R}^N$  is an observed measurement vector, and  $\epsilon$  is a noise vector distributed as  $\mathcal{N}(0, \nu I)$ . The objective is to estimate the unknown generative  $\mathbf{x}$  under the assumption that it is maximally sparse, meaning that  $\|\mathbf{x}\|_0$  is minimal. Here  $\|\cdot\|_0$  represents the canonical  $\ell_0$  norm sparsity metric, or a count of the number of nonzero elements in a vector. This sparse linear inverse problem is compounded considerably by the additional assumption that  $M > N$ , meaning the dictionary  $\Phi$  is *overcomplete*.

Now suppose that we have access to multiple measurement vectors from  $L$  different tasks of interest that are assembled as  $Y = [\mathbf{y}_1, \dots, \mathbf{y}_L] \in \mathbb{R}^{N \times L}$  and linked to a corresponding matrix of unknown coefficients  $X = [\mathbf{x}_1, \dots, \mathbf{x}_L] \in \mathbb{R}^{M \times L}$  via

$$\mathbf{y}_j = \Phi_j \mathbf{x}_j + \epsilon_j, \quad \forall j = 1, \dots, L. \quad (2)$$

If these measurement vectors and associated coefficients maintain some degree of dependency, for example the locations of zero-valued elements (or support sets) are statistically related, then it will generally be advantageous to jointly estimate  $X$  from  $Y$  as opposed to solving for each  $\mathbf{x}_j$  individually (Obozinski et al., 2011). Perhaps the simplest example of this is frequently referred to as simultaneous sparse approximation (Tropp, 2006) or multi-task compressive sensing (Ji et al., 2009). In brief, these paradigms follow from the assumption that  $X$  is maximally *row sparse*, implying that each column of  $X$  is maximally sparse with a common support pattern. This model has been

applied to compressive sensing of images and video (Ji et al., 2009), tracking (Hong et al., 2013), and medical image analysis (Wan et al., 2012). Moreover, it can be naturally extended to handle a richer set of dependencies by applying a known graph structure that groups subsets of columns together for joint estimation (Cevher et al., 2008; Shi et al., 2014), as opposed to strict enforcement of row sparsity across all measurements. Other pre-defined structural assumptions can be found in (Archambeau et al., 2011; Jalali et al., 2013; Rao et al., 2013; Yang & Ravikumar, 2013).

The limitation of all of these strategies is that they are predicated on prior knowledge of how tasks should be grouped together to optimally facilitate subsequent sparse estimation. In contrast, here we intend to develop a principled multi-task learning algorithm that simultaneously clusters tasks blindly while optimally estimating sparse coefficient vectors informed by these clusters. We should state at the outset that multi-task compressive sensing has been merged with cluster learning before (Qi et al., 2008). However, this algorithm relies on a complex hierarchical model anchored with an approximate Dirichlet process prior distribution on  $X$  (Blei & Jordan, 2006). Subsequent model inference then requires an additional variational mean-field approximation. Overall the fundamental underlying mechanics of the model have not been carefully analyzed nor understood, nor is there any guarantee that sparsity will necessarily result. Other even more complex hierarchical models have been applied to somewhat-related multi-task learning problems, e.g., (Hernandez-Lobato & Hernandez-Lobato, 2013); however, these models require complex inference procedures that must ultimately be justified by the validity of the assumed prior distributions rather than provable properties of the resulting estimators.

The remainder of the paper is organized as follows. In Section 2 we first motivate our design principles. A specific Bayesian model and corresponding objective function are then developed in Section 3. Next we derive updates rules for optimization purposes, leading to our *clustered sparse Bayesian learning algorithm* (C-SBL) in Section 4. We theoretically and empirically analyze this framework in Sections 5 and 6 respectively, revealing that it is consistent with our original motivational principles. Moreover, estimation results on synthetic data and real images demonstrate improved estimation quality relative to existing algorithms when using compressive measurements. Overall, we summarize our contributions as follows:

- Analysis of specific, previously-unexamined theoretical principles that play a critical role in multi-task sparse estimation problems.
- Development of a robust sparse Bayesian algorithm that adheres to these principles to an extent not seen in any existing algorithm we are aware of.
- Although we employ a Bayesian entry point for our

algorithmic strategy, final model justification is provided entirely based on rigorous properties of the underlying cost function that emerges, *including all approximations involved*, rather than any putative belief in the actual validity of assumed prior distributions.

## 2 MOTIVATING PRINCIPLES

When deriving an algorithm for joint clustering and multi-task sparse estimation, it is helpful to first define a few basic attributes that ideally any procedure might possess. Here we consider properties related to limiting behavior as the noise variance  $\nu$  varies from zero towards large values for each task.

First assume  $\nu \rightarrow 0$  and the following generative model. Let  $X^*$  denote the true coefficient matrix we would like to estimate using measurements  $\mathbf{y}_j = \Phi_j \mathbf{x}_j^*$ . We assume that the columns of  $X^*$  are partitioned into clusters with common sparsity profile or support within each cluster. Additionally let  $\Omega_k$  denote the column indices of  $X^*$  associated with cluster  $k = 1, \dots, K \leq L$ . For any matrix  $Z$  define  $Z_{\Omega_k}$  as the sub-matrix of columns associated with the index set  $\Omega_k$ . Then the relevant sparse linear inverse problem, assuming known clusters, becomes

$$\min_{\{X_{\Omega_k}\}} \sum_k |\Omega_k| \|X_{\Omega_k}\|_{row-\ell_0} \quad \text{s.t. } \mathbf{y}_j = \Phi_j \mathbf{x}_j, \forall j, \quad (3)$$

where  $\|\cdot\|_{row-\ell_0}$  counts the number of nonzero rows of a matrix, which is then weighted by the cardinality of the set  $\Omega_k$  in the objective function.<sup>1</sup>

Now assume the perturbation model

$$\bar{X}_k^* = A_k^x + \alpha^x R_k^x, \forall k, \quad (4)$$

where  $\bar{X}_{\Omega_k}^*$  denotes the nonzero rows of  $X_{\Omega_k}^*$  associated with cluster  $k$ ,  $A_k^x$  is an arbitrary matrix of appropriate dimensions,  $\alpha^x > 0$  is an arbitrarily small scalar, and  $R_k^x$  is a random matrix with iid, continuously-distributed elements. Likewise, assume that

$$\Phi_j = A_j^\phi + \alpha^\phi R_j^\phi, \forall j, \quad (5)$$

with analogous definitions to those in (4), albeit with obviously different dimensions and values. Then we have the following:

**Lemma 1.** Suppose we are given any  $Y$  generated with  $\mathbf{y}_j = \Phi_j \mathbf{x}_j^*$  and  $\|\mathbf{x}_j^*\|_0 < N \forall j$ , where  $X^*$  satisfies (4)  $\forall k$  and  $\Phi_j$  satisfies (5)  $\forall j$ . Then  $X^*$  is the unique global minimum of both (3) and

$$\min_X \sum_j \|\mathbf{x}_j\|_0 \quad \text{s.t. } \mathbf{y}_j = \Phi_j \mathbf{x}_j, \forall j. \quad (6)$$

<sup>1</sup>Actually, this weighting factor is irrelevant to what follows in the noiseless case, but does play a role later when we consider noisy conditions.

The proof is relatively straightforward and comes from modifying Theorem 1 from (Baron et al., 2009). While perhaps notationally cumbersome to present, the message of this result is simple and widely applicable. In words, Lemma 1 implies that, under general conditions that apply to virtually any multi-task system of interest (since the sets  $\{A_k^x\}$   $\{A_j^\phi\}$  are arbitrary and the perturbations applied to them can be infinitesimally small), the unique maximally row-sparse solution to the clustering problem is equivalent to the global solution obtained by simply evaluating each task individually. The cluster structure itself does not provide any direct advantage, and we could just as well solve (6), and without noise we can theoretically resolve any number of clusters between 1 and  $L$ .

With this in mind then, in the limit  $\nu \rightarrow 0$  we would prefer to have a clustering algorithm whose global optimum is equivalent to (6). However, we need not solve this problem directly, which in general is NP-hard. Rather we favor an algorithm that can, to the extent possible, leverage cluster information to steer the algorithm towards the global solution of (6) while avoiding bad local optima.

Now consider larger values of noise, i.e.,  $\nu > 0$ , where we would like to solve something akin to

$$\min_X \sum_j \|\mathbf{y}_j - \Phi_j \mathbf{x}_j\|_2^2 + \nu \sum_k |\Omega_k| \|X_{\Omega_k}\|_{\text{row-}\ell_0}. \quad (7)$$

In general, when the noise level is high we cannot hope to resolve a large number of clusters, and eventually we must merge to a single cluster as  $\nu$  becomes sufficiently large. In this regime the issue is not so much one of avoiding bad local minima as it is enhancing the effective signal-to-noise ratio as much as possible. Note that the smaller  $K$  is, the more tasks per cluster, which has a substantial benefit in terms of signal-to-noise ratio. This can be easily visualized via the special case where  $\Phi_j^\top \Phi_j = I \forall j$ . Given this simplification, (7) has a closed-form solution given by

$$x_{i,j}^* = z_{i,j} \mathcal{I} \left[ \sum_{j \in \Omega_{c(j)}} z_{i,j}^2 > \nu |\Omega_{c(j)}| \right], \quad (8)$$

where  $\mathbf{z}_j \triangleq \Phi_j^\top \mathbf{y}_j$ ,  $c(j)$  denotes the cluster index of task  $j$ , and  $\mathcal{I}$  is an indicator function. Thus the optimal solution represents a hard-thresholding operation, where the threshold is dictated by an average across tasks within each cluster. If we have only a single cluster, meaning  $c(j) = 1 \forall j$  and  $\Omega_1 = \{1, \dots, L\}$ , then this threshold value is maximally robust to noise given that all tasks are averaged together to increase the SNR of the threshold.

To conclude then, there are (at least) three important considerations:

1. At high SNR, local minima avoidance while finding maximally sparse solutions is paramount. We would also favor that, for a given clustering, maximally row-sparse solutions can be obtained by evading any sub-optimal local extrema where possible.

2. At low SNR when it is impossible to resolve many clusters anyway, the issue is more about merging clusters to hopefully improve the implicit SNR.
3. In intermediate regimes we would like to accomplish a bit of both.

In Section 5 we provide theoretical evidence that our proposed algorithm is favorable with respect to points 1 and 2, while Section 6 presents empirical evidence in practical support of point 3.

### 3 MODEL DESCRIPTION

While perhaps not immediately obvious at first, this section will develop a Bayesian model that ultimately reflects the previously stated principles. Consistent with the observation model in (1), we adopt the Gaussian likelihood function

$$p(Y|X) \propto \prod_j \exp \left[ -\frac{1}{2\nu} \|\mathbf{y}_j - \Phi_j \mathbf{x}_j\|_2^2 \right]. \quad (9)$$

For present purposes we will assume that the noise variance  $\nu$  is known (ultimately though this value can be learned from the data). For the prior distribution on each  $\mathbf{x}_j$  we build upon the basic sparse Bayesian learning framework from (Tipping, 2001) which in the present context would involve a zero-mean Gaussian with an independent diagonal covariance; however, this would not allow for task clustering. Instead we assume the prior distribution

$$p(X|\Lambda, W) \propto \prod_j \exp \left[ -\frac{1}{2} \mathbf{x}_j^\top \Gamma_j^{-1} \mathbf{x}_j \right], \quad (10)$$

where  $\Lambda \in \mathbb{R}^{M \times K}$  and  $W \in \mathbb{R}^{L \times K}$  are hyperparameter matrices;  $\Lambda$  is constrained to have all non-negative elements,  $W \in \mathcal{S}$  is defined such that each row denoted as  $\mathbf{w}^j$  is an element of the probability simplex, i.e.,

$$\mathcal{S} \triangleq \{\mathbf{w}^j : \sum_k w_{j,k} = 1, w_{j,k} \in [0, 1]\}. \quad (11)$$

With some abuse of notation, we say that  $W \in \mathcal{S}$  if every row  $\mathbf{w}^j \in \mathcal{S}$ . Finally,  $\Gamma_j$  is the diagonal covariance matrix produced via

$$\Gamma_j^{-1} = \sum_k w_{j,k} \Lambda_k^{-1}, \quad (12)$$

where  $\Lambda_k$  is defined as a diagonal matrix formed from the  $k$ -th column of matrix  $\Lambda$ .

Although the unknown  $\mathbf{x}_j$  from each task are assumed to be independent via the above distributions, they will nonetheless become linked via the common set of hyperparameters that will subsequently be estimated from the data. Additionally, from (12) we are expressing what amounts to the  $j$ -th precision matrix as a linear combination of  $K$  diagonal precision matrix basis functions. Although we could have

equally considered a linear basis expansion with respect to covariances, we chose precisions for algorithmic reasons detailed below. Additionally, the value of  $K$  can be viewed as an upper bound on the number of clusters we can expect in our data; for all experiments we simply choose  $K = L$ , the number of tasks.

Given this likelihood and prior, the posterior distribution  $p(\mathbf{x}_j | \mathbf{y}_j; \Lambda, W)$  is also a Gaussian with mean

$$\hat{\mathbf{x}}_j = \Gamma_j \Phi_j^\top (\nu I + \Phi_j \Gamma_j \Phi_j^\top)^{-1} \mathbf{y}_j. \quad (13)$$

Thus if  $\Lambda$  and  $W$  were known, we have access to a simple closed-form estimator for  $\mathbf{x}_j$ . The most challenging responsibility then becomes estimating these unknown hyperparameters. The empirical Bayesian solution to this problem is to first apply hyperpriors to  $\Lambda$  and  $W$ , integrate out the unknown  $X$ , and then compute MAP estimates via

$$\max_{\Lambda > 0, W \in \mathcal{S}} \int p(Y|X)p(X; \Lambda, W)p(\Lambda)p(W)dX. \quad (14)$$

For the covariance bases we simply assume a flat hyperprior  $p(\Lambda) = 1$ . In contrast, we assume  $p(W) \propto \exp[-1/2 \sum_{j,k} f(w_{j,k})]$ , where  $f$  is a function designed to promote a clustering effect as will be described shortly. Given the above, applying a  $-2$  log transformation to (14) produces the equivalent problem

$$\min_{\Lambda > 0, W \in \mathcal{S}} \sum_j \left[ \mathbf{y}_j \Sigma_{y_j}^{-1} \mathbf{y}_j + \log |\Sigma_{y_j}| \right] + \sum_{j,k} f(w_{j,k}), \quad (15)$$

where

$$\Sigma_{y_j} \triangleq \nu I + \Phi_j \Gamma_j \Phi_j^\top.$$

To facilitate later optimization, it will help to modify the log-det term in (15) as follows. First, using standard determinant identities we have

$$\log |\Sigma_{y_j}| \equiv T1 + T2 \quad (16)$$

$$\triangleq \log \left| \sum_k w_{j,k} \Lambda_k^{-1} + \frac{1}{\nu} \Phi_j^\top \Phi_j \right| - \log \left| \sum_k w_{j,k} \Lambda_k^{-1} \right|,$$

where irrelevant constants have been omitted. Using the fact that  $\log |\cdot|$  is a concave function in the space of positive definite, symmetric matrices,  $W \in \mathcal{S}$ , and Jensen's inequality, it follows that

$$\sum_k w_{j,k} \log |\Lambda_k| \geq - \log \left| \sum_k w_{j,k} \Lambda_k^{-1} \right|. \quad (17)$$

This upper bound has the appeal that it is linear in elements of  $W$  which will facilitate the derivation of update rules to be presented shortly. We will henceforth be concerned with minimizing the new objective function

$$\mathcal{L}(\Lambda, W) \triangleq \sum_j \left[ \mathbf{y}_j \Sigma_{y_j}^{-1} \mathbf{y}_j \right] + \sum_{j,k} f(w_{j,k}) \quad (18)$$

$$+ \sum_j \log \left| \sum_k w_{j,k} \Lambda_k^{-1} + \frac{1}{\nu} \Phi_j^\top \Phi_j \right| + \sum_{j,k} w_{j,k} \log |\Lambda_k|.$$

**Sparsity Promotion:** The log-det term in the original cost (15) is a concave, non-decreasing function of each  $\Gamma_j$ , and hence it favors sparse diagonal elements, which in turn produces a sparse  $\mathbf{x}_j$  estimate via the left multiplication in (13). But this sparsity can only be achieved if diagonal elements of the embedded basis functions  $\Lambda_k$  also converge to zero.<sup>2</sup> By virtue of the basis expansion (12) in terms of precisions, this then implies that the sparsity profile or support of  $\Gamma_j$  will mirror the sparsity profile of the *intersection* of all  $\Lambda_k$  associated with nonzero coefficients  $w_{j,k}$ . Typically this will encourage only a single unique basis function to be active for a given task  $j$ .

Note that the cost function modification using Jensen's inequality above does not interfere with this sparsity promotion agency. In fact, the upper bound gap has a minimal value of zero when either  $\mathbf{w}^j$  equals an indicator vector (all zeros and a single one), or when all  $\Lambda_k$  are equal to one another. The former will lead to a maximal  $\ell_0$  norm solution, the latter a maximal row-sparse solution.

**Cluster Promotion:** We now turn to the related clustering issues and the role of  $f$ . For this purpose, it is instructive to elucidate exactly what we mean by a cluster. We define a cluster as a group of tasks that share a common diagonal support for  $\Gamma_j$ . Without  $f$ , it is easy to show that for any value of  $\nu$ , if  $K = L$  the globally optimal solution to (18) will involve the  $k$ -th column of  $W$ ,  $\mathbf{w}_k$ , equal to a unique indicator vector for all  $k$ , each  $\Gamma_j$  will then be represented with a unique  $\Lambda_k$ , and no clustering will occur at all. In fact, there will be no clustering effect for either the purpose of avoiding local minima when  $\nu$  is small, nor for improving the effective SNR when  $\nu$  is large.

To mitigate this effect,  $f$  can be chosen to encourage  $W$  to have columns with multiple nonzero values, which is tantamount to requiring that groups of tasks must share one or more  $\Lambda_k$  basis matrices. However, because the support of any  $\Gamma_j$  will be the intersection of  $\Lambda_k$  supports associated with  $w_{j,k} > 0$ , these tasks will either share only a single  $\Lambda_k$ , or alternatively multiple different  $\Lambda_k$  will converge to the same basis matrix (or at least one with a common support). In either case, the net effect is hard clustering, where each task  $j \in \Omega_k$  will be assigned some effective  $\Lambda_k$ , and the total number of unique such basis matrices will be some  $\tilde{K} < L$ . Additionally, within each such cluster, it can be shown by extending the analysis in (Wipf et al., 2011) that the net effect on the final estimation step is as if there were

<sup>2</sup>While technically division by zero is undefined, we can still accommodate (12) and all attendant update rule derivations by considering the appropriate limiting cases along with judicious use of the Matrix Inversion Lemma and the Moore-Penrose Pseudoinverse in place of direct inverses.

an explicit, concave and nondecreasing penalty on the  $\ell_2$  row norms of  $\hat{X}_{\Omega_k}$ , which naturally favors row-sparsity.

For these reasons we choose

$$f(w) = \beta w \log w, \quad (19)$$

where  $\beta > 0$  is a constant. This  $f$  is convex over the domain  $[0, 1]$  and has a minimal value between zero and one, and therefore favors either sharing of basis functions along columns of  $W$  or merging different  $\Lambda_k$  values together via the mechanism outlined above. Importantly, many elements of  $W$  will still be pushed to exactly zero to shut off basis matrices from other clusters, provably so in certain circumstances although space here prevents a detailed treatment (Section 6 does provide empirical evidence for this however). While certainly other selections for  $f$  could potentially be more effective, this simple choice serves our purposes sufficiently well and leads to convenient update rules.

## 4 ALGORITHM DERIVATION

Optimization of (18) will involve expanding a majorization-minimization scheme suggested in (Wipf & Nagarajan, 2010) for single-task sparse estimation, where auxiliary variables are introduced to upper bound various terms in the objective function. First we use the bound

$$\frac{1}{\nu} \|\mathbf{y}_j - \Phi_j \mathbf{x}_j\|_2^2 + \mathbf{x}_j^\top \Gamma_j^{-1} \mathbf{x}_j \geq \mathbf{y}_j^\top \Sigma_{y_j}^{-1} \mathbf{y}_j \quad (20)$$

for all  $\mathbf{x}_j$ , with equality iff  $\mathbf{x}_j$  is given by (13). Now define  $\mathbf{a}_j$  as a vector formed from the diagonal of  $\sum_k w_{j,k} \Lambda_k^{-1}$ . Because the term  $T1$  in (16) is a concave, non-decreasing function of  $\mathbf{a}_j$ , we define  $h^*(\mathbf{z})$  as the concave conjugate function (Boyd & Vandenberghe, 2004) of  $h(\mathbf{a}_j) = \log \left| \sum_k w_{j,k} \Lambda_k^{-1} + \frac{1}{\nu} \Phi_j^\top \Phi_j \right|$  defined as

$$h^*(\mathbf{z}_j) \triangleq \inf_{\mathbf{a}_j} (\mathbf{z}_j^\top \mathbf{a}_j - h(\mathbf{a}_j)). \quad (21)$$

By construction we may then upper bound  $T1$  via

$$\mathbf{z}_j^\top \mathbf{a}_j - h^*(\mathbf{z}_j) \geq \log \left| \sum_k w_{j,k} \Lambda_k^{-1} + \frac{1}{\nu} \Phi_j^\top \Phi_j \right| \quad (22)$$

for all  $\mathbf{z}_j \geq 0$ , with equality iff  $\mathbf{z}_j$  is the gradient of  $T1$  with respect to  $\mathbf{a}_j$ . This can be computed in closed form using

$$\mathbf{z}_j = \nabla_{\mathbf{a}_j} (T1) = \text{diag} \left[ \left( \sum_k w_{j,k} \Lambda_k^{-1} + \frac{1}{\nu} \Phi_j^\top \Phi_j \right)^{-1} \right]. \quad (23)$$

With these upper bounds fixed, we can then optimize over  $\Lambda$  and  $W$ . First, with  $W$  fixed, optimization over  $\Lambda$  decouples and we may consider each  $\lambda_{i,k}$  individually. Collecting relevant terms we have

$$\min_{\lambda_{i,k} > 0} \sum_j \frac{w_{j,k}}{\lambda_{i,k}} (x_{i,j}^2 + z_{i,j}) + w_{j,k} \log \lambda_{i,k}. \quad (24)$$

Computing derivatives, equating to zero, and checking first-order optimality conditions we arrive at the optimal solution

$$\lambda_{i,k}^{opt} = \frac{\sum_j w_{j,k} (x_{i,j}^2 + z_{i,j})}{\sum_j w_{j,k}}, \quad \forall i, k. \quad (25)$$

Finally we fix  $\Lambda$  and optimize over  $W$ , solving separately for each row  $\mathbf{w}^j$  via

$$\min_{\mathbf{w}^j \in \mathcal{S}} \sum_{i,k} w_{j,k} \left( \frac{x_{i,j}^2 + z_{i,j}}{\lambda_{i,k}} \right) + w_{j,k} \log \lambda_{i,k} + \beta w_{j,k} \log w_{j,k}. \quad (26)$$

There exist many strategies to perform the requisite convex optimization over  $\mathbf{w}^j$ . Since (26) can be computed in closed form without the constraint  $\sum_k w_{j,k} = 1$ , we simply solve without the constraint and then normalize the resulting solution, which is a form of projected gradient method. In our experiments we found this procedure to be adequate for obtaining good results, but certainly a more precise alternative could be substituted for this step. Additionally, although these updates can be implemented such that each step is guaranteed to reduce or leave (18) unchanged, this alone is insufficient to guarantee formal convergence to a stationary point. The latter requires, for example, that the additional conditions of Zangwill's Global Convergence Theorem hold (Zangwill, 1969). However, we have not encountered any convergence issues in practice.

We refer to the aggregation of these update rules as a clustered sparse Bayesian learning (C-SBL) algorithm. The basic algorithm flow-chart/summary can be found in the supplementary file. Finally, there are only two parameters to set when using C-SBL, specifically  $\nu$  and  $\beta$ . The former can actually be learned from the data using an update rule originally proposed in (Tipping, 2001). In contrast, for  $\beta$  we adopt a simple heuristic to balance this value according to problem size. For all the simulations reported in Section 6,  $\nu$  was learned and  $\beta$  was set using this fixed rule without any additional tuning as the problem settings change.

## 5 ANALYSIS

**Low-Noise Cost Function Behavior:** We now analyze some of the properties of the underlying C-SBL cost function from (18) that make it especially suitable for the clustered sparse estimation problem. First we examine the limiting case  $\nu \rightarrow 0$ , mirroring some of our observations from Section 2, where we discussed connections with maximally sparse solutions. We also define  $\text{spark}[\Phi]$  as the smallest number of linearly dependent columns in some matrix  $\Phi$  (Donoho and Elad, 2004). In this regard we have the following:

**Theorem 1.** Assume that an optimal solution  $X^*$  to (6) exists with  $\|\mathbf{x}_j^*\|_0 < N$  and  $\text{spark}[\Phi_j] = N + 1$  for all  $j$ . Additionally, let  $\Lambda^*, W^*$  denote any global solution

of  $\lim_{\nu \rightarrow 0} \inf_{\Lambda > 0, W \in \mathcal{S}} \mathcal{L}(\Lambda, W)$ . Then the value of (13) as  $\nu \rightarrow 0$  given by  $\Gamma_j^* \Phi_j (\Phi_j \Gamma_j^* \Phi_j^\top)^\dagger \mathbf{y}_j$ , when combined across all  $j$  with  $\Gamma_j^* = \left( \sum_k w_{j,k}^* (\Lambda_k^*)^{-1} \right)^{-1}$ , forms a globally optimal solution to (6).

This result can be proven by adapting Theorem 4 from (Wipf et al., 2011), which applies to single task compressive sensing models. Note that the spark assumption is very mild and will be satisfied almost surely by any dictionary constructed via (5). Therefore, the C-SBL cost function clearly favors maximally sparse solutions in the low-noise regime as desired. Importantly however, while the global optimum of C-SBL may be equivalent to (6), the entire cost function landscape is not identical, and exploiting the cluster structure, and row-sparsity within clusters, can be advantageous in avoiding distracting local minima. Two important distinctions play a role in this regard.

First, the inclusion of the penalty term  $\sum_{j,k} f(w_{j,k})$ , by favoring solutions in clusters, naturally steers away from unpromising areas of the parameter space without correlation structure among tasks. Secondly, if we are able to determine the correct cluster structure, then there is a natural mechanism embedded in (18) to leverage the resulting row-sparsity to avoid local solutions, sometimes provably so. For example, assume for simplicity that  $\Phi_j = \Phi \forall j$ , meaning the same dictionary is used for all tasks. Also define the condition number of any matrix  $A$  as  $\kappa(A) = \|A^{-1}\|_2 \|A\|_2$ , where  $\|\cdot\|_2$  is the spectral norm.

Now assume that our measurements have been partitioned into  $\bar{K} \leq L$  clusters  $\Omega_k$ , where  $Y_{\Omega_k}$  are the columns of  $Y$  associated with cluster  $k$ . Such a clustering could be provided by an oracle, or alternatively can be viewed as an intermediate point during the optimization process whereby for every task  $j \in \Omega_k$ ,  $\Gamma_j = \Lambda_k$  for some unique  $\Lambda_k$ . We may then consider the remaining multi-task sparse estimation problems to estimate the corresponding maximally row-sparse  $X_{\Omega_k}^*$  within each cluster, holding the cluster assignments fixed, similar to problem (3).

In this scenario, Jensen's inequality collapses to an equality, the C-SBL cost function (18) decouples, and we may equivalently consider each cluster  $k$  as a separate subproblem to minimize

$$\mathcal{L}_k(\Lambda_k) \triangleq \text{tr} \left[ Y_{\Omega_k} Y_{\Omega_k}^\top (\Sigma_k)^{-1} \right] + |\Omega_k| \log |\Sigma_k|, \quad (27)$$

where  $\Sigma_k \triangleq \nu I + \Phi \Lambda_k \Phi^\top$ . Then we have the following:

**Theorem 2.** Let  $\text{spark}(\Phi) = N + 1$ . Also, let  $X_{\Omega_k}^*$  be a maximally row-sparse feasible solution to  $Y_{\Omega_k} = \Phi X_{\Omega_k}$  with  $D \triangleq \|X_{\Omega_k}^*\|_{\text{row-}\ell_0}$ . Define  $\bar{X}_{\Omega_k}^*$  as the associated collection of nonzero rows. Then if  $X_{\Omega_k}^*$  satisfies

$$\inf_{\Psi > 0} \kappa(\Psi \bar{X}_{\Omega_k}^* (\bar{X}_{\Omega_k}^*)^\top \Psi) < \frac{N}{D} \quad (28)$$

with  $\Psi \in \mathbb{R}^{D \times D}$  diagonal, then  $\lim_{\nu \rightarrow 0} \inf_{\Lambda_k > 0} \mathcal{L}_k(\Lambda_k)$  has a unique local minimum (or stationary point)  $\Lambda_k^*$ , and this point will satisfy  $\Lambda_k^* \Phi^\top (\Phi \Lambda_k^* \Phi^\top)^\dagger Y_{\Omega_k} = X_{\Omega_k}^*$ .

The supplementary file contains details of the proof. Theorem 2 dictates circumstances under which we are guaranteed to recover the maximally row-sparse solution within each cluster (assuming we are given an algorithm that converges to a stationary point), meaning we are guaranteed to solve (18) without resorting to brute-force optimization of the more challenging NP-hard problem (6). Moreover, the most relevant criteria under which this occurs depends only on the conditioning of the nonzero rows in  $X_{\Omega_k}^*$ . In words, if these rows contain complementary information regarding the true sparsity profile, as evidenced by a high condition number, no locally minimizing solutions exist. A weaker related result has already been known in the information theory community, but this result adapted to the present context would require that rows of  $\bar{X}_{\Omega_k}^*$  be strictly orthogonal (Kim et al., 2012). Additionally, Theorem 2 is independent of any RIP conditions or other strong structural assumptions on  $\Phi$  typical of compressive sensing recovery results.

Note that arguably the most common strategy for promoting row-sparse solutions is to solve problems of the form

$$\min_{X_{\Omega_k}} \sum_j h(\|\mathbf{x}_{\Omega_k}^j\|_2) \quad \text{s.t. } Y_{\Omega_k} = \Phi X_{\Omega_k}, \quad (29)$$

where  $h$  is an arbitrary non-decreasing function, and  $\mathbf{x}_{\Omega_k}^j$  denotes the  $j$ -th row of  $X_{\Omega_k}$ . Interestingly though, specialized counter-examples can be used to show that, for any such  $h$  (including the selection  $h(z) = z$  that leads to the convex  $\ell_{1,2}$  mixed-norm (Obozinski et al., 2011) commonly used in compressive sensing), there will always exist a  $\Phi$  and  $Y_{\Omega_k}$ , consistent with the stipulations of Theorem 2 such that there is guaranteed to be a stationary point not equal to  $X_{\Omega_k}^*$  when solving (29). Hence the C-SBL cost function maintains an inherent advantage at the cluster level from an optimization standpoint.

**High-Noise Cost Function Behavior:** Now we briefly consider the scenario where  $\nu$  becomes large. We first observe that the data dependent term in (18) tends towards  $\sum_j \|\mathbf{y}_j\|_2^2 / \nu + O(\nu^{-1})$  as  $\nu$  increases. Likewise the remaining  $\nu$ -dependent penalty term converges as  $\log |\Gamma_j^{-1} + (1/\nu) \Phi_j^\top \Phi_j| \rightarrow \log |\sum_k w_{j,k} \Lambda_k^{-1}| + O(\nu^{-1})$ .

By Jensen's inequality, the resulting combined factor

$$\sum_{j,k} w_{j,k} \log |\Lambda_k| + \sum_j \log \left| \sum_k w_{j,k} \Lambda_k^{-1} \right| \quad (30)$$

has a minimal value of zero when either  $w^j$  equals an indicator vector for all  $j$ , or when  $\Lambda_k$  equals some  $\Lambda'$  for all  $k$ . The former scenario will cause the weight penalty

$\sum_{j,k} f(w_{j,k})$  to become large. However, if all  $\Lambda_k = \Lambda'$ , then all of these penalty factors can effectively be minimized. Assuming the contribution from  $O(\nu^{-1})$  terms is small, this will then minimize the overall objective function. Moreover, with all  $\Lambda_k = \Lambda'$ , we by definition collapse to a single cluster, multi-task sparse estimation model as was motivated in Section 2 at low SNR.

## 6 EXPERIMENTS

This section provides empirical validation for the proposed C-SBL algorithm. We compare performance against the traditional convex  $\ell_1$  penalized regression estimator commonly using in compressive sensing, as well as three related sparse Bayesian algorithms that have previously been applied to similar problems. These include the original sparse Bayesian learning (SBL) (Tipping, 2001), a multiple measurement vector (MMV) extension of SBL (Ji et al., 2009), and the Dirichlet Process (DP) prior adaptation of multi-task Bayesian compressive sensing (Qi et al., 2008). The latter is arguably the closest competitor to C-SBL given its ability to learn clusters with sparse support. An additional sparse Bayesian algorithm from (Zhang & Rao, 2011) also addresses a multi-task sparse learning setting based upon related variational principles; however, this method cannot learn clusters, our central purpose, nor does code appear to be available for handling different sensing matrices  $\Phi_j$  for different tasks. Therefore we do not include comparisons here. We will begin with synthetic data simulations to demonstrate model properties followed by efforts to reconstruct image sequences from compressive measurements.

**Synthetic Data:** For the first experiment we generate data from  $\bar{K} = 5$  clusters. Within every cluster are 5 tasks each for a total of  $L = 25$  tasks. Each corresponding  $X_{\Omega_k}^*$  is generated with a random row-sparsity pattern distinct from one another, and with nonzero rows distributed as  $\bar{X}_{\Omega_k}^* \sim \mathcal{N}(0, 1)$  (i.e., each task has its own independent nonzero coefficients). The associated task-specific dictionaries are generated via  $\Phi_j \sim \mathcal{N}(0, 1/N)$ ; we set  $M = 256$ ,  $D \triangleq \|X_{\Omega_k}^*\|_{\text{row}-\ell_0} = 30$ , and the number of measurements per task  $N$  is varied. We then compute  $\mathbf{y}_j = \Phi_j \mathbf{x}_j^* \forall j$  in each instance and run the respective algorithms to compare the recovery performance, averaging across 50 trials.

Results are presented in Figure 1(a), where we display the normalized mean-squared error metric given by  $\langle \|\hat{X} - X^*\|_2^2 / \|X^*\|_2^2 \rangle$ . We observe that C-SBL has the lowest reconstruction error among all the methods. Additionally based on Lemma 1,  $X^*$  will almost surely be the globally optimal solution to (6). While it has been proven that regular SBL also has the same global optimum to (6) (Wipf et al., 2011), this algorithm is blind to any structure between tasks and therefore may become trapped at suboptimal local minima, leading to relatively poorer performance. On the other hand, C-SBL is more likely to reach the global

optima by exploiting cluster information. Interestingly, the DP algorithm, which also putatively leverages these clusters, does not perform significantly better than SBL, suggesting that it is non-trivial to optimally use the additional structure.

In contrast, with a different data generation mechanism, DP has demonstrated improvement over SBL but not C-SBL. Here we recreate a close approximation to experiments conducted in (Qi et al., 2008).<sup>3</sup> We begin with  $D = 27$  nonzero rows but with both amplitudes and supports shared across tasks. An innovations component is then added, whereby an additional 3 elements of each task are given random nonzero values, with task-specific, randomly generated support. Figures 1(b) and 1(c) display results as different parameters are varied. Indeed in this revised scenario DP does significantly outperform SBL; however, C-SBL retains its advantage over all algorithms.

Finally we consider reconstructions in the presence of noise. For this purpose we generate data in the same manner as was used to generate Figure 1(a), and fix  $N = 75$ ,  $M = 256$ , and  $D = 30$  while varying the SNR using additive Gaussian white noise. We also include an ideal oracle estimator that knows the true clusters. Results are displayed in Figure 1(d), where again C-SBL is observed to perform well, and in excess of 15dB SNR nearly matches even the oracle.

**Image Clustering and Reconstruction:** Here we consider a real-world application motivated in (Qi et al., 2008) that involves simultaneously reconstructing multiple images from different dynamic scenes using compressive measurements. In this scenario, tasks are images and each cluster represents a group of snapshots taken from a given dynamic scene that are likely to have a similar sparsity profile in the wavelet domain. Moreover, we may expect to have different cluster sizes and noise levels across snapshots, and moving objects behave like the innovations applied in producing Figures 1(b) and 1(c).

For this experiment we choose 5 dynamic scenes (5 clusters), each having  $\{5, 3, 3, 4, 4\}$  tasks respectively. Images have a resolution of  $64 \times 64$ , although the supplementary file contains higher resolution examples. Data are sampled using the 'db4' 2D wavelet transform using 4 scales as provided by Matlab. Each Gaussian sensing matrix  $\Phi_j$  is  $N = 2275 \times M = 5986$ , with iid elements generated as before. Although undoubtedly better performance could be obtained by selecting different transforms and/or applying different sampling rates to different scales, this is not our primary focus here. Overall we are merely adopting an established benchmark and inserting C-SBL into this pipeline

<sup>3</sup>Note that certain simulation specifics needed to exactly reproduce the results from (Qi et al., 2008) were missing (e.g. SNR), and we were unfortunately unable to obtain code from the authors.

Figure 1: Synthetic data reconstruction performance comparisons; in all cases  $M = 256$ . (a) MSE versus  $N$ , with  $D = 30$ . Tasks belonging to the same cluster share the same support; nonzero coefficients are independent. (b) MSE versus  $N$ . Tasks belonging to the same cluster share the same support and coefficients over  $D = 27$  nonzero rows. Each task then has an additional 3 randomly positioned, independent nonzero elements (innovations). (c) Same as (b), only now  $N = 70$  and the total support cardinality  $S \triangleq D + 3$  is varied. (d) MSE versus SNR. Data generated as in Figure 1(b), with  $N = 75$ ,  $D = 30$ , and additive Gaussian white noise applied to achieve the desired SNR.

unaltered or specially tuned.

Figure 2 shows example reconstruction results of four out of five of the different scenes. For space consideration we only show a single reconstructed image frame from each scene cluster and compare three algorithms: C-SBL, DP, and MMV. The supplementary file contains the full results and other details. Figure 3(a) shows the normalized MSE trajectory as a function of iteration number up to convergence. In terms of both MSE (Figure 3(a)) and visual inspection (Figure 2 and supplementary), C-SBL outperforms other algorithms. In terms of per-iteration computational complexity all algorithms are approximately equal, scaling quadratically in  $M$ , and linearly in  $N$  and  $L$  with the proper implementation.

Finally, Figures 3(b) and 3(c) display the beneficial hard clustering effect of C-SBL with regard to ground truth as revealed through heat-maps of the estimated cluster matrices  $W$ . Here column permutations are irrelevant as the column labels are arbitrary. By employing C-SBL, tasks within the same group (as partitioned by the ground truth in Figure 3(b)) return nonzeros along the same columns of the estimated  $W$  (Figure 3(c)). In this way, C-SBL uses multiple bases  $\Lambda_k$  to model the clusters (different scenes in Figure 2) as evidenced by multiple nonzeros in the rows of

$W$ . However, this is the artifact of many different  $\Lambda_k$  fusing together within a true cluster, and all of these bases within a cluster must eventually share the same support (and typically magnitudes as well) by virtue of the support intersection property described in Section 3. Consequently, we can infer that C-SBL correctly learns the correct five clusters ultimately leading to the best performance (see supplementary file for DP clustering results, which fail to mirror the ground truth).

## 7 CONCLUSION

In this paper we have derived a novel Bayesian model and attendant analyses for solving multi-task sparse linear inverse problems by exploiting unknown cluster structure among the tasks. Although Bayesian models have been deployed for solving related problems, these often involve organizing postulated distributional assumptions into a complex hierarchy such that approximate inference techniques must be applied that are difficult to unpack and rationalize. In contrast, herein we rely only on a simple empirical prior and then justify this parameterization using rigorous properties of the underlying cost function that emerges. This ‘semi-Bayesian’ strategy promotes understanding of the central mechanisms at work in producing a successful algorithm, including all approximations involved, and potentially suggests targeted enhancements.

Figure 2: Reconstructions of  $64 \times 64$  images from four of the five dynamic scenes (the fifth scene would not fit owing to space considerations, but is contained in the supplementary file). From left to right: Original image, C-SBL, DP, MMV. Sampling rate is  $N/M = 0.38$ . See supplementary file for full data, higher resolution, lower sampling rate examples.

## Abstract

For undirected graphical models, belief propagation often performs remarkably well for approximate marginal inference, and may be viewed as a heuristic to minimize the Bethe free energy. Focusing on binary pairwise models, we demonstrate that several recent results on the Bethe approximation may be generalized to a broad family of related pairwise free energy approximations with arbitrary counting numbers. We explore approximation error and shed light on the empirical success of the Bethe approximation.

## 1 INTRODUCTION

Undirected graphical models, also called Markov random fields (MRFs), have become a central tool in machine learning, providing a powerful and compact way to describe relationships between variables. Fundamental problems are to compute the normalizing partition function, and to solve for the marginal distribution of a subset of variables (marginal inference). Both tasks are computationally intractable (Cooper, 1990), prompting great interest in approximate algorithms that perform well. One popular approach is *belief propagation* (BP, Pearl, 1988). When the underlying model topology is acyclic, this returns exact values in linear time. If the method is applied to models with cycles, termed *loopy belief propagation* (LBP), results are often strikingly good but not always, and it may not converge at all (McEliece et al., 1998).

Yedidia et al. (2001) demonstrated that fixed points of LBP correspond to stationary points of the *Bethe free energy*  $\mathcal{F}_B$  (Bethe, 1935), see §2 for definitions. Further, Heskes (2002) showed that stable fixed points correspond to local minima of the Bethe free energy. In this paper, we summarize recent results on the Bethe approximation (Welling and Teh, 2001; Weller and Jebara, 2013, 2014a,b; Weller et al., 2014), and in each case consider

how the result may be generalized by considering the broad class of pairwise entropy approximations specified by arbitrary *counting numbers*, which includes the Bethe and *tree-reweighted* approximations (TRW, Wainwright et al., 2005) as special cases. We discuss consequences and related applications, including in §5 minimizing the approximate free energy, which Weller and Jebara (2014a) recently showed, for the specific case of the Bethe approximation on attractive models, can be approximated to any  $\epsilon$ -accuracy with a *fully polynomial-time approximation scheme* (FPTAS).

In §6, we compare this family of entropy approximations to the *true* entropy, and consider how differences interact with the other form of approximation typically employed: the marginal polytope, which enforces global variable consistency, is relaxed to the local polytope, which enforces only local (pairwise) consistency. We also provide fresh insights on balanced and frustrated cycles by considering the loop series approach of Sudderth et al. (2007).

### 1.1 RELATED WORK

Related work is discussed throughout the text but here we clarify the context and contributions of our results up to §5 that build to show how to approximate the global optimum of the approximate free energy to arbitrary accuracy for general counting numbers.

**Context.** All for attractive binary pairwise models: The problem of identifying a most probable configuration (MAP inference) is solvable in polynomial-time via graph cuts (Greig et al., 1989); this generalizes to multi-label pairwise models with submodular cost functions (Schlesinger and Flach, 2006). However, aside from restricted cases (e.g. low treewidth or the *fully polynomial-time randomized approximation scheme* (FPRAS) of Jerrum and Sinclair (1993) for uniform external field), there is no way to estimate the partition function  $Z$  accurately in polynomial-time. LBP is a heuristic to find the Bethe partition function by minimizing the Bethe free energy, with  $\log Z_B = -\min \mathcal{F}_B$ , and for these mod-

els we know that  $Z_B$  is a lower bound and usually a good estimate of  $Z$  (Sudderth et al., 2007; Ruoizzi, 2012; Weller and Jebara, 2014b), but LBP may find only a local optimum or not converge at all. Various methods (e.g. CCCP, Yuille, 2002) were introduced which converge but only to a local minimum of  $\mathcal{F}_B$  with no time guarantee. Shin (2012) introduced the first polynomial-time method but this returns an approximately stationary point of the Bethe  $\mathcal{F}_B$  (i.e. a point where  $|\text{derivative of } \mathcal{F}_B| < \epsilon$ , which is useful for loop series methods, but this point may have  $\mathcal{F}_B$  value far from the global optimum; attractive not required) subject to a sparsity condition that max degree is  $O(\log n)$ . Weller and Jebara (2013) derived a PTAS for the global optimum of  $\mathcal{F}_B$  with the same sparsity condition. Weller and Jebara (2014a) improved this, providing the first FPTAS for  $\log Z_B$  for an attractive model with any topology. These applied only for the Bethe approximation.

**Contributions.** Here we broaden analysis significantly to consider any counting numbers, relying on our new Theorems 2, 5, 6 and 7, and Lemmas 3 and 4. All these extend previous results that applied only to the Bethe approximation. It is somewhat remarkable that it emerges that an attractive model admits a FPTAS for  $\log Z_A$  for any counting numbers. This is significant theoretically and will allow the benefits of non-convex free energy approximations to be explored further in future work. Theorems 2, 5 and 6 importantly apply to general (non-attractive models), as does Algorithm 1, allowing  $\log Z_A$  with any counting numbers to be computed to arbitrary accuracy, though with no polynomial-time guarantee if not attractive - still this will be useful to learn insights from small models and to benchmark accuracy of faster methods.

## 2 PRELIMINARIES

We adopt notation consistent with (Welling and Teh, 2001; Weller and Jebara, 2013, 2014a,b). Consider a binary pairwise model with  $n$  variables  $X_1, \dots, X_n \in \mathbb{B} = \{0, 1\}$  and graph topology  $(\mathcal{V}, \mathcal{E})$  with  $m = |\mathcal{E}|$  edges; that is  $\mathcal{V}$  contains nodes  $\{1, \dots, n\}$  where  $i$  corresponds to  $X_i$ , and  $\mathcal{E} \subseteq V \times V$  contains an edge for each pairwise score relationship. Let  $\mathcal{N}(i)$  be the neighbors of  $i$ . Let  $x = (x_1, \dots, x_n)$  be one particular configuration, and define its *energy*  $E(x)$  via the relationships

$$p(x) = \frac{e^{-E(x)}}{Z}, \quad E = -\sum_{i \in \mathcal{V}} \theta_i x_i - \sum_{(i,j) \in \mathcal{E}} W_{ij} x_i x_j, \quad (1)$$

where the partition function  $Z = \sum_x e^{-E(x)}$  is the normalizing constant, and  $\{\theta_i, W_{ij}\}$  specify the potentials of the model.<sup>1</sup> If  $W_{ij} \geq 0$ , the edge  $(i, j)$  is *attractive* (tending to pull its variables toward the same value); if  $W_{ij} < 0$  then it

<sup>1</sup>It is easily shown (Wainwright and Jordan, 2008) that any binary pairwise model may be reparameterized to the form in (1).

is *repulsive* (tending to push apart its variables to different values). A model is attractive iff all its edges are attractive.

### 2.1 VARIATIONAL INFERENCE AND COUNTING NUMBERS

Given any joint probability distribution  $p(X_1, \dots, X_n)$  over all variables, the Gibbs free energy is defined as  $\mathcal{F}_G(p) = \mathbb{E}_p(E) - S(p)$ , where  $S(p)$  is the (Shannon) entropy of the distribution. By considering KL divergence, it is easily shown (Wainwright and Jordan, 2008) that minimizing  $\mathcal{F}_G$  over the set of all globally valid marginals (termed the *marginal polytope*) yields a value of exactly  $-\log Z$  at the true marginal distribution, given in (1).

Since this minimization is often computationally intractable, two pairwise approximations are typically made:

1. The marginal polytope is relaxed to the *local polytope*  $\mathbb{L}$ , where only *local* consistency is required - that is we deal with a *pseudomarginal* vector  $q$ , which in our context may be considered  $\{q_i = q(X_i = 1) \forall i \in \mathcal{V}, \mu_{ij}(x_i, x_j) = q(x_i, x_j) \forall (i, j) \in \mathcal{E}\}$ , subject to constraints  $q_i = \sum_{x_j \in \mathbb{B}} \mu_{ij}(1, x_j), q_j = \sum_{x_i \in \mathbb{B}} \mu_{ij}(x_i, 1) \forall (i, j) \in \mathcal{E}$ .

The local polytope constraints imply that, given  $q_i$  and  $q_j$ ,

$$\mu_{ij} = \begin{pmatrix} 1 + \xi_{ij} - q_i - q_j & q_j - \xi_{ij} \\ q_i - \xi_{ij} & \xi_{ij} \end{pmatrix} \quad (2)$$

for some  $\xi_{ij} \in [\max(0, q_i + q_j - 1), \min(q_i, q_j)]$ .

Thus we may adopt a minimal representation with pseudomarginals specified by  $\{q_i \forall i \in \mathcal{V}\}$  singleton and  $\{\xi_{ij} \forall (i, j) \in \mathcal{E}\}$  pairwise terms.

2. The entropy  $S$  is replaced by an approximation  $S_A$  that incorporates singleton and pairwise entropy terms via *counting numbers*  $\{c_i \forall i \in \mathcal{V}, \rho_{ij} \forall (i, j) \in \mathcal{E}\}$ :

$$S_A(q) = \sum_{i \in \mathcal{V}} c_i S_i - \sum_{(i,j) \in \mathcal{E}} \rho_{ij} I_{ij}. \quad (3)$$

Here  $S_i(q_i)$  is the entropy of the singleton distribution of  $X_i$ , and  $I_{ij}(\mu_{ij})$  is the mutual information of edge  $(i, j)$  given by  $I_{ij} = S_i + S_j - S_{ij}$ , where  $S_{ij}(\mu_{ij})$  is the entropy of the pairwise distribution  $\mu_{ij}$ . Note that always  $I_{ij} \geq 0$ .<sup>2</sup>

In this paper, we shall consider the approximate partition function  $Z_A$  obtained by minimizing the corresponding approximate free energy  $\mathcal{F}_A$ , defined as follows,

$$-\log Z_A = \min_{q \in \mathbb{L}} \mathcal{F}_A(q), \quad \mathcal{F}_A(q) = \mathbb{E}_q(E) - S_A(q). \quad (4)$$

We shall also be interested in the approximate marginals given by the arg min of (4).

Eaton and Ghahramani (2013) showed that any discrete model may be arbitrarily well approximated by a binary pairwise model, though the state space may be large.

<sup>2</sup>Some instead define  $S_A = \sum_{i \in \mathcal{V}} c'_i S_i + \sum_{(i,j) \in \mathcal{E}} c'_{ij} S_{ij}$ , which is equivalent via  $c'_{ij} = \rho_{ij}, c'_i = c_i - \sum_{j \in \mathcal{N}(i)} \rho_{ij}$ .

## 2.2 CHOICE OF COUNTING NUMBERS

In the standard Bethe entropy approximation  $S_B$ , all counting numbers  $c_i$  and  $\rho_{ij}$  are set to 1. This often performs very well, yet leads to a non-convex approximate free energy  $\mathcal{F}_B$  that can be hard to optimize.

Another choice yields the well-known *tree-reweighted* approximation (TRW, Wainwright et al., 2005)  $S_T$ . Here again all  $c_i = 1$  but now the edge weights  $\rho_{ij}$  are selected from the *spanning tree polytope*, resulting in all  $\rho_{ij} \leq 1$ . Since  $I_{ij} \geq 0$ , this immediately implies that  $S_T \geq S_B$ , and hence  $Z_T \geq Z_B$ . It is also known that TRW values are bounded by true values in that  $S_T \geq S$ , hence  $Z_T \geq Z$  (whereas for many counting numbers,  $S_A$  may be above or below  $S$ , similarly  $Z_A$  may be above or below  $Z$ ; indeed, in some cases including Bethe,  $S_A$  may even be negative). We note also that  $S_T$  is concave leading to the corresponding free energy approximation  $\mathcal{F}_T$  being convex, allowing easier optimization.

Other choices of counting numbers yield a rich family of approximations, which has been studied previously. Yedidia et al. (2005) discuss counting numbers for the broader concept of *regions* which may contain any number of variables (in particular more than two). This naturally relates to *generalized belief propagation* (GBP) and associated *Kikuchi free energy approximations*. Pakzad and Anantharam (2005) and Heskes (2006) derived sufficient conditions for such free energy approximations to be convex. In this paper, we consider only pairwise counting numbers. In this context, Meshi et al. (2009) explored a wide range of pairwise counting numbers to try to find a convex free energy approximation with performance competitive to Bethe. For a subrange of models, they observed that this was possible yet still overall, Bethe performed very well. This is one of the motivations for this work, to understand better why Bethe performs so well.

Following Yedidia et al. (2005) and Meshi et al. (2009), we say that an approximation is *variable valid* if  $c_i = 1 \forall i \in \mathcal{V}$ , and is *edge valid* if  $\rho_{ij} = 1 \forall (i, j) \in \mathcal{E}$ . Their earlier work showed that variable valid approximations typically perform well compared to others, and we shall focus more attention on these models, though many of our results apply more generally to arbitrary counting numbers. Note that if all variables are independent, then variable validity is required to return the true entropy. If variables are connected in a tree, then edge validity is necessary to be exact. Bethe is unique in always being both variable and edge valid.

On a related theme, Weller et al. (2014) teased apart the two aspects of the Bethe approximation, i.e. the polytope and entropy as described in §2.1. Their results indicate that even if the optimization of (4) is performed over the marginal polytope, still the Bethe entropy approximation typically performs better than TRW. We consider polytope effects in §6.2.

## 2.3 SUBMODULARITY

A (set) function  $f : 2^X \rightarrow \mathbb{R}$  is *submodular* if  $\forall S, T \subseteq X, f(S \cap T) + f(S \cup T) \leq f(S) + f(T)$ . For finite  $X$ , this is equivalent to diminishing returns, i.e.  $\forall S \subseteq T, x \in X \setminus T, f(T \cup \{x\}) - f(T) \leq f(S \cup \{x\}) - f(S)$ .

Submodular functions have been studied extensively (Edmonds, 1970; Lovász, 1983; Bach, 2013). In some ways, they are a discrete analogue of convex functions and can be minimized efficiently. The concept can be generalized to consider any *lattice*, i.e. a partially ordered set  $(L, \preceq)$  such that  $\forall x, y \in L, \exists$  a greatest lowest bound (glb or *meet*)  $x \wedge y \in L$  and a least upper bound (lub or *join*)  $x \vee y \in L$ . A (lattice) function  $f : L \rightarrow \mathbb{R}$  is *submodular* if  $\forall x, y \in L, f(x \wedge y) + f(x \vee y) \leq f(x) + f(y)$ .

For a pairwise function  $f$  over binary variables,  $f$  is submodular iff  $f(0, 0) + f(1, 1) \leq f(0, 1) + f(1, 0)$ . It is easily shown that the energy (or cost) of an edge  $(i, j)$  is submodular iff it is attractive, i.e. iff  $W_{ij} \geq 0$ . Further, the set of vectors in  $\mathbb{R}^n$  with  $x \preceq y$  if  $x_i \leq y_i$  for all components  $i$ , is a lattice. Here  $x \wedge y$  has  $i$ th component of  $\min(x_i, y_i)$  and  $x \vee y$  has  $i$ th component of  $\max(x_i, y_i)$ .

## 2.4 FLIPPING VARIABLES

The method of *flipping* (sometimes called *switching*) binary variables will be useful for our analysis in §3.3. Given a model on variables  $\{X_i\}$ , consider a new model on  $\{X'_i\}$  where we flip a subset  $\mathcal{R}$  of the variables, i.e.  $X'_i = 1 - X_i$  for variables  $i \in \mathcal{R} \subseteq \mathcal{V}$ , and  $X'_i = X_i$  for  $i \in \mathcal{V} \setminus \mathcal{R}$ . We identify new model parameters  $\{\theta'_i, W'_{ij}\}$  as in (Weller and Jebara, 2013, §3) in order to preserve energies of all states up to a constant, hence the probability distribution over states is unchanged. If all variables are flipped (i.e.  $\mathcal{R} = \mathcal{V}$ ), new parameters are given by

$$W'_{ij} = W_{ij}, \theta'_i = -\theta_i - \sum_{j \in \mathcal{N}(i)} W_{ij}. \quad (5)$$

If the original model was attractive, so too is the new model. In general, if a subset  $\mathcal{R} \subseteq \mathcal{V}$  is flipped, let  $\mathcal{E}_t = \{\text{edges with exactly } t \text{ ends in } \mathcal{R}\}$  for  $t = 0, 1, 2$ , then we obtain

$$W'_{ij} = \begin{cases} W_{ij} & (i, j) \in \mathcal{E}_0 \cup \mathcal{E}_2, \\ -W_{ij} & (i, j) \in \mathcal{E}_1, \end{cases} \quad \theta'_i = \begin{cases} \theta_i + \sum_{(i,j) \in \mathcal{E}_1} W_{ij} & i \in \mathcal{V} \setminus \mathcal{R}, \\ -\theta_i - \sum_{(i,j) \in \mathcal{E}_2} W_{ij} & i \in \mathcal{R}. \end{cases} \quad (6)$$

The proof of the following result for general counting numbers follows the argument used by Weller and Jebara (2013) for the specific case of the Bethe approximation.

**Lemma 1.** *Flipping variables changes affected pseudo-marginal matrix entries' locations but not values. For*

any counting numbers,  $\mathcal{F}_A$  is unchanged up to a constant, hence the locations of stationary points are unaffected.

## 2.5 ATTRACTIVE AND BALANCED MODELS

A model is *attractive* iff all its edges are attractive, i.e. iff  $W_{ij} \geq 0 \forall (i, j) \in \mathcal{E}$ . As suggested by §2.3, attractive models have desirable properties, e.g. a MAP assignment may be found in polynomial time (Greig et al., 1989), and as shown in §5, we can construct a FPTAS for  $Z_A$  for any counting numbers. We remark that, as observed by Harary (1953), a general model (which may contain repulsive edges) can be mapped to an attractive model by flipping a subset of variables iff the initial model is *balanced*, that is iff it contains no *frustrated* cycles, i.e. a cycle with an odd number of repulsive edges. Hence, results that apply to attractive models may readily be extended to the wider class of balanced models.

## 3 FIRST DERIVATIVES OF $\mathcal{F}_A$

Combining (4) with (1), (2) and (3), yields

$$\begin{aligned} \mathcal{F}_A(q) = & - \sum_{i \in \mathcal{V}} \theta_i q_i - \sum_{(i,j) \in \mathcal{E}} W_{ij} \xi_{ij} \\ & - \sum_{i \in \mathcal{V}} c_i S_i + \sum_{(i,j) \in \mathcal{E}} \rho_{ij} (S_i + S_j - S_{ij}). \end{aligned} \quad (7)$$

### 3.1 OPTIMUM PAIRWISE PSEUDOMARGINALS

Differentiating (7) with respect to  $\xi_{ij}$ , we obtain

$$\begin{aligned} \frac{\partial \mathcal{F}_A}{\partial \xi_{ij}} = & -W_{ij} - \rho_{ij} \frac{\partial S_{ij}}{\partial \xi_{ij}} \\ = & -W_{ij} + \rho_{ij} \log \left[ \frac{\xi_{ij}(1 + \xi_{ij} - q_i - q_j)}{(q_i - \xi_{ij})(q_j - \xi_{ij})} \right]. \end{aligned}$$

Note that this is independent of the singleton counting numbers  $\{c_i\}$ . Welling and Teh (2001) considered the specific case of the Bethe approximation, where  $\rho_{ij} = 1$ . Solving the general case for  $\frac{\partial \mathcal{F}_A}{\partial \xi_{ij}} = 0$  leads to a quadratic equation,

$$\alpha_{ij} \xi_{ij}^2 - [1 + \alpha_{ij}(q_i + q_j)] \xi_{ij} + (1 + \alpha_{ij}) q_i q_j = 0, \quad (8)$$

where we define  $\alpha_{ij} = e^{W_{ij}/\rho_{ij}} - 1$ . Observe that here  $W_{ij}/\rho_{ij}$  plays the ‘edge count modified’ role typically performed by  $W_{ij}$  in the standard Bethe approximation. It is easily shown that (8) has just one feasible solution (Welling and Teh, 2001; Weller and Jebara, 2013), as given in the following result.

**Theorem 2.** *For general counting numbers, given singleton pseudomarginals, optimum pairwise terms (which minimize the approximate free energy) are given by*

$$\xi_{ij}^*(q_i, q_j) = \frac{1}{2\alpha_{ij}} \left( x_{ij} - \sqrt{x_{ij}^2 - 4\alpha_{ij}(1 + \alpha_{ij})q_i q_j} \right),$$

where  $\alpha_{ij} = e^{W_{ij}/\rho_{ij}} - 1$ ,  $x_{ij} = 1 + \alpha_{ij}(q_i + q_j)$ .

Henceforth we shall often consider  $\mathcal{F}_A$  as a function of just the singleton pseudomarginals  $\{q_i\}$ , with all pairwise  $\xi_{ij}$  terms being implicitly specified by their optimum values as given by Theorem 2.

As noted by Weller and Jebara (2013), (8) may be rewritten as  $\xi_{ij} - q_i q_j = \alpha_{ij}(q_i - \xi_{ij})(q_j - \xi_{ij})$ . The terms in parentheses are elements of the pairwise marginal (2), constrained to be  $\geq 0$ . By its definition,  $\alpha_{ij}$  takes the same sign as  $W_{ij}/\rho_{ij}$ , hence the following result holds.

**Lemma 3.**  $\frac{W_{ij}}{\rho_{ij}} \geq 0 \Rightarrow \xi_{ij} \geq q_i q_j$ ,  $\frac{W_{ij}}{\rho_{ij}} \leq 0 \Rightarrow \xi_{ij} \leq q_i q_j$ .

We remark that, given singleton marginals  $\{q_i\}$ , a lower edge counting number  $|\rho_{ij}|$  implies a more extreme pairwise marginal term in the sense of greater  $|\xi_{ij} - q_i q_j|$ . This is true, for example, of TRW compared to Bethe.

### 3.2 FIRST DERIVATIVES WRT $q_i$ , ASSUMING OPTIMUM PAIRWISE PSEUDOMARGINALS

We follow the approach of Welling and Teh (2001), noting that at the optimum pairwise pseudomarginals,  $\frac{\partial \mathcal{F}_A}{\partial \xi_{ij}} = 0$  for all edges, hence, holding  $q_j$  fixed  $\forall j \neq i$ ,

$$\begin{aligned} \frac{d\mathcal{F}_A}{dq_i} \Big|_{\{q_j\}} = & \frac{\partial \mathcal{F}_A}{\partial q_i} \Big|_{\{q_j, \xi_{ij}\}} + \sum_{j \in \mathcal{N}(i)} \frac{\partial \mathcal{F}_A}{\partial \xi_{ij}} \frac{\partial \xi_{ij}}{\partial q_i} \\ = & -\theta_i - c_i \frac{\partial S_i}{\partial q_i} + \sum_{j \in \mathcal{N}(i)} \rho_{ij} \frac{\partial}{\partial q_i} (S_i - S_{ij}) \\ = & -\theta_i + c_i \log \frac{q_i}{1 - q_i} \\ & + \sum_{j \in \mathcal{N}(i)} \rho_{ij} \left( -\log \frac{q_i}{1 - q_i} + \log \frac{q_i - \xi_{ij}}{1 + \xi_{ij} - q_i - q_j} \right) \\ = & -\theta_i + c_i \log \frac{q_i}{1 - q_i} + \sum_{j \in \mathcal{N}(i)} \rho_{ij} \log Q_{ij}, \end{aligned} \quad (9)$$

where as in (Weller and Jebara, 2014b), we define<sup>3</sup>

$$Q_{ij} = \left( \frac{q_i - \xi_{ij}}{1 + \xi_{ij} - q_i - q_j} \right) \left( \frac{1 - q_i}{q_i} \right). \quad (10)$$

Considering (10) and Lemma 3 yields the following.

**Lemma 4.** *If edge  $(i, j)$  is attractive, i.e.  $W_{ij} \geq 0$ , then  $\rho_{ij} \log Q_{ij} \leq 0$ .*

Gradient descent methods may be used to try to minimize  $\mathcal{F}_A$  but note these may find only a local optimum.

<sup>3</sup>Note  $Q_{ij} = \frac{\partial}{\partial q_i} (S_i - S_{ij}) = \frac{p(X_j=0|X_i=1)}{p(X_j=0|X_i=0)}$  by (2).

### 3.3 BOUNDS ON FIRST DERIVATIVES WRT $q_i$

We generalize the approach of Weller and Jebara (2014a) to bound the range of first derivatives (9) for free energy approximations with arbitrary counting numbers. An important application is the construction of an  $\epsilon$ -sufficient mesh to estimate  $\log Z_A$ , see §5.

Initially assume a model that is locally attractive around  $X_i$ , i.e.  $W_{ij} \geq 0 \forall j \in \mathcal{N}(i)$ . From (9) and Lemma 4, we obtain  $\frac{\partial \mathcal{F}_A}{\partial q_i} \leq -\theta_i + c_i \log \frac{q_i}{1-q_i}$ .

Now flip all variables, see §2.4, to consider a model with  $\{X'_i = 1 - X_i \forall i \in \mathcal{V}\}$ , keeping the same counting numbers. We obtain  $W'_{ij} = W_{ij}$  and can apply the result above to yield

$$\begin{aligned} \frac{\partial \mathcal{F}_A}{\partial q'_i} &\leq -\theta'_i + c_i \log \frac{q'_i}{1-q'_i} \\ \Leftrightarrow -\frac{\partial \mathcal{F}_A}{\partial q_i} &\leq \theta_i + W_i^+ - c_i \log \frac{q_i}{1-q_i} \quad (\text{see §2.4}), \end{aligned}$$

where we define  $W_i^+ = \sum_{j \in \mathcal{N}(i): W_{ij} \geq 0} W_{ij}$ . Combine this with the earlier result to yield a sandwich inequality,

$$-\theta_i + c_i \log \frac{q_i}{1-q_i} - W_i^+ \leq \frac{\partial \mathcal{F}_A}{\partial q_i} \leq -\theta_i + c_i \log \frac{q_i}{1-q_i}.$$

Now generalize to consider the case that  $X_i$  has some neighbors  $X_j \in \mathcal{R}$  to which it is adjacent by repulsive edges, i.e. where  $W_{ij} < 0$ . First flip just the variables in  $\mathcal{R}$ , see §2.4, and then apply the above sandwich result to yield the following Theorem, where we define the nonnegative value  $W_i^- = \sum_{j \in \mathcal{N}(i): W_{ij} \leq 0} -W_{ij}$ .

**Theorem 5.** *For arbitrary counting numbers, assuming optimum pairwise pseudomarginals, first derivatives of  $\mathcal{F}_A$  are sandwiched in the range*

$$-\theta_i + c_i \log \frac{q_i}{1-q_i} - W_i^+ \leq \frac{\partial \mathcal{F}_A}{\partial q_i} \leq -\theta_i + c_i \log \frac{q_i}{1-q_i} + W_i^-.$$

Note that both upper and lower bounds are monotonic in  $q_i$  (increasing with  $q_i$  if  $c_i > 0$ , else nonincreasing), ranging from  $-\infty$  to  $\infty$ , separated by the constant value  $W_i^- + W_i^+ = \sum_{j \in \mathcal{N}(i)} |W_{ij}|$ . See Figure 1 for an example.

## 4 SECOND DERIVATIVES OF $\mathcal{F}_A$

We extend the analysis of Weller and Jebara (2013) to derive all terms of the Hessian  $H$  for free energy approximations  $\mathcal{F}_A$  with arbitrary counting numbers.

**Theorem 6** ( $H_{ij} = \frac{\partial^2 \mathcal{F}_A}{\partial q_i \partial q_j}$  second derivatives of  $\mathcal{F}_A(q_1, \dots, q_n)$  at optimum pairwise marginals  $\xi_{ij}$ ).

$$H_{ij} = \begin{cases} \frac{q_i q_j - \xi_{ij}}{\rho_{ij} T_{ij}} & \text{if } i \neq j, (i, j) \in \mathcal{E} \\ 0 & \text{if } i \neq j, (i, j) \notin \mathcal{E} \end{cases},$$

$$H_{ii} = \frac{c_i}{q_i(1-q_i)} + \sum_{j \in \mathcal{N}(i)} \left( \frac{q_j(1-q_j)}{\rho_{ij} T_{ij}} - \frac{\rho_{ij}}{q_i(1-q_i)} \right),$$

Figure 1: An example of upper and lower bounds for  $\frac{\partial \mathcal{F}_A}{\partial q_i}$ . Blue curves show monotonic upper  $f_i^U(q_i)$  and lower  $f_i^L(q_i)$  bound curves from Theorem 5, separated by constant  $W_i^- + W_i^+$ . In preprocessing, the search space is shrunk to within the dashed red lines, within which  $|\frac{\partial \mathcal{F}_A}{\partial q_i}| \leq W_i^- + W_i^+ = \sum_{j \in \mathcal{N}(i)} |W_{ij}|$ .

where  $\xi_{ij}$  takes its optimum value from Theorem 2, and  $T_{ij} = q_i q_j (1 - q_i)(1 - q_j) - (\xi_{ij} - q_i q_j)^2 \geq 0$ , with equality iff  $q_i$  or  $q_j \in \{0, 1\}$ . Proof in Appendix.

These second derivatives may be combined with the earlier gradients (9) for more efficient local minimization of  $\mathcal{F}_A$ .

## 4.1 SUBMODULARITY OF $\mathcal{F}_A$

Considering the expression for  $H_{ij}$  from Theorem 6 together with Lemma 3, observe that provided  $\rho_{ij} \neq 0$  and  $q_i, q_j \notin \{0, 1\}$ ,  $W_{ij} \geq 0 \Leftrightarrow \frac{\partial^2 \mathcal{F}_A}{\partial q_i \partial q_j} \leq 0$  (whatever the sign of  $\rho_{ij}$ ). Since third derivatives exist and are finite in this range, this yields the following result.

**Theorem 7.** *For any counting numbers with  $\rho_{ij} \neq 0 \forall (i, j) \in \mathcal{E}$ , and any discretization, an attractive model yields a submodular discrete optimization problem to estimate  $\log Z_A$ . Proof in Appendix.*

This means that considering  $\mathcal{F}_A(q_1, \dots, q_n)$  with pairwise marginals given by Theorem 2, for any discrete mesh  $\mathcal{M} = \prod_{i=1}^n M_i$ , where  $M_i$  is a finite set of points for  $q_i$  in  $[0, 1]$ , and for any counting numbers, then the discrete optimization to find the point in  $\mathcal{M}$  with lowest  $\mathcal{F}_A$  is submodular for any attractive model (hence can be solved efficiently).

## 5 OPTIMIZING THE APPROXIMATE FREE ENERGY $\mathcal{F}_A$

True marginal inference is NP-hard (Cooper, 1990), even to approximate (Dagum and Luby, 1993). However, Weller and Jebara (2014a) derived an algorithm to approximate the Bethe log-partition function,  $\log Z_B$ , to within any

Figure 2: Stylized example for optimizing the approximate free energy over two variables. The search space is first shrunk to exclude the outer red region, then the inner blue region is discretized using an  $\epsilon$ -sufficient mesh. The red dot indicates the (continuous) global minimum. On the mesh: the purple dot has the closest location, guaranteed to have value within  $\epsilon$ , while the green dot is the lowest point, hence is the discretized optimum returned.

$\epsilon$  by constructing an  $\epsilon$ -sufficient mesh  $\mathcal{M}(\epsilon)$ , i.e. a discrete mesh over the space of singleton marginals  $[0, 1]^n$  such that the mesh point  $q^*$  with  $\min_{q \in \mathcal{M}(\epsilon)} \mathcal{F}_B(q)$  is guaranteed to have  $\mathcal{F}_B(q^*)$  within  $\epsilon$  of the global optimum of  $-\log Z_B$ . In the case of an attractive model, the discrete optimization problem was shown to be submodular, leading to a FPTAS for  $\log Z_B$ . Using Theorems 5 and 7, we extend their approach to obtain similar results for any counting numbers.

The overall mesh method is outlined in Algorithm 1 and illustrated in Figure 2. Note that we need search only over the space of singleton marginals  $[0, 1]^n$ , since pairwise terms may be computed with Theorem 2. First the search space is shrunk using the bounds of Theorem 5, since we need check only where  $\frac{\partial \mathcal{F}_A}{\partial q_i}$  can be 0. Within this range,  $|\frac{\partial \mathcal{F}_A}{\partial q_i}| \leq W_i^- + W_i^+ = \sum_{j \in \mathcal{N}(i)} |W_{ij}|$ , see Figure 1. Next, discrete mesh points for each variable's singleton marginal  $q_i$  may be selected in its range such that the step size  $\delta_i$  satisfies  $\delta_i \max |\frac{\partial \mathcal{F}_A}{\partial q_i}| \approx \frac{\epsilon}{n}$ . This ensures that, wherever the global minimum is within the space,  $\mathcal{F}_A$  cannot rise by more than  $n \frac{\epsilon}{n} = \epsilon$  at the closest mesh point. This leads to a number of mesh points in dimension  $i$  of  $N_i = O(\frac{1}{\delta_i}) = O(\frac{n}{\epsilon} \sum_{j \in \mathcal{N}(i)} |W_{ij}|)$ . If an upper bound  $W$  on edge strengths is known such that  $|W_{ij}| \leq W \forall (i, j) \in \mathcal{E}$ , then the sum of mesh points in each dimension,  $N = \sum_{i \in \mathcal{V}} N_i = O(\frac{nmW}{\epsilon})$ , where  $m = |\mathcal{E}|$ .

If the model is attractive, we obtain a FPTAS since by Theorem 7, the resulting submodular multilabel optimization problem may be solved in time  $O(N^3) = O\left(\left(\frac{nmW}{\epsilon}\right)^3\right)$  using earlier graph cut results (Schlesinger and Flach, 2006; Greig et al., 1989; Goldberg and Tarjan, 1988). If the model is balanced, then a subset of variables may be efficiently identified such that flipping them yields an attractive

- 

model (see §2.4), hence the FPTAS extends to balanced models. If the model is not balanced, there is an extensive range of methods available, see (Koller and Friedman, 2009, §13) or (Kappes et al., 2013) for recent surveys.

Various refinements to improve efficiency are discussed by Weller and Jebara (2014a) for the Bethe case. All those techniques may also be applied here, and can help significantly in practice, though they do not improve the theoretical worst case.

Other approaches to attempt to minimize the Bethe free energy have been developed (Welling and Teh, 2001; Yuille, 2002; Heskes et al., 2003; Shin, 2012), and some generalize to other counting numbers, including the message passing methods of Hazan and Shashua (2008) (guaranteed to converge for a convex free energy), Wiegerinck and Heskes (2003) or Meshi et al. (2009), but unless  $\mathcal{F}_A$  is convex, none guarantees a solution close to the global optimum.

## 6 UNDERSTANDING APPROXIMATION ERROR

We examine how the entropy approximation  $S_A$  may lead to error in the marginals, then consider other factors affecting error in the estimate of the partition function.

### 6.1 EFFECT OF APPROXIMATE ENTROPY ON MARGINALS

It has previously been observed that in cyclic graphs, there are situations where the Bethe entropy tends to pull approximate singleton marginals toward extreme values near 0 or 1, and that this tends to occur as a ‘phase transition’ in behavior when edge weights rise above some threshold (Heskes, 2004; Mooij and Kappen, 2005).<sup>4</sup> One perspec-

<sup>4</sup>Note that we describe a transition in the accuracy of approximate singleton marginals. A quite different symmetry-breaking effect is the ‘ferromagnetic-paramagnetic’ transition that relates

tive on this is algorithmic stability (Wainwright and Jordan, 2008, §7.4). A different heuristic interpretation is that it occurs as a result of LBP overcounting information when going around cycles (Ihler, 2007). Here we extend the explanatory approach of Weller et al. (2014) by considering the entropy approximation and examining the effect of different counting numbers.

To illustrate the principles, we analyze a simple model with  $n$  vertices connected such that each vertex has exactly  $d$  neighbors (such models are called  $d$ -regular), with all edge potentials symmetric of weight  $W$  and no singleton potentials (we call these models *symmetric* and *homogeneous*). Using (9), it is easily shown that, for any counting numbers, there is a stationary point of  $\mathcal{F}_A$  at a location with  $q_i = \frac{1}{2} \forall i \in \mathcal{V}$ , which by symmetry clearly also give the true singleton marginals. However, for certain counting numbers, including the Bethe parameters, when  $W$  is above a critical threshold, this stationary point is no longer a minimum, and new minima emerge that pull singleton marginals away to extreme values. The following result considers an approximation with uniform counting numbers (i.e. all  $c_i = c, \rho_{ij} = \rho$ ), and demonstrates conditions for when  $q_i = \frac{1}{2} \forall i \in \mathcal{V}$  is not a minimum, by explicitly providing a direction showing that the Hessian  $H$  is not positive semidefinite.

**Lemma 8.** *For a symmetric homogeneous  $d$ -regular model on  $n$  vertices, let  $H$  be the Hessian of the approximate free energy at  $q_i = \frac{1}{2} \forall i \in \mathcal{V}$ , using uniform counting numbers  $c_i = c \forall i \in \mathcal{V}, \rho_{ij} = \rho \forall (i, j) \in \mathcal{E}$ , then  $\mathbf{1}^T H \mathbf{1} = n \left[ 4(c - d\rho) + \frac{d}{\rho\xi} \right]$ , where  $\xi = \frac{1}{2}\sigma\left(\frac{W}{2\rho}\right)$  is the uniform optimum edge marginal term, and  $\sigma(u) = \frac{1}{1+e^{-u}}$  is the standard sigmoid function. Proof in Appendix.*

Hence,  $q_i = \frac{1}{2} \forall i$  is not a minimum if  $\omega = 4(c - d\rho) + \frac{d}{\rho\xi} < 0$ . First, note that for the Bethe approximation  $c = \rho = 1$ , and this condition reduces to  $\xi > \frac{1}{4} \frac{d}{d-1} \Leftrightarrow W > 2 \log \frac{d}{d-2}$ . Indeed, when  $W$  rises above this critical threshold, singleton marginals will move away from  $\frac{1}{2}$  (Weller et al., 2014).

In general, higher singleton counting numbers  $c$  and lower edge counting numbers  $\rho$  raise  $\omega$ , making it harder to satisfy the condition. The effect of the density of connectivity  $d$  is less clear, and depends on the other parameters. For example, consider the TRW approximation with  $c = 1$  and uniform edge weights  $\rho = \frac{2(n-1)}{nd} < 1$ , declining with  $d$ , which are optimum in this setting (Weller et al., 2014, Lemma 7), then  $\omega$  is positive and increases rapidly with  $d$  (whereas Bethe suffers in this regard by keeping  $\rho = 1$  fixed).

To understand this behavior, recall the definition of  $S_A$  in (3). As singleton counting numbers  $c_i$  rise, we add more  $S_i$  which are concave, thereby increasing convexity to the true global distribution of states (mostly aligned or not).

Figure 3: Average over 20 runs of singleton marginal vs. uniform symmetric edge weight  $W$  for: exact inference, Bethe approximation, Bethe+marginal polytope, and TRW (all  $\rho_{ij} = 2/3$ ). Triangle topology with random singleton potentials  $\theta_i \sim [0, T_{max}]$ . For  $W > 0$ : Bethe and Bethe+marginal overlap, exact and TRW almost overlap. For  $W < 0$  (frustrated cycle): Bethe and TRW almost overlap, as do exact and Bethe+marginal.

of  $\mathcal{F}_A$  around  $\frac{1}{2}$  and making it more likely to be a minimum. On the other hand, increasing edge terms  $\rho_{ij}$  leads to more mutual information  $I_{ij}$  being subtracted, thereby increasing concavity of  $\mathcal{F}_A$  around  $\frac{1}{2}$  and potentially pushing marginals away from  $\frac{1}{2}$ . This perspective helps to understand why a convex free energy approximation leads to algorithmic stability (Wainwright and Jordan, 2008, §7.4).

The severity of this problem for estimating singleton marginals is high when true marginals are near  $\frac{1}{2}$ , which typically occurs for small singleton potentials, but it is less problematic when true marginals are themselves near 0 or 1. The effect is illustrated in Figure 3. Note how, for positive  $W$ , the Bethe marginals are pulled toward 1 whereas TRW is almost exactly correct. The effect for  $W < 0$  is dominated instead by a polytope effect, which we discuss in the next Section.

We remark that although the entropy approximation may have a dramatic effect on the accuracy of singleton marginals, particularly for low singleton potentials (where true marginals are near  $\frac{1}{2}$ ), the effect on estimating pairwise marginals and the partition function is less clear. In-

Figure 4: Illustration of the polytope effect on edge marginals. A-B and A-C are strongly coupled, B-C is very weakly coupled with all edges symmetric and attractive, and no singleton potentials. Edge marginals are shown. For B-C, above the edge (red) is the optimum in the marginal polytope (global consistency), below the edge (blue) is the optimum for the local polytope. See §6.2.

deed, Bethe typically outperforms TRW on these measures (Weller et al., 2014).

## 6.2 EFFECT OF LOCAL POLYTOPE

We revisit and expand on an example from Weller et al. (2014) to show that the impact of each of the two aspects (i.e. polytope and entropy, see §2.1) of an approximation to the partition function can pull in opposite directions. Hence, improving just the entropy approximation could lead to a *worse* approximation.

Consider the model in Figure 4, where 3 variables are connected in a triangle. Two edges are strongly attractive, and the third is very weakly attractive. The strong edge  $A - B$  ensures that  $A$  and  $B$  take the same value, similarly for  $B - C$ . Hence, in the globally consistent marginal polytope,  $B$  and  $C$  must take the same value. The global states 000 and 111 each have probability of almost  $\frac{1}{2}$ , and the pairwise marginals are shown along the edges of Figure 4. Since the model is almost a tree, we know that  $Z_B \approx Z$ . We shall examine how this arises by starting with exact inference, then switch to use the Bethe entropy approximation on the marginal polytope, and then relax the constraint set to the local polytope. We shall ignore the energy terms since they are equal here for true or approximate inference.

As noted, there are 2 states that dominate the global probability distribution, hence true  $S \approx \log 2$ . Computing the Bethe entropy on the marginal polytope, we obtain  $S_B \approx 3 \log 2 - 3 \log 2 = 0$ , which is too low by  $\log 2$ . However, when the polytope is relaxed, a better optimum is found by maximizing the edge entropy of  $B - C$  as shown under the edge in Figure 4. Since only local consistency is required, there is no longer any need for  $B$  to be equal to  $C$  and we gain the difference in edge entropy of  $2 \log 2 - \log 2 = \log 2$ , thus exactly offsetting the deficit due to Bethe entropy on the marginal polytope.

This example demonstrates that focusing exclusively on the entropy approximation, without also considering the

polytope approximation, may lead to difficulties. We highlight another aspect of the polytope approximation, in that it introduces half-integral vertices (Wainwright and Jordan, 2008). In a balanced cycle (even number of repulsive edges), this is of little consequence since the optimum energy (MAP solution) is always at an integral vertex, but in a frustrated cycle (odd number of repulsive edges, see §2.5), the energy can cause singleton marginals to be pulled towards  $\frac{1}{2}$ .<sup>5</sup> Hence, although the Bethe entropy pulls these marginals away from  $\frac{1}{2}$  on balanced cycles, the polytope effect pushes the other way on frustrated cycles, which in some cases may provide a helpful ‘balance’. Since many optimization techniques (including message passing methods) exploit the efficiencies possible with the local polytope approximation, it may in fact be desirable overall to have an entropy approximation such as Bethe, for this offsetting effect. See Figure 3 in the region  $W < 0$  for an illustration, where the Bethe+marginal optimization was performed using the Frank-Wolfe algorithm (Frank and Wolfe, 1956).

## 6.3 BOUNDS ON $Z_A$

While the TRW approximation has  $Z_T \geq Z$  by construction, until recently there were no guarantees on the performance of the Bethe approximation, though it typically yields very good results. Sudderth et al. (2007) proved that  $Z_B \leq Z$  for a range of attractive binary pairwise models, and conjectured that this bound holds for all attractive models. This was proved true by Ruozzi (2012) using the method of graph covers, and then also by Weller and Jebara (2014b) by combining the idea of clamping variables with analyzing properties of the derivatives of  $\mathcal{F}_B$ .

In this Section, we use the loop series method (Sudderth et al., 2007; Chertkov and Chernyak, 2006) to show that for certain other models, we can prove that  $Z_B \geq Z$ . For such models, this immediately implies that the Bethe approximation is better for estimating  $Z$  than any approximation with  $c_i = 1 \forall i \in \mathcal{V}$  (variable valid) and  $\rho_{ij} \leq 1 \forall (i, j) \in \mathcal{E}$  (from the definition of  $S_A$ , see §2.1-2.2). In particular, for these models,  $Z \leq Z_B \leq Z_T$ .

Sudderth et al. (2007) showed that  $Z/Z_B = 1 +$  a series of terms, one term for each *generalized loop*, which is a subgraph such that no vertex has degree 1, and demonstrated that each of the terms in the series is  $\geq 0$  for certain models, and hence  $Z_B \leq Z$  for these cases. See Appendix for background on this approach. In particular, if there is exactly one cycle in the model, then there is only one term in the series and if the cycle is attractive, then this term is positive. We note that this immediately generalizes to a cycle that is balanced (see §2.5 for definitions).

Here we apply similar analysis (Sudderth et al., 2007, §3-4, or see Appendix), and observe that if there is exactly one

<sup>5</sup>This can lead the Bethe optimum of a strongly frustrated cycle to occur at a location where  $S_B < 0$ .

cycle and it is frustrated, then the term is negative, thus proving that for such models,  $Z_B \geq Z$ .

Interestingly, Weller and Jebara (2014b) have shown that for the case of a model with one balanced cycle,  $\frac{1}{2}Z \leq Z_B \leq Z$ , so although  $Z_B$  is lower than  $Z$ , it cannot be by much even for very strong edge weights; whereas for a single frustrated cycle, there is no limit to how large  $Z_B/Z$  can rise. This suggests that for a general model, the accuracy of  $Z_B$  will depend on the blend of balanced and frustrated cycles, where in a sense frustrated cycles cause greater trouble than balanced cycles, though to understand how the effects combine in a model with multiple cycles will require further analysis. Since  $Z_B$  performs well even for attractive models (Sudderth et al., 2007), this indicates that, for estimating the partition function, practitioners should use approximations with  $\rho_{ij} < 1$  (such as TRW) with caution.

The loop series method extends to models with more than one cycle but the analysis becomes more complicated. Again using the approach of Sudderth et al. (2007), we can conclude more generally that  $Z_B \geq Z$  for any model such that every generalized loop contains an odd number of repulsive edges (this is a sort of generalized frustrated cycle), and the Bethe optimum marginals for every variable that has an odd degree  $\geq 3$  in any generalized loop, are either all  $\leq \frac{1}{2}$  or all  $\geq \frac{1}{2}$  (see Appendix).

#### 6.4 DERIVATIVES WRT COUNTING NUMBERS

We are interested in exploring which counting numbers lead to accurate inference as measured by errors in the estimates of the partition function and marginals. Considering (7) and using the envelope theorem (Milgrom, 1999, Theorem 1), we have right derivatives:

$$\begin{aligned} \frac{\partial \log Z_A}{\partial c_i} &= \max_{q \in X} S_i(q_i), \\ \frac{\partial \log Z_A}{\partial \rho_{ij}} &= \max_{q \in X} [S_{ij}(\mu_{ij}) - S_i(q_i) - S_j(q_j)], \end{aligned} \quad (11)$$

where  $X$  is the set of all  $\arg \min \mathcal{F}_A$ .<sup>6</sup> The left derivatives correspondingly take the min rather than the max of the same expressions. If the minimum of  $\mathcal{F}_A$  is unique, as is the case for any convex  $\mathcal{F}_A$ , then the right and left derivatives are equal.

For tractable models, where the exact partition function  $Z$  may be computed, this will allow exploration over the range of counting numbers that yield accurate partition functions. It will be interesting to investigate robustness

<sup>6</sup>This generalizes an earlier result for convex free energies (Meshi et al., 2009, Prop 5.2), which itself generalized a result of Wainwright et al. (2005). The envelope theorem is similar to Danskin's theorem (Bertsekas, 1995). Recall  $\log Z_A = -\min \mathcal{F}_A$ . Intuitively, for multiple  $\arg \min$  locations, each may vary at a different rate, thus for the right derivative, we must take the max of the derivative over all the locations.

of the quality of the partition function estimate to changes in model potentials, and accuracy of marginals, though this is outside the scope of the current work.

Others have investigated ways to optimize counting numbers. Wiegerinck and Heskes (2003) proposed a method using linear response theory. They also discussed alpha-divergence measures, an idea developed further by Minka (2005), who fascinatingly frames (fractional) BP and (power) EP under a general framework of iterative minimization of alpha-divergence, yielding insight into which measures may be expected to perform well for different objectives, though concluding that this is difficult to predict.

## 7 CONCLUSION

We have shown how recent results for the Bethe approximation may be extended to handle the broad range of pairwise approximations using any counting numbers. Our analysis builds on earlier work (Welling and Teh, 2001; Yedidia et al., 2005; Meshi et al., 2009; Sudderth et al., 2007; Weller and Jebara, 2013, 2014a), providing new insights and deepening our understanding of how best to perform inference in practice. This is important given the popularity of LBP and TRW approximations. Further, it provides a valuable toolbox for further exploration.

Areas for future investigation include trying to understand better how to predict which approach will work well for a given model, and analyzing the performance of message passing algorithms with different counting numbers (where our  $\epsilon$ -accurate approach provides a valuable benchmark).

## Abstract

Branching processes are a class of continuous-time Markov chains (CTMCs) with ubiquitous applications. A general difficulty in statistical inference under partially observed CTMC models arises in computing transition probabilities when the discrete state space is large or uncountable. Classical methods such as matrix exponentiation are infeasible for large or countably infinite state spaces, and sampling-based alternatives are computationally intensive, requiring integration over all possible hidden events. Recent work has successfully applied generating function techniques to computing transition probabilities for linear multi-type branching processes. While these techniques often require significantly fewer computations than matrix exponentiation, they also become prohibitive in applications with large populations. We propose a compressed sensing framework that significantly accelerates the generating function method, decreasing computational cost up to a logarithmic factor by only assuming the probability mass of transitions is sparse. We demonstrate accurate and efficient transition probability computations in branching process models for blood cell formation and evolution of self-replicating transposable elements in bacterial genomes.

## 1 INTRODUCTION

Continuous-time branching processes are widely used in stochastic modeling of population dynamics, with applications including cell biology, genetics, epidemiology, quantum optics, and nuclear fission [Renshaw, 2011]. With the exception of the well-studied class of birth-death processes, which have known expressions for many quantities relevant to probabilistic inference [Crawford et al., 2014], branching processes pose significant inferential challenges. In

particular, closed forms for finite-time *transition probabilities*, the conditional probability that a trajectory ends at a given state, given a starting state and time interval, are unavailable. These transition probabilities are crucial in many inferential approaches, comprising the observed likelihood function when data from the process are available at a set of discrete times. The likelihood function is of central importance in frequentist and Bayesian methods, and any statistical framework involving observed data likelihood evaluation requires transition probability computations. Without the ability to fully leverage the branching structure, studies must rely on general CTMC estimation techniques or model approximations [Rosenberg et al., 2003, Golinelli et al., 2006, El-Hay et al., 2006].

Computation of transition probabilities is the usual bottleneck in model-based inference using CTMCs [Hajiaghayi et al., 2014], requiring a marginalization over the infinite set of possible end-point conditioned paths. Classically, this marginalization is accomplished by computing the matrix exponential of the infinitesimal generator of the CTMC. However, this procedure has cubic runtime complexity in the size of the state space, becoming prohibitive even for state spaces of moderate sizes. Alternatives also have their shortcomings: *uniformization* methods use a discrete-time “skeleton” chain to approximate the CTMC but rely on a restrictive assumption that there is a uniform bound on all rates [Grassmann, 1977, Ross, 1987, Rao and Teh, 2011]. Typically, practitioners resort to sampling-based approaches via Markov chain Monte Carlo (MCMC). Specifically, particle-based methods such as sequential Monte Carlo (SMC) and particle MCMC [Doucet et al., 2000, Andrieu et al., 2010] offer a complementary approach whose runtime depends on the number of imputed transitions rather than the size of the state space. However, these SMC methods have several limitations—in many applications, a prohibitively large number of particles is required to impute waiting times and events between transitions, and degeneracy issues are a common occurrence, especially in longer time series. A method by Hajiaghayi et al. [2014] accelerates particle-based methods by marginalizing holding times analytically, but has cubic

runtime complexity in the number of imputed jumps between observations and is recommended for applications with fewer than one thousand events occurring between observations.

Recent work by Xu et al. [2014] has extended techniques for computing transition probabilities in birth-death models to linear multi-type branching processes. This approach involves expanding the probability generating function (PGF) of the process as a Fourier series, and applying a Riemann sum approximation to its inversion formula. This technique has been used to compute numerical transition probabilities within a maximum likelihood estimation (MLE) framework, and has also been applied within Expectation Maximization (EM) algorithms [Doss et al., 2013, Xu et al., 2014]. While this method provides a powerful alternative to simulation and avoids costly matrix operations, the Riemann approximation to the Fourier inversion formula requires  $\mathcal{O}(N^b)$  PGF evaluations, where  $b$  is the number of particle types and  $N$  is the largest population size at endpoints of desired transition probabilities. This complexity is no worse than linear in the size of the state space, but can also be restrictive: a two-type process in which each population can take values in the thousands would require millions of PGF evaluations to produce transition probabilities over an observation interval. This can amount to hours of computation in standard computing architectures, because evaluating PGFs for multi-type branching processes involves numerically solving systems of ordinary differential equations (ODEs). Such computations become infeasible within iterative algorithms.

In this paper, we focus our attention on the efficient computation of transition probabilities in the presence of sparsity, presenting a novel compressed sensing framework that dramatically reduces the computational cost of inverting the PGF. We apply our compressed sensing generating function (CSGF) algorithm to a branching process model used to study hematopoiesis — a process of blood cell formation — as well as a birth-death-shift process with applications to molecular epidemiology, and see that the sparsity assumption is valid for scientifically realistic rates of the processes obtained in previous statistical studies. We compare performance of CSGF to transition probability computations without taking advantage of sparsity, demonstrating a high degree of accuracy while achieving significant improvements in runtime.

## 2 MARKOV BRANCHING PROCESSES

A branching process is a Markov process in which a collection of *independently acting* individuals, or particles, can reproduce and die according to a probability distribution. We consider continuous-time, multi-type branching processes that take values over a discrete state space. In this setting, each particle type can have a distinct mean lifespan

and reproductive probabilities, and lives for an exponentially distributed length of time. At time of death, a particle can give rise to particles of its own type as well as other types.

Denote a linear, multi-type branching process by the random vector  $\mathbf{X}(t)$  taking values in a discrete state space  $\Omega$ , with  $X_i(t)$  denoting the number of type  $i$  particles present at time  $t \geq 0$ . For exposition and notational simplicity, we will focus on the two-type case. Each type  $i$  particle produces  $k$  type 1 particles and  $l$  type 2 particles with *instantaneous rates*  $a_j(k, l)$  upon completion of its lifespan, and the rates of no event occurring are defined as

$$\alpha_1 := a_1(1, 0) = - \sum_{(k,l) \neq (1,0)} a_1(k, l)$$

$$\alpha_2 := a_2(0, 1) = - \sum_{(k,l) \neq (0,1)} a_2(k, l),$$

so that  $\sum_{k,l} a_i(k, l) = 0$  for  $i = 1, 2$ . The linearity assumption implies that overall rates are multiplicative in the number of particles. For example, the infinitesimal probability of jumping to  $k$  type 1 and  $l$  type 2 particles beginning with  $j$  type 1 particles over a short interval of time  $h$  is

$$\Pr \{ \mathbf{X}(h) = (k, l) | \mathbf{X}(0) = (j, 0) \} = j \cdot a_1(k, l) \cdot h + o(h).$$

Subsequently, offspring of each particle evolve according to the same set of instantaneous rates, and these rates  $a_j(k, l)$  do not depend on  $t$  so that the process is *time-homogeneous*. Together these assumptions imply that each type  $i$  particle has exponentially distributed lifespan with rate  $-\alpha_i$ , and  $\mathbf{X}(t)$  evolves over time as a CTMC [Guttorp, 1995].

### 2.1 Transition probabilities

Dynamics of a CTMC are determined by its transition function

$$p_{\mathbf{x}, \mathbf{y}}(t) = \Pr(\mathbf{X}(t+s) = \mathbf{y} | \mathbf{X}(s) = \mathbf{x}), \quad (1)$$

where time-homogeneity implies independence of the value of  $s$  on the right hand side. When the state space  $\Omega$  is small, one can exponentiate the  $|\Omega|$  by  $|\Omega|$  *infinitesimal generator* or rate matrix  $\mathbf{Q} = \{q_{\mathbf{x}, \mathbf{y}}\}_{\mathbf{x}, \mathbf{y} \in \Omega}$ , where the entries  $q_{\mathbf{x}, \mathbf{y}}$  denote the instantaneous rates of jumping from state  $\mathbf{x}$  to  $\mathbf{y}$ , to compute transition probabilities:

$$\mathbf{P}(t) := \{p_{\mathbf{x}, \mathbf{y}}(t)\}_{\mathbf{x}, \mathbf{y} \in \Omega} = e^{\mathbf{Q}t} = \sum_{k=0}^{\infty} \frac{(\mathbf{Q}t)^k}{k!}. \quad (2)$$

These transition probabilities are fundamental quantities in statistical inference for data generated from CTMCs. For instance, if  $\mathbf{X}(t)$  is observed at times  $t_1, \dots, t_J$  and  $\mathbf{D}$  represents the 2 by  $J$  matrix containing the observed data, the *observed data log-likelihood* is given by

$$\ell_o(\mathbf{D}; \boldsymbol{\theta}) = \sum_{j=1}^{J-1} \log p_{\mathbf{X}(t_j), \mathbf{X}(t_{j+1})}(t_{j+1} - t_j; \boldsymbol{\theta}), \quad (3)$$

where the vector  $\theta$  parametrizes the rates  $a_j(k, l)$ . Maximum likelihood inference that seeks to find the value  $\hat{\theta}$  that optimizes (3) as well as Bayesian methods where likelihood calculations arise in working with the posterior density (up to a proportionality constant) fundamentally rely on the ability to calculate transition probabilities. Having established their importance in probabilistic inference, we focus our discussion in this paper on computing these transition probabilities in a continuous-time branching process.

## 2.2 Generating function methods

Matrix exponentiation is cubic in  $|\Omega|$  and thus prohibitive in many applications, but we may take an alternate approach by exploiting properties of the branching process. Xu et al. [2014] extend a generating function technique used to compute transition probabilities in birth-death processes to the multi-type branching process setting. The probability generating function (PGF) for a two-type process is defined

$$\begin{aligned} \phi_{jk}(t, s_1, s_2; \theta) &= \mathbb{E}_{\theta} \left( s_1^{X_1(t)} s_2^{X_2(t)} \mid X_1(0) = j, X_2(0) = k \right) \\ &= \sum_{l=0}^{\infty} \sum_{m=0}^{\infty} p_{(jk),(lm)}(t; \theta) s_1^l s_2^m; \end{aligned} \quad (4)$$

this definition extends analogously for any  $m$ -type process. We suppress dependence on  $\theta$  for notational convenience. Bailey [1964] provides a general technique to derive a system of differential equations governing  $\phi_{jk}$  using the Kolmogorov forward or backward equations given the instantaneous rates  $a_j(k, l)$ . It is often possible to solve these systems analytically for  $\phi_{jk}$ , and even when closed forms are unavailable, numerical solutions can be efficiently obtained using standard algorithms such as Runge-Kutta methods [Butcher, 1987].

With  $\phi_{jk}$  available, transition probabilities are related to the PGF (4) via differentiation:

$$p_{(jk),(lm)}(t) = \frac{1}{l!} \frac{1}{m!} \frac{\partial^l}{\partial s_1^l} \frac{\partial^m}{\partial s_2^m} \phi_{jk}(t) \Big|_{s_1=s_2=0}. \quad (5)$$

This repeated differentiation is computationally intensive and numerically unstable for large  $l, m$ , but following Lange [1982], we can map the domain  $s_1, s_2 \in [0, 1] \times [0, 1]$  to the boundary of the complex unit circle, setting  $s_1 = e^{2\pi i w_1}, s_2 = e^{2\pi i w_2}$ . The generating function becomes a Fourier series whose coefficients are the desired transition probabilities

$$\phi_{jk}(t, e^{2\pi i w_1}, e^{2\pi i w_2}) = \sum_{l,m=0}^{\infty} p_{(jk),(lm)}(t) e^{2\pi i l w_1} e^{2\pi i m w_2}.$$

Applying a Riemann sum approximation to the Fourier inversion formula, we can now compute the transition prob-

abilities via integration instead of differentiation:

$$\begin{aligned} p_{(jk),(lm)}(t) &= \int_0^1 \int_0^1 \phi_{jk}(t, e^{2\pi i w_1}, e^{2\pi i w_2}) e^{-2\pi i l w_1} \\ &\quad \times e^{-2\pi i m w_2} dw_1 dw_2 \\ &\approx \frac{1}{N^2} \sum_{u=0}^{N-1} \sum_{v=0}^{N-1} \phi_{jk} \left( t, e^{2\pi i u/N}, e^{2\pi i v/N} \right) \\ &\quad \times e^{-2\pi i l u/N} e^{-2\pi i m v/N}. \end{aligned} \quad (6)$$

In practice, the set of transition probabilities  $S = \{p_{(jk),(lm)}(t)\}$  for all  $l, m = 0, \dots, N$ , given initial values of  $(j, k)$ , can be obtained via the Fast Fourier Transform (FFT), described in Section 4. It is necessary to choose  $N > l, m$ , since exponentiating the roots of unity can yield at most  $N$  distinct values:

$$e^{-2\pi i m v/N} = e^{-2\pi i (mv \bmod N)/N}.$$

This is related to the Shannon-Nyquist criterion [Shannon, 2001], which dictates that the number of samples required to recover a signal must match its highest frequency. Thus, calculating “high frequency” coefficients—when  $l, m$  take large values—requires  $\mathcal{O}(N^2)$  numerical ODE solutions, which becomes computationally expensive for large  $N$ .

**Sparsity:** Given an initial state  $\mathbf{X}(0) = (j, k)$ , the support of transition probabilities is often concentrated over a small range of  $(l, m)$  values. For example, if  $\mathbf{X}(t) = (800, 800)$ , then the probability that the entire process becomes extinct,  $\mathbf{X}(t+s) = (0, 0)$ , is effectively zero unless particle death rates are very high or  $s$  is a very long time interval. In many realistic applications,  $p_{(800,800),(l,m)}(s)$  has non-negligible mass on a small support, for instance only over  $l, m$  values between 770 and 820. While their values can be computed using Equation (6) for a choice of  $N > 820$ , requiring  $N^2$  ODE evaluations toward computing only  $(820 - 770)^2$  nonzero probabilities seems wasteful. Similarly, in an example with high birth rates but low death rates, probabilities  $p_{(800,800),(l,m)}(s)$  may be concentrated around some mean values of  $(l, m)$  much larger than  $(j, k)$ , and other processes may feature concentration of probability mass in one or several modes. While sparsity is not always available—for instance, support may be spread out in applications when observation times are very far apart—a general sparsity assumption is very reasonable when data are observed relatively frequently relative to the branching process rates. To exploit the sparsity in such settings, we bridge aforementioned branching process techniques to the literature of *compressed sensing*.

## 3 COMPRESSED SENSING

Originally developed in an information theoretic setting, the principle of compressed sensing (CS) states that an un-

known sparse signal can be recovered accurately and often perfectly from significantly fewer samples than dictated by the Shannon-Nyquist rate, at the cost of solving a convex optimization problem [Donoho, 2006, Candès, 2006]. CS is a robust tool to collect high-dimensional sparse data from a low-dimensional set of measurements and has been applied to a plethora of fields, leading to dramatic reductions in the necessary number of measurements, samples, or computations. In our setting, the transition probabilities play the role of a target sparse signal of Fourier coefficients. The data reduction made possible via CS then translates to reducing necessary computations to a much smaller random subsample of PGF evaluations, which play the role of measurements used to recover the signal.

### 3.1 Overview

In the CS framework, the unknown signal is a vector  $\mathbf{x} \in \mathbb{C}^N$  observed through a measurement  $\mathbf{b} = \mathbf{V}\mathbf{x} \in \mathbb{C}^M$  with  $M \ll N$ . Here  $\mathbf{V}$  denotes an  $M \times N$  *measurement matrix* or sensing matrix. Since  $M < N$ , the system is underdetermined and inversion is highly ill-posed—the space of solutions is an infinite affine subspace, but CS theory shows that recovery can be accomplished under certain assumptions by seeking the *sparsest* solution. Let  $\psi$  be an orthonormal basis of  $\mathbb{C}^N$  that allows a  $K$ -sparse representation of  $\mathbf{x}$ : that is,  $\mathbf{x} = \psi\mathbf{s}$  where  $\mathbf{s}$  is a sparse vector of coefficients such that  $\|\mathbf{s}\|_0 < K$ . Candès [2006] proves that recovery can then be accurately accomplished by finding the sparsest solution

$$\hat{\mathbf{s}} = \underset{\mathbf{s}}{\operatorname{argmin}} \|\mathbf{s}\|_0 \quad \text{s.t.} \quad \mathbf{A}\mathbf{s} = \mathbf{b} \quad (7)$$

where  $\mathbf{A} = \mathbf{V}\psi$  is the composition of the measurement and sparsifying matrices. In practice, this non-convex objective is combinatorially intractable to solve exactly, and is instead solved by proxy via  $\ell_1$ -relaxation, resulting in a convex optimization program. In place of Equation (7), we optimize the unconstrained penalized objective

$$\hat{\mathbf{s}} = \underset{\mathbf{s}}{\operatorname{argmin}} \frac{1}{2} \|\mathbf{A}\mathbf{s} - \mathbf{b}\|_2^2 + \lambda \|\mathbf{s}\|_1, \quad (8)$$

where  $\lambda$  is a regularization parameter enforcing sparsity of  $\mathbf{s}$ . The signal  $\mathbf{x}$ , or equivalently  $\mathbf{s}$ , can be recovered perfectly using only  $M = CK \log N$  measurements for some constant  $C$  when  $\mathbf{A}$  satisfies the *Restricted Isometry Property* (RIP) [Candès and Tao, 2005, Candès, 2008]—briefly, this requires that  $\mathbf{V}$  and  $\psi$  to be *incoherent* so that rows of  $\mathbf{V}$  cannot sparsely represent the columns of  $\psi$  and vice versa. Coherence between  $\mathbf{V}$ ,  $\psi$  is defined as

$$\mu(\mathbf{V}, \psi) = \sqrt{n} \max_{i,j} |\langle \mathbf{V}_i, \psi_j \rangle|,$$

and low coherence pairs are desirable. It has been shown that choosing random measurements  $\mathbf{V}$  satisfies RIP with overwhelming probability [Candès, 2008]. Further, given

$\psi$ , it is often possible to choose a known ideal distribution from which to sample elements in  $\mathbf{V}$  such that  $\mathbf{V}$  and  $\psi$  are maximally incoherent.

### 3.2 Higher dimensions

CS theory extends naturally to higher-dimensional signals [Candès, 2006]. In the 2D case which will arise in our applications (Section 5), the sparse solution  $\mathbf{S} \in \mathbb{C}^{N \times N}$  and measurement

$$\mathbf{B} = \mathbf{A}\mathbf{S}\mathbf{A}^T \in \mathbb{C}^{M \times M} \quad (9)$$

are matrices rather than vectors, and we solve

$$\hat{\mathbf{S}} = \underset{\mathbf{S}}{\operatorname{argmin}} \frac{1}{2} \|\mathbf{A}\mathbf{S}\mathbf{A}^T - \mathbf{B}\|_2^2 + \lambda \|\mathbf{S}\|_1. \quad (10)$$

This can always be equivalently represented in the vector-valued framework: vectorizing

$$\operatorname{vec}(\mathbf{S}) = \tilde{\mathbf{s}} \in \mathbb{C}^{N^2}, \quad \operatorname{vec}(\mathbf{B}) = \tilde{\mathbf{b}} \in \mathbb{C}^{M^2},$$

we now seek  $\tilde{\mathbf{b}} = \tilde{\mathbf{A}}\tilde{\mathbf{s}}$  as in Equations (7), (8), where  $\tilde{\mathbf{A}} = \mathbf{A} \otimes \mathbf{A}$  is the Kronecker product of  $\mathbf{A}$  with itself. In practice, it can be preferable to solve (10), since the number of entries in  $\tilde{\mathbf{A}}$  grows rapidly and thus the vectorized problem requires a costly construction of  $\tilde{\mathbf{A}}$  and can be cumbersome in terms of memory.

## 4 CSGF METHOD

We propose an algorithm that allows for efficient PGF inversion within a compressed sensing framework. We focus our exposition on two-type models: linear complexity in  $|\Omega|$  is less often a bottleneck in single-type problems, and all generating function methods as well as compressed sensing techniques we describe extend to settings with an arbitrary number of particle types.

We wish to compute the transition probabilities  $p_{jk,lm}(t)$  given any  $t > 0$  and  $\mathbf{X}(0) = (j, k)$ . These probabilities can be arranged in a matrix  $\mathbf{S} \in \mathbb{R}^{N \times N}$  with entries

$$\{\mathbf{S}\}_{l,m} = p_{jk,lm}(t).$$

Without the CS framework, these probabilities are obtained following Equation (6) by first computing an equally sized matrix of PGF solutions

$$\tilde{\mathbf{B}} = \left\{ \phi_{jk} \left( t, e^{\frac{2\pi i u}{N}}, e^{\frac{2\pi i v}{N}} \right) \right\}_{u,v=0}^{N-1} \in \mathbb{C}^{N \times N}. \quad (11)$$

For large  $N$ , obtaining  $\tilde{\mathbf{B}}$  is computationally expensive, and our method seeks to bypass this step. When  $\tilde{\mathbf{B}}$  is computed, transition probabilities are then recovered by taking the fast Fourier transform  $\mathbf{S} = \operatorname{fft}(\tilde{\mathbf{B}})$ . To better understand how this fits into the CS framework, we can equivalently write

the fast Fourier transform in terms of matrix operations  $\mathbf{S} = \mathbf{F}\tilde{\mathbf{B}}\mathbf{F}^T$ , where  $\mathbf{F} \in \mathbb{C}^{N \times N}$  denotes the discrete Fourier transform matrix (see Supplement). Thus, the sparsifying basis  $\psi$  is the Inverse Discrete Fourier Transform (IDFT) matrix  $\psi = \mathbf{F}^*$  given by the conjugate transpose of  $\mathbf{F}$ , and we have  $\tilde{\mathbf{B}} = \psi\mathbf{S}\psi^T$ .

When the solution matrix  $\mathbf{S}$  is expected to have a sparse representation, our CSGF method seeks to recover  $\mathbf{S}$  without computing the full matrix  $\tilde{\mathbf{B}}$ , instead beginning with a much smaller set of PGF evaluations  $\mathbf{B} \in \mathbb{C}^{M \times M}$  corresponding to random entries of  $\tilde{\mathbf{B}}$  selected uniformly at random. Denoting randomly sampled indices  $\mathcal{I}$ , this smaller matrix is a projection  $\mathbf{B} = \mathbf{A}\mathbf{S}\mathbf{A}^T$  in the form of Equation (9) where  $\mathbf{A} \in \mathbb{C}^{M \times N}$  is obtained by selecting a subset of rows of  $\psi$  corresponding to  $\mathcal{I}$ . Uniform sampling of rows corresponds to multiplying by a measurement matrix encoding the *spike basis* (or standard basis): formally, this fits into the framework described in Section 3.1 as  $\mathbf{A} = \mathbf{V}\psi$ , with measurement matrix rows  $\mathbf{V}_j(l) = \delta(j-l)$ . The spike and Fourier bases are known to be *maximally incoherent* in any dimension, so uniformly sampling indices  $\mathcal{I}$  is optimal in our setting.

Now in the compressed sensing framework, computing the reduced matrix  $\mathbf{B}$  only requires a logarithmic proportion  $|\mathbf{B}| \propto K \log |\tilde{\mathbf{B}}|$  of PGF evaluations necessary in Equation (11). Computing transition probabilities in  $\mathbf{S}$  is thus reduced to a signal recovery problem, solved by optimizing the objective in Equation (10).

#### 4.1 Solving the $\ell_1$ problem

There has been extensive research on algorithms for solving the  $\ell_1$  regularization objective in Equation (8) and related problems [Tibshirani, 1996, Beck and Teboulle, 2009a]. As mentioned previously, vectorizing the problem so that it can be represented in the form (8) requires wasteful extra memory; instead we choose to solve the objective in Equation (10) using a *proximal gradient descent* (PGD) algorithm.

PGD is useful for solving minimization problems with objective of the form  $f(x) = g(x) + h(x)$  with  $g$  convex and differentiable, and  $h$  convex but not necessarily differentiable. Letting

$$g(\mathbf{S}) = \frac{1}{2} \|\mathbf{A}\mathbf{S}\mathbf{A}^T - \mathbf{B}\|_2^2, \quad h(\mathbf{S}) = \lambda \|\mathbf{S}\|_1,$$

we see that Equation (10) satisfies these conditions. A form of generalized gradient descent, PGD iterates toward a solution with

$$x_{k+1} = \underset{z}{\operatorname{argmin}} [g(x_k) + \nabla g(x_k)^T(z - x_k) + \frac{1}{2L_k} \|z - x_k\|_2^2 + h(z)], \quad (12)$$

where  $L_k$  is a step size that is either fixed or determined via line-search. This minimization has known closed-form solution

$$x_{k+1} = \operatorname{softh}(x_k - L_k \nabla g(x_k), L_k \lambda), \quad (13)$$

where  $\operatorname{softh}$  is the soft-thresholding operator

$$[\operatorname{softh}(x, \alpha)]_i = \operatorname{sgn}(x_i) \max(|x_i| - \alpha, 0). \quad (14)$$

This results in an *iterative soft-thresholding algorithm* that solves the convex problem (10) with rate of convergence  $\mathcal{O}(1/k)$  when  $L_k$  is fixed. The  $\operatorname{softh}()$  operation is simple and computationally negligible, so that the main computational cost is in evaluating  $\nabla g(x_k)$ . We derive a closed form expression for the gradient in our setting:

$$\nabla g(\mathbf{S}) = -\mathbf{A}^*(\mathbf{B} - \mathbf{A}\mathbf{S}\mathbf{A}^T)\bar{\mathbf{A}}, \quad (15)$$

where  $\bar{\mathbf{A}}$ ,  $\mathbf{A}^*$  denote complex conjugate and conjugate transpose of  $\mathbf{A}$  respectively. In practice, the inner term  $\mathbf{A}\mathbf{S}\mathbf{A}^T$  is obtained as a subset of the inverse fast Fourier transform of  $\mathbf{S}$  rather than by explicit matrix multiplication. The computational effort in computing  $\nabla g(\mathbf{S})$  therefore involves only the two outer matrix multiplications.

We implement a fast variant of PGD using momentum terms [Beck and Teboulle, 2009b] based on an algorithm introduced by Nesterov, and select step sizes  $L_k$  via a simple line-search subroutine [Beck and Teboulle, 2009a]. The accelerated version includes an *extrapolation step*, where the soft-thresholding operator is applied to a momentum term

$$y_{k+1} = x_k + \omega_k(x_k - x_{k-1})$$

rather than to  $x_k$ ; here  $\omega_k$  is an extrapolation parameter for the momentum term. Remarkably, the accelerated method still only requires one gradient evaluation at each step as  $y_{k+1}$  is a simple linear combination of previously computed points, and has been proven to achieve the optimal worst-case rate of convergence  $\mathcal{O}(1/k^2)$  among first order methods [Nesterov, 1983]. Similarly, the line-search procedure involves evaluating a bound that also only requires one evaluation of  $\nabla g$  (see Supplement for further implementation details).

Algorithm 1 provides a summary of the CSGF method in pseudocode.

## 5 EXAMPLES

We will examine the performance of CSGF in two applications: a stochastic two-compartment model used in statistical studies of *hematopoiesis*, the process of blood cell production, and a birth-death-shift model that has been used to study the evolution of *transposons*, mobile genetic elements.

### 5.1 Two-compartment hematopoiesis model

Hematopoiesis is the process in which self-sustaining primitive hematopoietic stem cells (HSCs) specialize, or *differentiate*, into progenitor cells, which further specialize to eventually produce mature blood cells. In addition to far-reaching clinical implications — stem cell transplantation is a mainstay of cancer therapy — understanding hematopoietic dynamics is biologically interesting, and provides critical insights of general relevance to other areas of stem cell biology [Orkin and Zon, 2008]. The stochastic model, depicted in Figure 1, has enabled estimation of hematopoietic rates in mammals from data in several studies [Catlin et al., 2001, Golinelli et al., 2006, Fong et al., 2009]. Without the ability to compute transition probabilities, an estimating equation approach by Catlin et al. [2001] is statistically inefficient, resulting in uncertain estimated parameters with very wide confidence intervals. Nonetheless, biologically sensible rates are inferred. Golinelli et al. [2006] observe that transition probabilities are unknown for a linear birth-death process (compartment 1) coupled with an inhomogeneous immigration-death process (compartment 2), motivating their computationally intensive reversible jump MCMC implementation.

However, we can equivalently view the model as a two-type branching process. Under such a representation, it becomes possible to compute transition probabilities via Equation (6). The type one particle population  $X_1$  corresponds to hematopoietic stem cells (HSCs), and  $X_2$  represents progenitor cells. With parameters as denoted in Figure 1, the nonzero instantaneous rates defining the process are

$$\begin{aligned} a_1(2, 0) &= \rho, & a_1(0, 1) &= \nu, & a_1(1, 0) &= -(\rho + \nu), \\ a_2(0, 0) &= \mu, & a_2(0, 1) &= -\mu. \end{aligned} \quad (16)$$

Having newly formulated the model as a two-type branch-

Figure 1: HSCs can self-renew, producing new HSCs at rate  $\rho$ , or differentiate into progenitor cells at rate  $\nu$ . Further progenitor differentiation is modeled by rate  $\mu$ .

ing process, we derive solutions for its PGF, defined in Equation (4), with details in the Supplement:

**Proposition 5.1** *The generating function for the two-type model described in (16) is given by  $\phi_{jk} = \phi_{1,0}^j \phi_{0,1}^k$ , where*

$$\begin{cases} \phi_{0,1}(t, s_1, s_2) = 1 + (s_2 - 1)e^{-\mu t} \\ \frac{d}{dt} \phi_{1,0}(t, s_1, s_2) = \rho \phi_{1,0}^2(t, s_1, s_2) - (\rho + \nu) \phi_{1,0}(t, s_1, s_2) \\ \quad + \nu \phi_{0,1}(t, s_1, s_2). \end{cases} \quad (17)$$

We see that  $\phi_{0,1}$  has closed form solution so that evaluating  $\phi_{jk}$  only requires solving one ODE numerically, and with the ability to compute  $\phi_{jk}$ , we may obtain transition probabilities using Equation (6). In this application, cell populations can easily reach thousands, motivating the CSGF approach to accelerate transition probability computations.

### 5.2 Birth-death-shift model for transposons

Our second application examines the birth-death-shift (BDS) process proposed by Rosenberg et al. [2003] to model evolutionary dynamics of transposable elements or *transposons*, genomic mobile sequence elements. Each transposon can (1) duplicate, with the new copy moving to a new genomic location; (2) shift to a different location; or (3) be removed and lost from the genome, independently of all other transposons. These respective birth, shift, and death events occur at per-particle instantaneous rates  $\beta, \sigma, \delta$ , with overall rates proportional to the total number of transposons. Transposons thus evolve according to a linear *birth-death-shift* Markov process in continuous time. In practice, genotyping technologies allow for this process to be discretely monitored, necessitating computation of finite-time transition probabilities.

Rosenberg et al. [2003] estimate evolutionary rates of the *IS6110* transposon in the *Mycobacterium tuberculosis* genome from a San Francisco community study dataset [Cattamanchi et al., 2006]. Without transition probabilities, the authors maximize an approximate likelihood by assuming at most one event occurs per observation interval, a rigid assumption that severely limits the range of applications. Doss et al. [2013] revisit their application, inferring similar rates of *IS6110* evolution using a one-dimensional birth-death model that ignores shift events. Xu et al. [2014] show that the BDS model over any finite observation interval can be modeled as a two-type branching process, where

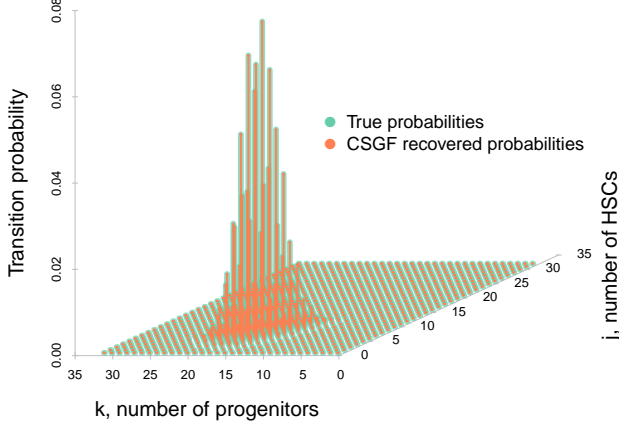

Figure 2: Illustrative example of recovered transition probabilities in hematopoiesis model described in Section 5. Beginning with 15 HSCs and 5 progenitors over a time period of one week, the CSGF solution  $\hat{\mathbf{S}} = \{\hat{p}_{(15,5),(j,k)}(1)\}$ ,  $j, k = 0, \dots, 31$ , perfectly recovers transition probabilities  $\mathbf{S}$ , using fewer than half the measurements.

$X_1$  denotes the number of initially occupied genomic locations and  $X_2$  denotes the number of newly occupied locations (see figure in Supplement). In this representation, full dynamics of the BDS model can be captured, and generating function techniques admit transition probabilities, leading to rate estimation via MLE and EM algorithms. Transposon counts in the tuberculosis dataset are low, so that Equation (6) can be computed easily, but their method does not scale well to applications with high counts in the data.

The nonzero rates defining the two-type branching process representation of the BDS model are given by

$$\begin{aligned} a_1(1, 1) &= \beta, & a_1(0, 1) &= \sigma, & a_1(0, 0) &= \delta, \\ a_1(1, 0) &= -(\beta + \sigma + \delta), & a_2(0, 2) &= \beta, \\ a_2(0, 1) &= -(\beta + \delta), & a_2(0, 0) &= \delta. \end{aligned} \quad (18)$$

and its PGF is governed by the following system derived in [Xu et al., 2014]:

$$\begin{cases} \phi_{0,1}(t, s_1, s_2) = 1 + \left[ \frac{\beta}{\delta - \beta} + \left( \frac{1}{s_2 - 1} + \frac{\beta}{\beta - \delta} \right) e^{(\delta - \beta)t} \right]^{-1} \\ \frac{d}{dt} \phi_{1,0}(t, s_1, s_2) = \beta \phi_{1,0} \phi_2 + \sigma \phi_{0,1} + \delta - (\beta + \sigma + \delta) s_1, \end{cases} \quad (19)$$

again with  $\phi_{jk} = \phi_{1,0}^j \phi_{0,1}^k$  by particle independence.

### 5.3 Results

To compare the performance of CSGF to the computation of Equation (6) without considering sparsity, we first compute sets of transition probabilities  $\mathbf{S}$  of the hematopoiesis model using the full set of PGF solution measurements  $\tilde{\mathbf{B}}$  as described in Equation (11). These “true signals” are

compared to the signals computed using CSGF  $\hat{\mathbf{S}}$ , recovered using only a random subset of measurements  $\mathbf{B}$  following Algorithm 1. Figure 2 provides an illustrative example with small cell populations for visual clarity—we see that the support of transition probabilities is concentrated (sparse), and the set of recovered probabilities  $\hat{\mathbf{S}}$  is visually identical to the true signal.

In each of the aforementioned applications, we calculate transition probabilities  $\mathbf{S} \in \mathbb{R}^{N \times N}$  for maximum populations  $N = 2^7, 2^8, \dots, 2^{12}$ , given rate parameters  $\theta$ , initial population  $\mathbf{X}(0)$ , and time intervals  $t$ . Each computation of  $\mathbf{S}$  requires  $N^2$  numerical evaluations of the ODE systems (17), (19). For each value of  $N$ , we repeat this procedure beginning with ten randomly chosen sets of initial populations  $\mathbf{X}(0)$  each with total size less than  $N$ . We compare the recovered signals  $\hat{\mathbf{S}}$  computed using CSGF to true signals  $\mathbf{S}$ , and report median runtimes and measures of accuracy over the ten trials, with details in the following sections.

Figure 3: Randomly selected probabilities and largest probabilities recovered using CSGF are nearly identical to their true values. Probabilities displayed here correspond to a randomly selected BDS model trial with  $N=512$ ; transition probabilities  $\hat{\mathbf{S}}$  via CSGF are recovered from a sample  $\mathbf{B}$  requiring fewer than 2% of ODE computations used to compute  $\mathbf{S} = \text{fft}(\tilde{\mathbf{B}})$ .

**Parameter settings:** In the hematopoiesis example, we set per-week branching rates  $\theta_{\text{hema}} = (0.125, 0.104, 0.147)$  and observation time  $t = 1$  week based on biologically sensible rates and observation time scales of data from previous studies of hematopoiesis in mammals [Catlin et al., 2001, Golinelli et al., 2006, Fong et al., 2009]. For the BDS application, we set per-year event rates  $\theta_{\text{bds}} = (0.0156, 0.00426, 0.0187)$  estimated in [Xu et al., 2014], and  $t = 0.35$  years, the average length between observations in the San Francisco tuberculosis dataset [Cattamanchi et al., 2006].

In each case, we computed  $M^2 = 3K \log N^2$  total random measurements to obtain  $\mathbf{B}$  for CSGF, and we set the regu-

Table 1: Runtimes and error, hematopoiesis model. The third column reports total runtime of the generating function approach without using sparsity. Total runtimes using CSGF are the sum of the runtime for computing the subset of ODE solutions (fourth column) and runtime for PGD.

| 4096 | 150 | 40732.7   | 57.4  | 2234.7             | $4.01 \times 10^{-4}$  | $5.32 \times 10^{-2}$   |

larization parameters  $\lambda_{\text{hsc}} = \sqrt{\log M}$ ,  $\lambda_{\text{bds}} = \log M$ , with more regularization in the BDS application as lower rates and a shorter observation interval leads us to expect more sparsity. While careful case-by-case tuning to choose  $\lambda$ ,  $M$  would lead to optimal results, we set them in this simple manner across *all* trials to demonstrate a degree of robustness, still yielding promising performance results. In practice one may apply standard cross-validation procedures to select  $\lambda$ ,  $M$ , and because the target solution is a set of transition probabilities, checking that entries in the recovered solution  $\hat{\mathbf{S}}$  sum close to 1 offers a simpler available heuristic. Finally, though one may expedite convergence of PGD by supplying an informed initial guess with positive values near values  $\mathbf{X}(0)$  in practice, we initialize PGD with an uninformative initial value  $\mathbf{S}_1 = \mathbf{0}$  in all cases.

**Accuracy:** In both models and for all values of  $N$ , each signal was reconstructed very accurately. Errors are reported in Tables 1 and 2 for the hematopoiesis and BDS models respectively. Maximum absolute errors for each CSGF recovery

$$\varepsilon_{\max} = \max_{kl} |\{\hat{\mathbf{S}}\}_{kl} - \{\mathbf{S}\}_{kl}| = \max_{kl} |\hat{p}_{ij,kl}(t) - p_{ij,kl}(t)|$$

are on the order of  $10^{-3}$  at worst. Because  $\varepsilon_{\max}$  is typically attained at large probabilities, we include the maximum absolute error relative to the largest transition probability

$$\varepsilon_{\text{rel}} = \frac{\varepsilon_{\max}}{\max_{kl} \{S\}_{kl}},$$

providing a more conservative measure of accuracy. We still see that  $\varepsilon_{\text{rel}}$  is on the order of  $10^{-2}$  in all cases. Addi-

tional analysis and discussion of accuracy in terms of relative error are included in the Supplement, although the measures here arguably give more insight to the performance of our algorithm. Visually, the accuracy of CSGF is stark: Figure 3 provides a side-by-side comparison of randomly selected transition probabilities recovered in the BDS model for  $N = 2^9$ .

**Running Times:** Tables 1 and 2 show dramatic improvements in runtime using CSGF, reducing the number of ODE computations logarithmically. For instance, with  $N = 4096$ , we see the time spent on PGF evaluations necessary for CSGF is less than 0.1% of the time required to compute  $\mathbf{S}$  in the BDS model, and around 0.5% of computational cost in the less sparse hematopoiesis application. Including the time required for solving Equation (10) via PGD, we see that computing  $\hat{\mathbf{S}}$  using CSGF reduces runtime by two orders of magnitude, requiring less than 6% of total computational time spent toward computing  $\mathbf{S}$  in the worst case. We remark that ODE solutions are computed using a C implementation of efficient solvers via package `deSolve`, while we employ a naive R implementation of PGD. We emphasize the logarithmic reduction in required numerical ODE solutions; an optimized implementation of PGD reducing R overhead will yield further real-time efficiency gains.

## 6 DISCUSSION

We have presented a novel adaptation of recent generating function techniques to compute branching process transi-

tion probabilities within the compressed sensing paradigm. While generating function approaches bypass costly matrix exponentiation and simulation-based techniques by exploiting mathematical properties in the branching structure, our contribution now makes these techniques scalable by additionally harnessing the available sparsity structure. We show that when sparsity is present in the set of transition probabilities, computational cost can be reduced up to a logarithmic factor over existing methods. Note that sparsity is the *only* additional assumption necessary to apply our CSGF method—no prior knowledge about where transition probabilities have support is necessary. Further, while our algorithm uses proximal gradient descent to solve the resulting constrained optimization problem, the framework we propose is very general, and users may choose among many standard optimization techniques to best suit their application.

Many real-world applications of branching process modeling feature such sparsity, and we have seen that CSGF achieves accurate results with significant efficiency gains in two such examples with realistic parameter settings from the scientific literature. Transition probabilities are often important, interpretable quantities in their own right, and are necessary within any likelihood-based probabilistic framework for partially observed CTMCs. Their tractability using CSGF opens doors to applying Bayesian and frequentist tools alike to settings in which such methods were previously infeasible. Finally, we note that other statistically relevant quantities such as expectations of particle dwell times and restricted moments can be computed using similar generating function techniques [Minin and Suchard, 2008], and the CSGF framework applies analogously when sparsity is present.

## Abstract

In this paper, we extend Smets' *transferable belief model* (TBM) with *probabilistic* priors. Our first motivation for the extension is about evidential reasoning when the underlying prior knowledge base is Bayesian. We extend standard Dempster models with prior probabilities to represent beliefs and distinguish between two types of induced mass functions on an extended Dempster model: one for believing and the other essentially for decision-making. There is a natural correspondence between these two mass functions. In the extended model, we propose two conditioning rules for evidential reasoning with probabilistic knowledge base. Our second motivation is about the partial dissociation of betting at the pignistic level from believing at the credal level in TBM. In our *extended* TBM, we coordinate these two levels by employing the extended Dempster model to represent beliefs at the credal level. Pignistic probabilities are derived not from the induced mass function for believing but from the one for decision-making in the model and hence need not rely on the choice of frame of discernment. Moreover, we show that the above two proposed conditionings and marginalization (or coarsening) are consistent with pignistic transformation in the extended TBM.

## 1 INTRODUCTION

Reasoning about uncertainty is a fundamental issue for Artificial Intelligence [HALPERN, 2005]. Numerous approaches have been proposed, including the Dempster-Shafer theory of belief functions [SHAFER, 1976] (also called the theory of evidence or simply DS theory). Ever since the pioneering works by Dempster and Shafer, the theory of belief functions has become a powerful formalism in Artificial Intelligence for knowledge representation

and decision-making.

The *transferable belief model* (TBM) is a model developed to justify the use of belief functions (including Dempster's rule of combination) to model someone's beliefs [SMETS AND KENNES, 1994]. A TBM  $M = \langle (\Omega, m), Betp \rangle$  is a two-level mental model which distinguishes between two aspects of beliefs on a frame of discernment  $\Omega$ , beliefs for weighted opinions, and beliefs for decision making. The two levels are: the credal level, where beliefs are entertained and represented by a mass function  $m$ , and the pignistic level, where beliefs are used to make decisions and quantified as a probability distribution  $Betp_m$ , which is derived from mass function  $m$  by the so-called *pignistic transformation* (usually denoted by  $Betp$ ). The justification for the use of pignistic probabilities is usually linked to "rational" behavior exhibited by an ideal agent involved in some betting or decision contexts. But those probabilities do not represent the agent's beliefs; they are only the functions needed to derive the best decision. Let's consider a motivating example in TBM [SMETS AND KENNES, 1994].

**Example 1.1** (Betting under total ignorance) Consider a guard in a huge power plant. On the emergency panel, alarms  $A_1$  and  $A_2$  are both on. The guard never heard about these two alarms. He takes the instruction book and discovers that  $A_1$  is on iff circuit  $C$  is in state  $C_1$  or  $C_2$  and that alarm  $A_2$  is on iff circuit  $D$  is in state  $D_1, D_2$  or  $D_3$ . He never heard about these  $C$  and  $D$  circuits. There, his beliefs on the  $C$  circuit will be characterized by a "vacuous" belief function  $bel^{\Omega_C}$  on space  $\Omega_C = \{C_1, C_2\}$ , i.e., a belief function whose mass function satisfies  $m^{\Omega_C}(\Omega_C) = 1$  (this particular belief function is the one that represents the state of total ignorance). By the application of pignistic transformation, his pignistic probabilities will be given by

$$Betp^{\Omega_C}(C_1) = Betp^{\Omega_C}(C_2) = \frac{1}{2}.$$

Similarly, for the  $D$  circuit, the guard's belief  $bel^{\Omega_D}$  on the space  $\Omega_D = \{D_1, D_2, D_3\}$  will be vacuous, i.e., its corresponding mass function  $m^{\Omega_D}(\Omega_D) = 1$ , and the pignistic probabilities are

$$\text{Betp}^{\Omega_D}(D_1) = \text{Betp}^{\Omega_D}(D_2) = \text{Betp}^{\Omega_D}(D_3) = \frac{1}{3}.$$

Now by reading the next page on the manual, the guard discovers that circuits  $C$  and  $D$  are so made that whenever  $C$  is in the state  $C_1$ , circuit  $D$  is in state  $D_1$  and vice versa. So he learns that  $C_1$  and  $D_1$  are equivalent (given what the guard knows) and that  $C_2$  and  $(D_2 \text{ or } D_3)$  are equivalent. In the TBM, this information does not modify his belief about which circuit is broken. Within the transferable belief model, the only requirement is that equivalent propositions should receive equal beliefs (it is satisfied as  $\text{bel}^{\Omega_C}(C_1) = \text{bel}^{\Omega_D}(D_1) = 0$ ). Pignistic probabilities depend not only on these beliefs but also on *the structure of the betting frame*. In contrast, according to Bayesian approach, equivalent propositions should receive identical beliefs and therefore identical probabilities. However,  $\text{Betp}^{\Omega_C}(C_1) = \frac{1}{2}$  and  $\text{Betp}^{\Omega_D}(D_1) = \frac{1}{3}$  although  $\text{bel}^{\Omega_C}(C_1) = \text{bel}^{\Omega_D}(D_1) = 0$ .

The fact that the TBM can cope easily with such states of ignorance results from the partial dissociation between the credal and the pignistic levels. But this kind of separation of betting from believing makes the TBM vulnerable to Dutch books in decision-making [SNOW, 1998].

In this paper, we extend Smets' TBM with a probabilistic prior to coordinate reasoning at the credal and pignistic levels. Our first motivation is about evidential reasoning when the underlying prior knowledge base is Bayesian. In order to incorporate the influence of the Bayesian knowledge base, we extend standard Dempster models, which are used for representing belief functions, with probabilistic priors. For an extended Dempster model  $M$  with a prior probability  $pr$ , there are two induced mass functions. The first one  $m_D$  is derived in the standard way from the Dempster part  $D$  of  $M$  without the prior probability and hence complies with the well-known DS theory, especially with Dempster's rule of combination. The second  $m_M$  is induced by combining  $m_D$  with the prior probability  $pr$ . Conversely,  $m_D$  can be obtained from  $m_M$  by removing the influence of  $pr$ . So, there is a natural correspondence between  $m_D$  and  $m_M$ . However, these two mass functions are essentially different:  $m_D$  measures the belief update and  $m_M$  absolute belief or weighted opinion. We propose a new combination rule for the mass functions  $m_M$ 's which incorporate prior probabilities. The new combination rule is shown to be parallel to Dempster's rule for the mass functions  $m_D$ 's without the influence of prior probabilities. According to the new combination rule, we provide two *prediction-style* conditioning rules: one for *certain* conditioning knowledge and the other for *uncertain* knowledge.

Our second motivation is to coordinate reasoning at the credal and pignistic levels. We extend Smets' TBM by employing an extended Dempster model  $M$  to represent beliefs at the credal level and provide a corresponding generalized pignistic transformation  $\text{Betp}$  for this extended TBM. We

prove that the above two new conditioning rules in  $M$  are consistent with this pignistic transformation. In our extended TBM, since beliefs are represented by the induced mass function  $m_D$  of the Dempster part of  $M$ , they are insensitive to the choice of frame. Pignistic probabilities are derived not from the induced mass function  $m_D$  of the Dempster part of  $M$  but from the induced mass function  $m_M$ , which have incorporated the prior probability  $pr$ . We show by transforming the prior probability that pignistic probabilities obtained in this way need not rely on the choice of frame of discernment.

## 2 BASIC DEFINITIONS AND NOTIONS

Let  $\Omega$  be a frame of discernment and  $\mathcal{A} = 2^\Omega$  be the Boolean algebra of events. A *mass function* (or *mass assignment*) is a mapping  $m : \mathcal{A} \rightarrow [0, 1]$  satisfying  $\sum_{A \in \mathcal{A}} m(A) = 1$ . A mass function  $m$  is called *normal* if  $m(\emptyset) = 0$ . Without further notice, all mass functions in this paper are assumed to be normal. A set is called *focal* if  $m(A) > 0$ . A mass function  $m$  is called *categorical* if it has only one focal set. A *belief function* is a function  $\text{bel} : \mathcal{A} \rightarrow [0, 1]$  satisfying the following conditions:

1.  $\text{bel}(\emptyset) = 0, \text{bel}(\Omega) = 1$ ; and
2.  $\text{bel}(\bigcup_{i=1}^n A_i) \geq \sum_{\emptyset \neq I \subseteq \{1, \dots, n\}} (-1)^{|I|+1} \text{bel}(\bigcap_{i \in I} A_i)$   
where  $A_i \in \mathcal{A}$  for all  $i \in \{1, \dots, n\}$ .

A mapping  $f : \mathcal{A} \rightarrow [0, 1]$  is a belief function if and only if its Möbius transform is a mass function [SHAFER, 1976]. In other words, if  $m : \mathcal{A} \rightarrow [0, 1]$  is a mass function, then it determines a belief function  $\text{bel} : \mathcal{A} \rightarrow [0, 1]$  as follows:  $\text{bel}(A) = \sum_{B \subseteq A} m(B)$  for all  $A \in \mathcal{A}$ . Moreover, given a belief function  $\text{bel}$ , we can obtain its corresponding mass function  $m$  as follows:  $m(A) = \sum_{B \subseteq A} (-1)^{|A \setminus B|} \text{bel}(B)$  for all  $A \in \mathcal{A}$ . Intuitively, for a subset event  $A$ ,  $m(A)$  measures the belief that an agent commits *exactly* to  $A$ , not the total belief  $\text{bel}(A)$  that an agent commits to  $A$ . The corresponding *plausibility function*  $pl : 2^\Omega \rightarrow [0, 1]$  is dual to  $\text{bel}$  in the sense that  $pl(A) = 1 - \text{bel}(\bar{A})$  for all  $A \subseteq \Omega$ . If  $m_1$  and  $m_2$  are two mass functions on  $\Omega$  induced by two *independent* evidential sources, the combined mass function is calculated according to *Dempster's rule of combination*: for any  $C \subseteq \Omega$ ,

$$(m_1 \oplus m_2)(C) = \frac{\sum_{A \cap B = C} m_1(A) m_2(B)}{\sum_{A \cap B \neq \emptyset} m_1(A) m_2(B)} \quad (1)$$

When an event  $E$  is observed, then the conditional mass function of  $m$  is obtained according to *Dempster conditioning*: for any  $C \subseteq \Omega$ ,

$$m(C | E) = \frac{\sum_{B \cap E = C} m(B)}{pl(E)} \quad (2)$$

A transferable belief model  $M = \langle (\Omega, m), \text{Betp} \rangle$  [SMETS AND KENNES, 1994] is a two-level mental model: the credal level where beliefs are represented by a mass function  $m$ , and the pignistic level where decisions are made by maximizing expected utility. Hence we must build a probability distribution to compute these expectations. This probability distribution is *based on* the agent's beliefs, but should not be understood as representing the agent's beliefs. It is just a probability distribution *derived from* the mass function through *pignistic transformation*  $\text{Betp}$ . The pignistic transformation for the above mass function  $m$  is given by

$$\text{Betp}_m(\{\omega\}) := \sum_{\omega \in B \subseteq \Omega} \frac{1}{|B|} m(B) \text{ for any } \omega \in \Omega.$$

Note that  $\text{Betp}_m$  is a probability distribution on  $\Omega$  and is called a *pignistic probability distribution*. When the context is clear, we usually use  $m$  to denote the belief model  $M$ .

In order to show the sensitivity of pignistic transformation to the choice of frames of discernment, we need to set up a setting in terms of *refinements and coarsenings* of frames of discernment. The idea that one frame  $\Omega$  of discernment is obtained from another frame  $\Theta$  by splitting some or all of the elements of  $\Theta$  may be represented mathematically by specifying, for each  $\theta \in \Theta$ , the subset  $\omega(\{\theta\})$  of  $\Omega$  consisting of those possibilities into which  $\theta$  has been split. Such a mapping  $\omega$  is called a *refining*. Whenever  $\omega : 2^\Theta \rightarrow 2^\Omega$  is a refining, we call  $\Omega$  a *refinement* of  $\Theta$  and  $\Theta$  a *coarsening* of  $\Omega$ . In this paper, we are particularly interested in the case when  $\Theta$  is the set of equivalence classes with respect to some partition  $\Pi$  of  $\Omega$ . So the mapping  $\omega(\{\Pi(w)\}) = \Pi(w)$  for each  $w \in \Omega$  is a refinement and  $\Theta$  is a coarsening of  $\Omega$  where  $\Pi(w)$  is the equivalence class of  $w$ . We denote this special coarsening  $\Theta$  of  $\Omega$  as  $\Omega/\Pi$ . On the other hand,  $\Omega/\Pi$  may be regarded as a subalgebra  $\mathcal{B}$  of the powerset of  $\Omega$  with the set of *atoms* forming the partition  $\Pi$  of  $\Omega$ . In the following sections, we won't distinguish between  $\Omega/\Pi$  and  $\langle \Omega, \mathcal{B} \rangle$ . For each  $A \subseteq \Omega$ , we define  $\mathbf{B}(A) := \bigcap \{B \in \mathcal{B} : A \subseteq B\}$ . In other words,  $\mathbf{B}(A)$  is the least element of  $\mathcal{B}$  that contains  $A$  as a subset and hence is called the *upper approximation* of  $A$  in  $\mathcal{B}$ . For example,  $\Pi = \{\{w_1\}, \{w_2, w_3\}, \{w_4, w_5, w_6\}\}$  is a partition of  $\Omega = \{w_1, w_2, w_3, w_4, w_5, w_6\}$ . Then the associated subalgebra  $\mathcal{B}$  consists of the sets  $\bigcup_{B \subseteq \Pi} B$  with the atoms  $\{w_1\}$ ,  $\{w_2, w_3\}$ , and  $\{w_4, w_5, w_6\}$  in  $\mathcal{B}$ . If  $A = \{w_1, w_3, w_5\}$ , then  $\mathbf{B}(A) = \Omega$ .

Let  $\langle \Omega, \mathcal{B} \rangle$  be a coarsening of  $\Omega$  where  $\mathcal{B}$  is a subalgebra of the powerset  $2^\Omega$  with its atoms forming a partition of  $\Omega$ . Each element  $B$  of  $\mathcal{B}$  is a disjoint union of some atoms in  $\mathcal{B}$ . Suppose that  $bel : 2^\Omega \rightarrow [0, 1]$  is a belief function on  $\Omega$  with  $m$  as its corresponding mass function. Then *the derived mass function*  $m_{\mathcal{B}}$  on the coarsening  $\langle \Omega, \mathcal{B} \rangle$  can be obtained through the formula: for any  $B \in \mathcal{B}$ ,  $m_{\mathcal{B}}(B) = \sum_{\mathbf{B}(A)=B, A \subseteq \Omega} m(A)$ . Let  $bel_{\mathcal{B}}$  denote

the corresponding belief function. It is easy to check that, for any  $B \in \mathcal{B}$ ,  $bel_{\mathcal{B}}(B) = bel(B)$ . Intuitively,  $bel_{\mathcal{B}}$  is the derived belief function on the coarsening frame of discernment with less distinctions. The beliefs in the same propositions in these two frames with different distinctions should be equal. In this sense, believing in terms of belief functions is insensitive to the choice of frame of discernment.

### 3 EXTENDED DEMPSTER MODELS

In order to motivate our work of extending Smets' transferable belief models with probabilistic priors, we first represent belief functions through Dempster models.

#### 3.1 EXTENDED DEMPSTER MODELS

**Definition 3.1** A *Dempster model* is a tuple  $\langle (U, Pr), \Gamma, \Omega \rangle$  where  $(U, Pr)$  is a probability space and  $\Gamma$  is a multivalued mapping from  $U$  to  $\Omega$ , i.e., a mapping from  $U$  to  $2^\Omega$ , the powerset of  $\Omega$ .  $\triangleleft$

The multivalued mapping  $\Gamma$  is essentially a random subset on  $\Omega$ , and it induces a mass function  $m$  on  $\Omega$ :  $m(A) := Pr(\Gamma^{-1}(A))$  for any  $A \subseteq \Omega$ . We have the corresponding belief function  $Bel(A) = \sum_{B \subseteq A} Pr(\Gamma^{-1}(B))$ . Conversely, any mass function on  $\Omega$  can be represented as the induced mass function of some Dempster model. Before we extend Dempster models with probabilistic priors on  $\Omega$ , we use the well-known three prisoner paradox to show the necessity of the probabilistic priors.

**Example 3.2** (The Three Prisoners Paradox [HALPERN, 2005]) Of three prisoners  $a, b$  and  $c$ , only one of them is to be executed but  $a$  does not know which one. He therefore says to the jailer, "Since either  $b$  and  $c$  is certainly going to be declared innocent, you will give me no information about my chances if you give me the name of one man, either  $b$  or  $c$ , who is going to be freed." Accepting this argument, the jailer truthfully replies, " $b$  will be freed." Thereupon  $a$  feels sad because of the Bayesian conditioning on  $U := \{a, b, c\}$ : before the jailer replied, his own chances of being executed was one-third, but afterwards there are only two people, himself and  $c$ , who could be the one being executed, and so his chances of execution increases and is one-half.

Is  $a$  justified in believing that his chances of being executed have increased? Now we formulate this problem in the framework of a Dempster model. Consider the set of all possible outcomes:  $\Omega := \{(a, b), (a, c), (b, c), (c, b)\}$  where, for example,  $(a, b)$  means that  $a$  is to be executed and the jailer says that  $b$  will be freed. Suppose that at first  $a$  assumes that the initial decision as to who will be executed is made at random but assumes *nothing* about how the jailer will act except that he will tel-

l the truth. Let the random choice of who will be executed be represented by the probability space  $(U, Pr)$  where  $Pr$  is the uniform distribution on  $U$ . A multivalued mapping  $\Gamma : U \rightarrow 2^\Omega$  for delineating the possible outcomes when  $a, b$  or  $c$  is to be executed is given by:  $\Gamma(a) = \{(a, b), (a, c)\}, \Gamma(b) = \{(b, c)\}, \Gamma(c) = \{(c, b)\}$ . So the induced mass function  $m$  at the credal level is given by:  $m(\{(a, b), (a, c)\}) = m(\{(b, c)\}) = m(\{(c, b)\}) = \frac{1}{3}$ . Let  $E_a$  denote the event that  $a$  will be executed and  $J_b$  the event that the jailer says that  $b$  will be freed. Then  $E_a = \{(a, b), (a, c)\}$  and  $J_b = \{(a, b), (c, b)\}$ . According to Dempster's rule of conditionalization, we get that  $Bel(E_a | J_b) = Pl(E_a | J_b) = \frac{1}{2}$ . So Dempster's conditioning provides the same answer as that by the above  $a$ 's conditioning on the "naive" space  $U$  according to Bayesian rule [GRÜNWARD AND HALPERN, 2003]. By applying Smets' pignistic transformation, we obtain its probability distribution at the pignistic level:  $Betp_m(a, b) = Betp_m(a, c) = 1/6$  and  $Betp_m(b, c) = Betp_m(c, b) = 1/3$ .

More generally, we may assume that the jailer will tell the truth and  $a$ 's knowledge about the jailer's preference over his possible choices is formulated by a probabilistic prior on  $\Omega$ , which is *independent* of the assumption that the executed prisoner is chosen at random. Now we extend standard Dempster models by incorporating this kind of probabilities and express the induced beliefs at the credal level.

**Definition 3.3** An *extended Dempster-model*  $M = \langle (U, Pr), \Gamma, (\Omega, pr) \rangle$  is a Dempster model  $\langle (U, Pr), \Gamma, \Omega \rangle$  plus a prior probability  $pr$  on  $\Omega$  where  $pr$  is independent of  $\Gamma$  with respect to  $Pr$ .  $\triangleleft$

Now we explain this independence through a representation result of extended Dempster models.

**Lemma 3.4** Every *extended Dempster model*  $M = \langle (U, Pr), \Gamma, (\Omega, pr) \rangle$  can be represented as a *standard Dempster model*  $\langle (U', Pr'), \Gamma', \Omega \rangle$  with an additional mapping  $\gamma'$  from  $U'$  to  $\Omega$  for some probability space  $(U', Pr')$  and some multivalued mapping  $\Gamma'$  from  $U'$  to  $\Omega$ .

**Proof.** For a given extended Dempster model  $M = \langle (U, Pr), \Gamma, (\Omega, pr) \rangle$ , we define a new probability space  $(U', Pr')$ , which is essentially the Cartesian product of  $(U, Pr)$  and  $(\Omega, pr)$ , as follows:

- $U' = U \times \Omega$ ;
- $Pr'(x, y) = Pr(x)pr(y)$  for any  $(x, y) \in U'$ .

Further we define a multivalued mapping  $\Gamma' : U' \rightarrow 2^\Omega$  and a mapping  $\gamma' : U' \rightarrow \Omega$  as follows:

- $\Gamma'(x, y) = \Gamma(x)$ ,
- $\gamma'(x, y) = y$  for any  $(x, y) \in U'$ .

It is easy to check that  $Pr'((\Gamma')^{-1}(A)) = Pr(\Gamma^{-1}(A))$ , and  $Pr'((\gamma')^{-1}(A)) = pr(A)$  for any  $A \subseteq \Omega$ .  $\square$

So, in the following sections of this paper, we won't distinguish these two forms of extended Dempster models and will sometimes write an extended Dempster model as  $M = \langle (U, Pr), \Gamma, \gamma, \Omega \rangle$  where  $\langle (U, Pr), \Gamma, \Omega \rangle$  is a standard Dempster model and  $\gamma$  is a mapping from  $U$  to  $\Omega$ . In  $M$ , the prior probability  $pr$  is obtained by  $pr(A) = Pr(\{u \in U : \gamma(u) \in A\})$ . In this paper,  $\Gamma = A$  is shorthand for the event  $\{u \in U : \Gamma(u) = A\}$ ,  $\gamma \in A$  for  $\{u \in U : \gamma(u) \in A\}$  and  $\gamma \in \Gamma$  denotes  $\{u \in U : \gamma(u) \in \Gamma(u)\}$ . In  $M$ , the independence of the prior probability  $pr$  of the multivalued mapping  $\Gamma$  with respect to  $Pr$  means the independence of  $\gamma$  and  $\Gamma$ : for any subsets  $A$  and  $B$  of  $\Omega$ ,

$$Pr(\Gamma = A \wedge \gamma \in B) = Pr(\Gamma = A)Pr(\gamma \in B).$$

Just as in a Dempster model, we associate each extended Dempster model  $M = \langle (U, Pr), \Gamma, \gamma, \Omega \rangle$  with a mapping  $m_M : 2^\Omega \rightarrow [0, 1]$  which incorporates the mapping  $\gamma$  as follows:

$$m_M(A) := Pr(\Gamma = A | \gamma \in \Gamma) \quad (3)$$

It is easy to see that, since  $\Gamma$  and  $\gamma$  are independent with respect to  $Pr$ ,  $Pr(\gamma \in \Gamma) = \sum_{A \subseteq \Omega} Pr(\gamma \in A \wedge \Gamma = A) = \sum_{A \subseteq \Omega} Pr(\gamma \in A)Pr(\Gamma = A)$ . And  $Pr(\gamma \in \Gamma)$  is used to measure the degree of *consistency* of the evidence represented by  $\Gamma$  with the prior represented by  $\gamma$ . It follows that

$$\begin{aligned} \sum_{A \subseteq \Omega} m_M(A) &= \sum_{A \subseteq \Omega} Pr(\Gamma = A | \gamma \in \Gamma) \\ &= \sum_{A \subseteq \Omega} \frac{Pr(\Gamma = A \wedge \gamma \in \Gamma)}{Pr(\gamma \in \Gamma)} \\ &= \sum_{A \subseteq \Omega} \frac{Pr(\Gamma = A \wedge \gamma \in A)}{Pr(\gamma \in \Gamma)} \\ &= \sum_{A \subseteq \Omega} \frac{Pr(\Gamma = A)Pr(\gamma \in A)}{Pr(\gamma \in \Gamma)} \\ &= 1 \end{aligned}$$

So such a defined mapping  $m_M$  is actually a mass function on  $\Omega$  and is called *the induced mass function* of  $M$ .

Next we show that extended Dempster models are as expressive as standard Dempster models in the sense that any mass function  $m$  on  $\Omega$  can be represented as the induced mass function  $m_M$  of some extended Dempster model  $M$ . We prove a lemma which implies this expressiveness result.

**Lemma 3.5** For any mass function  $m$  and probability distribution  $pr$  on  $\Omega$ , there is an extended Dempster model  $M = \langle (U, Pr), \Gamma, \gamma, \Omega \rangle$  such that

1.  $m_M(A) = m(A)$  for each  $A \subseteq \Omega$  where  $m_M$  is the induced mass function of  $M$ ;
2.  $pr(A) = Pr(\gamma^{-1}(A))$  for any  $A \subseteq \Omega$ .

**Proof.** Given a mass function  $m$  and a probability function  $pr$  on  $\Omega$ , we define a mapping  $m_D : 2^\Omega \rightarrow [0, 1]$  as follows: for any  $A \subseteq \Omega$ ,

$$m_D(A) = \frac{\frac{m(A)}{pr(A)}}{\sum_{A \subseteq \Omega} \frac{m(A)}{pr(A)}} \quad (4)$$

Since  $\sum_{A \subseteq \Omega} m_D(A) = 1$ ,  $m_D$  is a mass function on  $\Omega$ . It follows that there is a standard Dempster model  $\langle (U_D, Pr_D), \Gamma_D, \Omega \rangle$  such that  $m_D(A) = Pr_D(\Gamma_D^{-1}(A))$  for any  $A \subseteq \Omega$ . From the proof of Lemma 3.4, we know that the extended Dempster model  $\langle (U_D, Pr_D), \Gamma_D, (\Omega, pr) \rangle$  with the prior probability  $pr$  can be represented as a Dempster model  $\langle (U, Pr), \Gamma, \Omega \rangle$  with  $\gamma$  as a mapping from  $U$  to  $\Omega$ . For this equivalent representation  $M := \langle (U, Pr), \Gamma, \gamma, \Omega \rangle$  of the extended model, we have that

- $Pr(\Gamma = A) = Pr(\Gamma^{-1}(A)) = Pr_D(\Gamma_D^{-1}(A)) = m_D(A)$ ;
- $Pr(\gamma \in A) = Pr(\gamma^{-1}(A)) = pr(A)$ .

It follows that

$$\begin{aligned} Pr(\gamma \in \Gamma) &= \sum_{A \subseteq \Omega} Pr(\Gamma = A) Pr(\gamma \in A) \\ &= \sum_{A \subseteq \Omega} m_D(A) pr(A) \\ &= \sum_{A \subseteq \Omega} \frac{\frac{m(A)}{pr(A)}}{\sum_{A \subseteq \Omega} \frac{m(A)}{pr(A)}} pr(A) \\ &= \frac{\sum_{A \subseteq \Omega} m(A)}{\sum_{A \subseteq \Omega} \frac{m(A)}{pr(A)}} \\ &= \frac{1}{\sum_{A \subseteq \Omega} \frac{m(A)}{pr(A)}} \end{aligned}$$

So we have that the induced mass function  $m_M$ :

$$\begin{aligned} m_M(A) &= \frac{Pr(\Gamma = A | \gamma \in \Gamma)}{Pr(\gamma \in \Gamma)} \\ &= \frac{Pr(\gamma \in A) Pr(\Gamma = A)}{Pr(\gamma \in \Gamma)} \\ &= m(A). \end{aligned}$$

QED

From the above proof, we know that, for any extended Dempster model  $M = \langle (U, Pr), \Gamma, (\Omega, pr) \rangle$ , there are two *induced* mass functions on  $\Omega$ : the induced mass

function  $m_D(A) (= Pr(\Gamma = A))$  in the part  $D := \langle (U, Pr), \Gamma, \Omega \rangle$ , which is actually a standard Dempster model, and the induced mass function  $m_M(A) (= Pr(\Gamma = A | \gamma \in \Gamma))$  of  $M$ .  $m_D$  measures the *belief update* and is called *basic certainty value*, while  $m_M$  measures *absolute belief*. This distinction is crucial to our following extension of Smets' transferable belief models with probabilistic priors. In our extended belief models, we use mass functions  $m_D$  for believing and mass functions  $m_M$  for decision-making. Mass functions for believing are based on the theory of evidence while mass functions for decision-making are essentially Bayesian and hence consistent with pignistic transformation. Basic certainty values are used in the probabilistic interpretation of CF in MYCIN [HECKERMAN, 1985]. For a given extended Dempster model  $M = \langle (U, Pr), \Gamma, (\Omega, pr) \rangle$ , there is a one-to-one correspondence (see Eqs.(3) and (4)) between the induced mass function  $m_M$  of  $M$  and the induced  $m_D$  in the standard-Dempster-model part  $D = \langle (U, Pr), \Gamma, \Omega \rangle$ . Assume that  $pr$  is given. The induced mass function  $m_M$  can be expressed in terms of  $m_D$  as follows:  $m_M(A) = \frac{pr(A)m_D(A)}{\sum_{A \subseteq \Omega} pr(A)m_D(A)}$ . We denote this expression as  $m_M = m_D \circ pr$ . Moreover,  $m_D$  can be expressed in terms of  $m_M$ :  $m_D(A) = \frac{m_M(A)/pr(A)}{\sum_{A \subseteq \Omega} m_M(A)/pr(A)}$ , which is denoted as  $m_D = m_M/pr$ . From the proof of Lemma 3.5, we know that the two operations  $\circ$  and  $/$  are reverse to each other in the sense that  $(m_D \circ pr)/pr = m_D$  and  $(m_M/pr) \circ pr = m_M$ .

Let  $M_1 = \langle (U_1, Pr_1), \Gamma_1, (\Omega, pr) \rangle$  and  $M_2 = \langle (U_2, Pr_2), \Gamma_2, (\Omega, pr) \rangle$  be two extended Dempster models representing two *independent* bodies of evidence on the same probability space  $(\Omega, pr)$ . Let  $m_{D_1}$  and  $m_{D_2}$  be the two induced mass functions for belief updates in the standard-Dempster-model parts  $D_1 = \langle (U_1, Pr_1), \Gamma_1, \Omega \rangle$  and  $D_2 = \langle (U_2, Pr_2), \Gamma_2, \Omega \rangle$ , respectively. As in Dempster models,  $m_{D_1}$  and  $m_{D_2}$  are combined according to the well-known *Dempster's rule*: for any  $C \subseteq \Omega$ ,

$$(m_{D_1} \oplus_D m_{D_2})(C) = \frac{\sum_{A_1 \cap A_2 = C} m_{D_1}(A_1) m_{D_2}(A_2)}{K_D} \quad (5)$$

where  $K_D = \sum_{A_1 \cap A_2 \neq \emptyset} m_{D_1}(A_1) \cdot m_{D_2}(A_2)$  is the normalization factor. So the combination  $(m_{D_1} \oplus_D m_{D_2})$  also measures belief update for the same probability space  $(\Omega, pr)$ . Let  $m_{M_1}$  and  $m_{M_2}$  denote the two induced mass functions for *absolute belief* on the extended Dempster models  $M_1$  and  $M_2$ , respectively. Now we provide a *new* combination rule for the extended Dempster models as follows: for any  $C \subseteq \Omega$ ,

$$\begin{aligned} &(m_{M_1} \oplus_M m_{M_2})(C) \\ &= \frac{\sum_{A_1 \cap A_2 = C} \frac{pr(A_1 \cap A_2)}{pr(A_1)Pr(A_2)} m_{M_1}(A_1) m_{M_2}(A_2)}{K_M} \end{aligned} \quad (6)$$

where

$$K_M := \sum_{A_1 \cap A_2 \neq \emptyset} \frac{pr(A_1 \cap A_2)}{pr(A_1)pr(A_2)} m_{M_1}(A_1) m_{M_2}(A_2)$$

is the normalization factor. The following proposition says that the new combination  $\oplus_M$  of mass functions for absolute beliefs is consistent with the Dempster combination  $\oplus_D$  of their corresponding mass functions for belief updates.

**Proposition 3.6** *The combination  $m_{M_1} \oplus_M m_{M_2}$  of  $m_{M_1}$  and  $m_{M_2}$  for absolute belief satisfies the following property:*

$$m_{M_1} \oplus_M m_{M_2} = (m_{D_1} \oplus_D m_{D_2}) \circ pr. \quad (7)$$

**Proof.** For any  $A \subseteq \Omega$ ,

$$\begin{aligned} & \sum_{A \subseteq \Omega} [pr(A) \sum_{A_1 \cap A_2 = A} m_{D_1}(A_1) m_{D_2}(A_2)] \\ = & \sum_{A \subseteq \Omega} [pr(A) \sum_{A_1 \cap A_2 = A} \frac{m_{M_1}(A_1)}{pr(A_1)} \frac{m_{M_2}(A_2)}{pr(A_2)}] \\ = & \sum_{A \subseteq \Omega} [\sum_{A_1 \cap A_2 = A} \frac{pr(A)}{pr(A_1)pr(A_2)} \frac{m_{M_1}(A_1)}{K_1} \frac{m_{M_2}(A_2)}{K_2}] \end{aligned}$$

where  $K_1 = \sum_{A \subseteq \Omega} \frac{m_{M_1}(A)}{pr(A)}$  and  $K_2 = \sum_{A \subseteq \Omega} \frac{m_{M_2}(A)}{pr(A)}$ . The first equality comes from Eq.(3) and the second from Eq.(4). So we have

$$\begin{aligned} & ((m_{D_1} \oplus_D m_{D_2}) \circ pr)(A) \\ = & \frac{(m_{D_1} \oplus_D m_{D_2})(A) pr(A)}{\sum_{A \subseteq \Omega} (m_{D_1} \oplus_D m_{D_2})(A) pr(A)} \\ = & \frac{pr(A) \sum_{A_1 \cap A_2 = A} m_{D_1}(A_1) m_{D_2}(A_2)}{\sum_{A \subseteq \Omega} [pr(A) \sum_{A_1 \cap A_2 = A} m_{D_1}(A_1) m_{D_2}(A_2)]} \\ = & \frac{\sum_{A_1 \cap A_2 = A} \frac{pr(A)}{pr(A_1)pr(A_2)} \frac{m_{M_1}(A_1)}{K_1} \frac{m_{M_2}(A_2)}{K_2}}{\sum_{A \subseteq \Omega} [\sum_{A_1 \cap A_2 = A} \frac{pr(A)}{pr(A_1)pr(A_2)} \frac{m_{M_1}(A_1)}{K_1} \frac{m_{M_2}(A_2)}{K_2}]} \\ = & \frac{\sum_{A_1 \cap A_2 = A} \frac{pr(A)}{pr(A_1)pr(A_2)} m_{M_1}(A_1) m_{M_2}(A_2)}{\sum_{A \subseteq \Omega} [\sum_{A_1 \cap A_2 = A} \frac{pr(A)}{pr(A_1)pr(A_2)} m_{M_1}(A_1) m_{M_2}(A_2)]} \\ = & (m_{M_1} \oplus_M m_{M_2})(A) \end{aligned}$$

QED

### 3.2 TWO CONDITIONING RULES

There are two types of conditioning in Bayesian probability theory [DUBOIS AND DENOEU, 2012]. The first one is known as *revision*. Given a probability function  $Pr$  (which usually is a subjective probability), one learns a hard evidence in terms of a sure event  $C$ . The problem is to determine the new subjective probability measure  $Pr'$ , such that  $Pr'(C) = 1$ , according to some minimal change principle. The other one is called *prediction*. When dealing with prediction, we have at our disposal a model of uncertainty in the form of a probability

measure  $Pr$  issued from a representative set of statistical data. Moreover, given the knowledge  $C$  on the current state of the world, we combine this knowledge with the belief model  $Pr$  and predict some property  $A$  of the current world with its associated degree of belief  $Pr(A|C)$ . For belief functions, however, these two types of conditioning are *essentially* different and the mainstream literature is a revision theory of handling singular uncertain evidence [SHAFER, 1976], not so much an extension of Bayesian statistical prediction, although Dempster's pioneering works on upper and lower probabilities are motivated by statistical reasoning. The well-known Dempster's rule of conditioning, which is a special case of Dempster's rule of combination, can be viewed as a revision process. In general, prediction cannot be achieved using Dempster conditioning [DUBOIS AND DENOEU, 2012]. Fagin and Halpern [FAGIN AND HALPERN, 1991] and Jaffray [JAFFRAY, 1992] provided two prediction-style conditioning rules which generalize Bayesian prediction by interpreting belief functions as inner measures and lower probabilities, respectively.

In this paper, we provide a *new* prediction-style conditioning rule which is *consistent* with the revision style of conditioning performed according to Dempster's rule of conditioning. For a given extended Dempster model  $M = \langle (U, Pr), \Gamma, (\Omega, pr) \rangle$ , the prediction conditioning is carried out for the induced mass function  $m_M$  while the revision rule is for the induced mass function  $m_D$  of the part  $D = \langle (U, Pr), \Gamma, \Omega \rangle$  without the prior probability  $pr$ . These two conditioning are consistent in the sense of Proposition 3.6 when the certain knowledge  $C$  is represented by a categorical mass function with  $C$  as its only focal set. Our following rule for prediction-style conditioning provides a formula of how to compute conditional belief  $m_M(\cdot|C)$  on the knowledge  $C$ . Generally, for each  $E \subseteq \Omega$ , we transfer a proportion  $r_E \cdot m_M(E)$ , where  $0 \leq r_E \leq 1$ , to  $E \cap C$  and  $(1 - r_E) \cdot m_M(E)$  to  $E \cap \bar{C}$  [DUBOIS AND DENOEU, 2012]. In particular, when  $E \cap C = \emptyset$ , we set  $r_E = 0$ , which contributes nothing to  $E \cap C$ ; when  $E \subseteq C$ , we set  $r_E = 1$  and leave the whole  $m_M(E)$  to  $E$ . According to this idea, we obtain a *general* formula for conditioning:

$$m(A|C) := \frac{\sum_{E \cap C = A} r_E \cdot m_M(E)}{\sum_{E \cap C \neq \emptyset} r_E \cdot m_M(E)}.$$

It is easy to check that

- $m(A|C)$  is exactly the Dempster rule of conditioning in the case when  $r_E = 1$  iff  $E \cap C \neq \emptyset$ ;
- $m(A|C)$  is exactly the geometric rule of conditioning in the case when  $r_E = 0$  iff  $E \not\subseteq C$ .

In this paper, we define a *new* rule for prediction-style conditioning between the above two by setting  $r_E = \frac{pr(E \cap C)}{pr(E)}$ :

$$m_M(A|C) = \frac{\sum_{E \cap C = A} \frac{pr(E \cap C)}{pr(E)} \cdot m_M(E)}{K}$$

where  $K = \sum_{E \cap C \neq \emptyset} \frac{pr(E \cap C)}{pr(E)} \cdot m_M(E)$  is a normalization factor. It is easy to see that the conditioning  $m_M(\cdot|C)$  is a special case of the new combination rule for absolute beliefs (Eq.(6)) when the knowledge  $C$  is represented by a categorical mass function with  $C$  as its only focal set.

**Example 3.7** (Continue with Example 3.2) Assume that the jailer's preference over possible choices according to  $a$ 's knowledge is represented by a uniform distribution  $pr$  on  $\Omega$ . We obtain the induced mass function  $m_M : m_M(\{(a, b), (a, c)\}) = 1/2$ ,  $m_M(b, c) = 1/4$ ,  $m_M(c, b) = 1/4$  and hence the corresponding beliefs  $Bel_M(E_a|J_b) = 1/2 = Pl_M(E_a|J_b)$ .

By using our definition of conditioning rule  $m_M(\cdot|C)$  on the *certain* knowledge  $C$ , we define its corresponding Jeffrey's rule when the prior knowledge is uncertain and is represented by a probability function  $pr_e$  on a coarsening of  $\Omega$ :  $(\Omega, \mathcal{B})$  where  $\mathcal{B}$  is a subalgebra of the powerset  $2^\Omega$  with its atoms forming a partition of  $\Omega$ . Let  $At(\mathcal{B})$  denote the set of atoms of  $\mathcal{B}$ . A mass function  $m'_M$  on  $(\Omega, 2^\Omega)$  is said to be obtained from  $m_M$  by *belief kinematics* on  $(\Omega, \mathcal{B})$  if, for any  $B \in At(\mathcal{B})$ ,

$$m_M(A|B) = m'_M(A|B) \text{ for all } A \subseteq \Omega. \quad (8)$$

$m'_M$  is called the mass function proposed by *Jeffrey's rule* if it is obtained as follows: for any  $A \subseteq \Omega$ ,

$$m'_M(A) = \sum_{B \in At(\mathcal{B})} m_M(A|B)pr_e(B), \quad (9)$$

Intuitively, the above principle of belief kinematics on  $(\Omega, \mathcal{B})$  says that, even though  $m_M$  and  $m'_M$  may disagree on propositions on  $(\Omega, \mathcal{B})$ , they agree on their relevance to every proposition  $A \subseteq \Omega$ .

## 4 EXTENDED TRANSFERABLE BELIEF MODELS WITH PROBABILISTIC PRIORS

**Definition 4.1** Let  $m_M$  be the induced mass function of an extended Dempster model  $\langle (U, Pr), \Gamma, (\Omega, pr) \rangle$ . Its associated *pignistic probability function*  $Betp_{m_M}$  on  $\Omega$  is defined as follows: for any  $A \subseteq \Omega$ ,

$$Betp_{m_M}(A) = \sum_{E \subseteq \Omega} m_M(E) \frac{pr(E \cap A)}{pr(E)} \quad (10)$$

The transformation between  $m_M$  and  $Betp_{m_M}$  is called *the generalized pignistic transformation*. When the context is clear, we simply call it pignistic transformation.  $\triangleleft$

Since  $m_M(A) = \frac{m_D(A)pr(A)}{\sum_{E \subseteq \Omega} m_D(E)pr(E)}$ , the pignistic probability function can be expressed in terms of the mass function  $m_D$  for belief updates:  $Betp_{m_M}(A) = \frac{\sum_{E \subseteq \Omega} m_D(E)pr(E \cap A)}{\sum_{E \subseteq \Omega} m_D(E)pr(E)}$ . Note that Smets' pignistic transformation is not a special case of the above defined generalized pignistic transformation when the prior probability  $pr$  is the uniform distribution on  $\Omega$ .

**Example 4.2** (Continue with Example 3.7) We may *complete* the above partial model  $\langle \Omega, m \rangle$  and obtain a probabilistic model according to the uniform distribution  $pr$ . When  $a$  is to be executed, the "chances" of the jailer's saying  $b$  or  $c$  are equal. So  $a$  will distribute the mass  $m(E_a)$  equally between  $(a, b)$  and  $(a, c)$ . Then we have  $m(b, c) = m(c, b) = 1/3$  and  $m(a, b) = m(a, c) = 1/6$ , which is exactly the probability function according to Smets' pignistic transformation. Also we obtain the corresponding beliefs  $Bel(E_a|J_b) = 1/3 = Pl(E_a|J_b)$ , which is the same as expected according to Bayesian reasoning. However, this distribution is not the same as the one obtained according to the above generalized pignistic transformation in Eq.(10). Instead,  $Betp_{m_M}(a, b) = Betp_{m_M}(a, c) = Betp_{m_M}(c, b) = Betp_{m_M}(b, c) = 1/4$ .

Assume that  $m_1, \dots, m_l$  are induced mass functions on  $(\Omega, pr)$  and  $p_1, \dots, p_l$  are non-negative numbers such that  $\sum_{i=1}^l p_i = 1$ . It is interesting to note that pignistic transformation  $Betp$  satisfies the following *linearity property*:

$$Betp\left(\sum_{i=1}^l p_i m_i\right) = \sum_{i=1}^l p_i Betp(m_i). \quad (11)$$

This property is both the major requirement that led Smets to the solution for the pignistic transformation [SMETS, 2005] and the crucial step to show the commutativity of the diagrams in the following Theorem 4.5. In addition to the linearity property, Smets proposed other requirements: credal-pignistic link, projectivity, continuity, efficiency, anonymity and impossible event [SMETS, 2005]. These requirements lead to the *unique* solution of Smets' pignistic transformation. One can check that our *generalized* pignistic transformation meets all these requirements except the anonymity one. The anonymity requirement rephrases a general form of insufficient reason principle and hence is equivalent to the constraint that the prior probability in the extended Dempster model is uniform.

**Definition 4.3** An *extended transferable belief model* (ETBM)  $\mathbf{M} = \langle M, Betp \rangle$  is a two level mental model: the credal level where beliefs are represented by an extended Dempster model  $M = \langle (U, Pr), \Gamma, (\Omega, pr) \rangle$ , and the pignistic level where the pignistic probability function is obtained from the induced mass function  $m_M$  of  $M$  by the generalized pignistic transformation  $Betp$ .  $\triangleleft$

Smets' transferable belief model is a special case of the above defined extended transferable belief model when the prior probability is uniform.

**Theorem 4.4** Let  $Cond^p$  and  $Cond$  denote the above defined prediction style conditioning operator for mass functions and the standard one for Bayesian probability functions, respectively. We have that the following diagram commutes:

$$\begin{array}{ccc} (m_M, C) & \xrightarrow{Cond^p} & m_M(\cdot|C) \\ \downarrow Betp & & \downarrow Betp \\ (Pr, C) & \xrightarrow{Cond} & Pr(\cdot|C) \end{array}$$

**Theorem 4.5** Let  $m_M, pr_e$  and  $m'_M$  be as in Eq.(9). Probability measures  $Pr$  and  $Pr'$  denote the pignistic probability functions of  $m_M$  and  $m'_M$ , respectively. Then the following diagram commutes:

$$\begin{array}{ccc} (m_M, pr_e) & \xrightarrow{J} & m'_M \\ \downarrow Betp & & \downarrow Betp \\ (Pr, pr_e) & \xrightarrow{J} & Pr' \end{array}$$

where the first  $J$  is the Jeffrey conditioning for mass functions as defined in Eq.(9) and the second  $J$  denotes the standard Jeffrey conditioning in Bayesian probability theory. In other words, our Jeffrey's rule is nothing but the linearity property in Eq.(11).

The above two theorems tell us that in extended transferable belief models the two new conditioning rules are consistent with pignistic transformation; in other words, the following two strategies are equivalent: we can revise the pignistic probabilities which are transformed from the prior beliefs with Bayes rule applied to the (certain or uncertain) knowledge, or revise the prior beliefs at the credal level by the above two conditioning rules and recompute the pignistic transformation.

However, from Example 1.1, we know that marginalization or coarsening is *inconsistent* with pignistic transformation. That is to say, pignistic transformation is sensitive to the choice of frame of discernment, which causes the partial dissociation between the credal and pignistic levels. In the remainder of this section, we show that, in an extended TB-M, these two levels can be coordinated by transforming its prior probability function.

Let  $M = \langle (U, Pr), \Gamma, (\Omega, pr) \rangle$  be a given extended Dempster model. Let  $m_M$  and  $m_D$  denote the induced mass functions for absolute beliefs and belief updates, respectively. Let  $(\Omega, \mathcal{B})$  be a coarsening of  $\Omega$  where  $\mathcal{B}$  is a subalgebra of the powerset of  $\Omega$  with its atoms  $\mathcal{C} :=$

$\{B_1, \dots, B_n\}$  forming a partition of  $\Omega$ . So each element of  $\mathcal{B}$  is a disjoint union of some atoms from the basis  $\mathcal{C}$ . Correspondingly, the coarsening  $\Gamma^C$  of the multivalued mapping  $\Gamma$  must be defined in the following way: for any  $u \in U$ ,  $\Gamma^C(u) = \mathbf{B}(\Gamma(u))$  where  $\mathbf{B}$  denotes the operation of taking upper approximation in the subalgebra  $\mathcal{B}$ . The natural associated prior probability function  $pr_0^C$  in the coarsening frame is given by  $pr_0^C(B) := pr(B)$  for all  $B \in \mathcal{B}$ . Consider the coarsened extended Dempster model  $M_0^C = \langle (U, Pr), \Gamma^C, ((\Omega, \mathcal{B}), pr_0^C) \rangle$ . It is easy to check that the associated belief function for belief update remains unchanged: for any  $B \in \mathcal{B}$ ,  $(Bel_D)_B(B) = Bel_D(B)$  where  $Bel_D$  and  $(Bel_D)_B$  are the belief functions corresponding to the mass functions  $m_D$  and  $(m_D)_B$ , respectively. But the pignistic probabilities may change:  $Betp_{m_{M_0^C}}(B) \neq Betp_{m_M}(B)$  for some  $B \in \mathcal{B}$ .

In order to coordinate pignistic probabilities with coarsening, we need to *transform* the prior probability function  $pr_0^C$  to a new prior probability  $pr^C$  on the coarsening  $(\Omega, \mathcal{B})$  such that the pignistic probabilities on the new coarsening frame  $M^C := \langle (U, Pr), \Gamma^C, ((\Omega, \mathcal{B}), pr^C) \rangle$  are the same as those on the original extended Dempster model  $M = \langle (U, Pr), \Gamma, (\Omega, pr) \rangle$ : for all  $B_i \in \mathcal{C}$ ,  $Betp_{m_M}(B_i) = Betp_{m_{M^C}}(B_i)$ . This equality is equivalent to the following one:

$$\frac{\sum_{B \in \mathcal{B}} (m_D)_B(B) pr^C(B \cap B_i)}{\sum_{B \in \mathcal{B}} (m_D)_B(B) pr^C(B)} = Betp_{m_M}(B_i). \quad (12)$$

Let  $Pl(B_i)$  denote the sum  $\sum_{B_i \subseteq B} (m_D)_B(B)$ , where  $1 \leq i \leq n$ . It is easy to see that  $\sum_{B \in \mathcal{B}} (m_D)_B(B) pr^C(B) = \sum_{1 \leq i \leq n} pr^C(B_i) Pl(B_i)$  and  $\sum_{B \in \mathcal{B}} (m_D)_B(B) pr^C(B \cap B_i) = pr^C(B_i) Pl(B_i)$ . So the equality (12) is reduced to the following form: for any  $1 \leq i \leq n$ ,

$$\frac{pr^C(B_i)}{\sum_{1 \leq i \leq n} pr^C(B_i) Pl(B_i)} = \frac{Betp_{m_M}(B_i)}{Pl(B_i)}. \quad (13)$$

In this equation,  $pr^C(B_i)$  is the only unknown quantity. Since there are  $n$  equations with  $n$  unknowns in the group  $G$  of Eq.(13), this group has at least one solution. But we don't know whether this solution is nonnegative or not. Now we provide a *constructive* solution to  $G$ . Let  $K$  denote  $\sum_{B \in \mathcal{B}} pr^C(B_i) Pl(B_i)$  and  $a_i = \frac{Betp_{m_M}(B_i)}{Pl(B_i)}$ . The above group of equations can be simplified as follows:  $pr^C(B_i) = a_i K$ ,  $1 \leq i \leq n$ . Since  $\sum_{1 \leq i \leq n} pr^C(B_i) = 1$ , we get the following equation by adding the equations in  $G$  together:  $1 = (a_1 + a_2 + \dots + a_n)K$ . So we get:  $K = \frac{1}{\sum_{1 \leq i \leq n} \frac{Betp_{m_M}(B_i)}{Pl(B_i)}}$ . Finally we solve  $G$  and obtain the following solutions: for any  $1 \leq i \leq n$ ,

$$pr^C(B_i) = \frac{\frac{Betp_{m_M}(B_i)}{Pl(B_i)}}{\sum_{1 \leq i \leq n} \frac{Betp_{m_M}(B_i)}{Pl(B_i)}}. \quad (14)$$

**Theorem 4.6** *The above defined coarsening frame  $M^C = \langle (U, Pr), \Gamma^C, ((\Omega, \mathcal{B}), pr^C) \rangle$  with the prior probability  $pr^C$  given in Eq.(14) is consistent with pignistic transformation. Let  $m_{m_{M^C}}$  be the induced mass function of  $M^C$  and  $m_{D^C}$  be the induced mass function of the Dempster part  $D^C := \langle (U, Pr), \Gamma^C, (\Omega, \mathcal{B}) \rangle$ . Then we have:*

- $(m_D)_B(B) = m_{D^C}(B)$ ;
- $Betp_{m_{M^C}}(B) = Betp_{m_M}(B)$  for all  $B \in \mathcal{B}$ .

So  $pr^C$  serves as a coordinator between believing represented by  $m_{D^C} (= (m_D)_B)$  and betting by  $Betp_{m_{M^C}}$  on  $M^C$  by recording the sensitivity of the pignistic probabilities derived from  $m_{D^C}$ . Pignistic transformation provides a credal-pignistic link (Assumption 3.1 in [SMETS, 2005]);  $pr^C$  here offers another credal-pignistic link between pignistic probabilities ( $Betp_{m_M}(B_i)$ ) and plausibility  $Pl(B_i)$  (defined in terms of  $m_D$ ) for belief update.

As for Example 1.1, according to the above formulation, we have that  $Betp_{m_M^D}(D_1) = \frac{1}{3}$  and  $Betp_{m_M^D}(\{D_2, D_3\}) = \frac{2}{3}$ . So, since pignistic probabilities are insensitive to the choice of frame,  $Betp_{m_M^C}(C_1) = \frac{1}{3}$  and  $Betp_{m_M^C}(C_2) = \frac{2}{3}$ . Moreover, we get that  $Pl(C_1) = 1$  and  $Pl(C_2) = 1$ . Finally we obtain the prior probability on the frame  $\Omega^C : pr^C(C_1) = \frac{1}{3}$  and  $pr^C(C_2) = \frac{2}{3}$ .

## 5 RELATED WORKS AND CONCLUSIONS

Yen ([YEN, 1986]) extended the multivalued mapping in the DS theory to a probabilistic one that uses conditional probabilities to express the uncertain associations. He also proposed a combination similar to our rule in Eq.(6) and discussed its relationship to Dempster's rule of combination. Moreover, he distinguished between mass functions for belief update and those for absolute beliefs. Such a distinction motivated our definition of generalized pignistic transformation in extended TBM. But his framework differs from ours in that Yen considered probabilistic multivalued mapping while our probabilistic extension is about prior knowledge base. Our method of combining evidence with prior knowledge is similar to [MAHLER, 1996, FIXSEN AND MAHLER, 1997]. Mahler proposed a similar combination rule and investigated its relationship with Bayesian parallel combination. More importantly, he pointed out the connection between his combination rule and pignistic transformation. He extended DS theory mainly from the perspective of random sets while we stick to the Dempster-model approach. Our work essentially differs from those papers in that we focus on both the partial dissociation of betting from believing and the (in)sensitivity of pignistic probabilities to the choice of frame of discernment. Wilson [WILSON, 1993] did study

the sensitivity problem of pignistic probabilities in TBM. But he stayed within the DS theory without considering any probabilistic extension.

In order to translate DS models into probability models which are consistent with belief-function semantics (especially Dempster's rule of combination), Cobb and Shenoy [COBB AND SHENOY, 2006] proposed another probability transformation method called *plausibility transformation* as an alternative to pignistic transformation. Plausibility transformation enjoys many interesting properties. The most important one is the so-called regularity property, i.e., plausibility transformation turns Dempster combination of belief functions into "pointwise" combination of probability functions. But, as Cobb and Shenoy [COBB AND SHENOY, 2006] pointed out, another important operation in DS belief networks, coarsening (or marginalization), is not invariant under this transformation. In fact there is no probability transformation for DS models with Dempster's rule of combination that enjoys the regularity property and makes coarsening invariant [COBB AND SHENOY, 2006]. For a more comprehensive survey of probability transformation, one may refer to [CUZZOLIN, 2015]. There are many proposals for Jeffrey's rule in DS theory [MA ET AL., 2010, MA ET AL., 2011, SMETS, 1993, ZHOU ET AL., 2014]. But none of these Jeffrey's rules was proposed from the perspective of pignistic transformation as in this paper. Our proposed conditioning rules are consistent with pignistic transformation.

In order to focus on pignistic transformation, we simplify the presentation in this paper by taking a closed world assumption, which is different from Smets' open world assumption for TBM. Moreover, here we choose to represent beliefs with Dempster models, which is opposed to Smets' TBM without probabilistic interpretation. So we would like to investigate the extension of TBM with probabilistic priors under the open-world assumption and its probabilistic interpretation.

## Abstract

Learning accurate Bayesian networks (BNs) is a key challenge in real-world applications, especially when training data are hard to acquire. Two approaches have been used to address this challenge: 1) introducing expert judgements and 2) transferring knowledge from related domains. This is the first paper to present a generic framework that combines both approaches to improve BN parameter learning. This framework is built upon an extended multinomial parameter learning model, that itself is an auxiliary BN. It serves to integrate both knowledge transfer and expert constraints. Experimental results demonstrate improved accuracy of the new method on a variety of benchmark BNs, showing its potential to benefit many real-world problems.

## 1 INTRODUCTION

Directed probabilistic graphical models, also known as Bayesian networks (BNs), are a natural framework for describing probabilistic dependencies among variables in many real-world problems, such as medical symptom diagnosis (Velikova et al., 2014) and software defect prediction (Fenton and Neil, 2014). However, in problem domains with limited or no relevant training data, there are major challenges in accurately learning BN parameters (Friedman et al., 1999).

There are several methods for handling parameter learning with limited or no relevant data, described in a rich literature of books, articles and software packages, which are briefly summarized in (Druzdel and Van Der Gaag, 2000; Neapolitan, 2004; O’Hagan et al., 2006). Without considering any domain knowledge, the simplest learning approaches usually fail to accurately estimate parameters in a small dataset. To mitigate this problem, it may be possible to elicit numerical assessments from expert judgements, but this process is inefficient and error-prone.

Researchers have shown that experts tend to feel more comfortable providing qualitative or semi-numerical judgments (Feelders and van der Gaag, 2006) with less cognitive effort. Such judgments expressed as constraints between parameters of interest (e.g. “the probability of people getting cancer is smaller than 1%”) are more reliable than numerical assessments, and have drawn considerable attention recently. In the work of (Zhou et al., 2014a), these kinds of constraints are modelled as nodes in an auxiliary BN model called MPL-C (Multinomial Parameter Learning model with Constraints), which includes nodes modelling training data statistics. The MPL-C improves parameter estimation accuracy by constraining the estimation with the expert constraints.

An alternative approach to improving BN learning in scarce data situations is to transfer knowledge from different but related BNs that may have more training data available (Luis et al., 2010). For example, transferring knowledge from the same medical diagnosis network learned in a different country. This can be effective if data for one or more sufficiently related source domains is available. However, the practical limitation is that transfer is contingent on availability of suitable related sources, and the relatedness of each source to the target task may not be known in advance. Estimating relatedness is thus important but challenging in practice, particularly when there are multiple potential sources of possibly varying relatedness.

While incorporating either parameter constraints or transfer learning from related data in source domains can improve parameter estimation accuracy, there exists no generic learning framework to synergistically exploit the benefits of both approaches. Achieving this is non-trivial because typical approaches to transfer (Luis et al., 2010) and to constrained learning (Zhou et al., 2014a) use very different formalisations. In this paper we generalise the state-of-the-art MPL-C model for learning with expert constraints to also exploit knowledge from related source domains via a bootstrap approach. The new model called MPL-TC (Multinomial Parameter Learning model with Transferred prior and Constraints) synergistically exploits both forms of external

knowledge to improve learning performance in a target BN.

The rest of the paper is organized as follows. Section 2 discusses the related work. Section 3 provides a formalisation of the BN parameter learning problem. Section 4 introduces the MPL-C model and shows how it can be used to learn with parameter constraints. Section 5 describes our novel generalisation for constrained parameter learning with transfer from auxiliary sources (MPL-TC). Our method estimates relatedness to pick the best source to transfer from, and takes a bootstrap approach for generating target parameter priors from the source data. Section 6 gives empirical results on a set of benchmark datasets. Section 7 concludes the paper and discusses the future work.

## 2 RELATED WORK

Several models have been proposed to integrate parameter constraints and improve learning accuracy. The constrained convex optimization (CO) formulation (Altendorf et al., 2005; Niculescu et al., 2006; de Campos and Ji, 2008; de Campos et al., 2008; Liao and Ji, 2009; de Campos et al., 2009; Yang and Natarajan, 2013) is the most popular way to estimate the constrained parameters. In this setting, the algorithm seeks the globally optimal estimation (maximal data log-likelihood) with respect to the parameter constraints. The parameters also can be estimated by Monte Carlo methods (Chang et al., 2008), where only the samples that satisfy the constraints are kept. Recently, auxiliary BN models (Zhou et al., 2014a,b) have been developed for solving this problem. This approach provides an extensible framework for parameter learning with additional information. However, these auxiliary models only use uniform parameter priors to regularize learning, which can be improved by informative priors (Neapolitan, 2004).

In the context of transfer learning in BNs, the multi-task framework of (Niculescu-mizil and Caruana, 2007) considers structure transfer. However, it assumes that all sources are equally related and simply learns the parameters for each task independently. The transfer framework of (Luis et al., 2010) (referred to as CPTAgg in this paper) measures the relatedness of tasks via calculating K-L divergence between target and source CPTs, and employs the heuristic weighted sum model for aggregating target and selected source parameters. The weights are proportional to the number of training samples. Finally, the study (Oyen and Lane, 2012) considers multi-task structure learning, again with independently learned parameters. Their model shows transfer performs poorly without knowledge of relatedness. However, they address this by using manually specified relatedness.

No previous work considers a generic BN parameter learning framework combining both transferred knowledge and constraints as discussed in this paper. Using the bootstrap approach for variability measurement in BNs is not new.

For example, Friedman et al. (1999) study the robustness of network features based on DAGs learned on bootstrap resamples. Elidan (2011) uses bootstrap aggregation (bagging) to find a stable prediction model through improved computation of the log-likelihood score. However, to the best of our knowledge, this is the first work to use bootstrap to measure the variability of source MLEs and generate *TNormal*<sup>1</sup> parameter priors for transfer purpose.

## 3 BACKGROUND

A Bayesian network (BN) consists of three components: variables  $V = \{X_1, X_2, X_3, \dots, X_n\}$  corresponding to nodes of the BN, a set of numerical parameters  $\theta$  of the variables in  $V$ , and a Directed Acyclic Graph (DAG)  $G$  encoding the statistical dependencies among the variables. For discrete variables, the probability distribution is described by a conditional probability table (CPT) that contains the probability of each value of the variable given each instantiation of its parents as defined by graph  $G$ . We write this as  $p(X_i|\pi_i)$  where  $\pi_i$  denotes the set of parents of variable  $X_i$  in DAG  $G$ . Thus, the BN defines a simplified joint probability distribution over  $V$  given by:

$$p(X_1, X_2, \dots, X_n) = \prod_{i=1}^n p(X_i|\pi_i) \quad (1)$$

Let  $r_i$  denote the cardinality of the space of  $X_i$ , and  $|\pi_i|$  represent the cardinality of the space of parent configurations of  $X_i$ . The  $k$ -th probability value of a conditional probability distribution  $p(X_i|\pi_i = j)$  can be represented as  $\theta_{ijk} = p(X_i = k|\pi_i = j)$ , where  $\theta_{ijk} \in \theta$ ,  $1 \leq i \leq n$ ,  $1 \leq j \leq |\pi_i|$  and  $1 \leq k \leq r_i$ .

In our BN parameter learning setting, we have data  $D$  combined with  $V$  and  $G$  to form the problem domain  $\mathcal{D} = \{V, G, D\}$ . Within a domain  $\mathcal{D}$ , the goal of parameter learning is to determine parameters for all  $p(X_i|\pi_i)$ . Given data  $D$ , the estimation of CPT parameters  $\theta$  is conventionally solved by the Maximum Likelihood Estimation (MLE),  $\hat{\theta} = \arg \max_{\theta} \log p(D|\theta)$ . Let  $N_{ijk}$  be the number of data samples in  $D$  for which  $X_i$  takes its  $k$ -th value and its parents set  $\pi_i$  takes its  $j$ -th value, and  $N_{ij} = \sum_{k=1}^{r_i} N_{ijk}$ . The MLE estimate for each parameter is:

$$\hat{\theta}_{ijk} = \frac{N_{ijk}}{N_{ij}} \quad (2)$$

However, it is common (even for large datasets) that certain parent-child state combinations seldom appear, and MLE learning fails in this situation. Another classic parameter learning algorithm (Maximum a Posteriori, MAP) mitigates this by introducing a Dirichlet prior on  $\theta$  so that:  $\hat{\theta} = \arg \max_{\theta} \log p(D|\theta)p(\theta)$ . This results in the MAP estimate  $\hat{\theta}_{ijk} = \frac{N_{ijk} + \alpha_{ijk}}{N_{ij} + \alpha_{ij}}$ . Intuitively, the hyperparameters  $\alpha_{ijk}$  in the Dirichlet prior correspond to an expert's

<sup>1</sup>The abbreviation of *Truncated Normal* distribution.

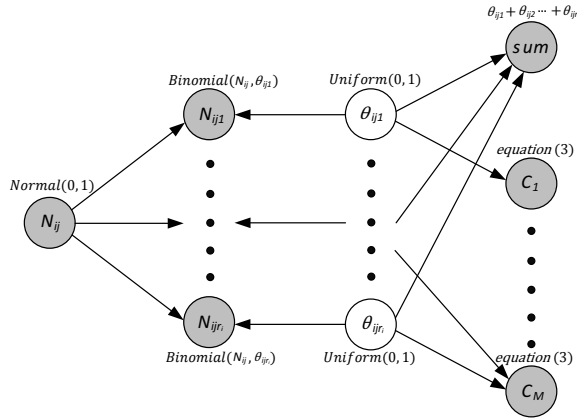

guess of the corresponding virtual data counts. When there is no expert judgment, the K2 ( $\alpha_{ijk} = 1$ ) or BDeu<sup>2</sup> ( $\alpha_{ijk} = \frac{1}{|\pi_i| r_i}, \forall i, j, k$ ) priors are commonly used (Heckerman et al., 1995).

## 4 MPL-C MODEL

For parameter learning with constraints, the auxiliary multinomial parameter model has been proposed (MPL-C (Zhou et al., 2014a)). This method treats the parameters of interest and constraints as nodes in an auxiliary model. The parameter learning process is achieved via auxiliary model inference given observed data statistics and constraint conditions.

### 4.1 MODEL CONSTRUCTION

We use the estimation of probability distribution  $p(X_i | \pi_i = j)$  (i.e., the  $j$ -th column<sup>3</sup> of the CPT associated with the variable  $X_i$ ) as an example to illustrate the construction of the MPL-C model. Suppose there are  $r_i$  states, and the goal is to learn the  $r_i$  probability parameters  $\theta_{ij1}, \dots, \theta_{ijr_i}$  corresponding to these states. Assume we have  $N_{ijk}$  data observations of the  $k$ -th state ( $1 \leq k \leq r_i$ ) and the total number of observations is  $N_{ij}$ . Then we can create a multinomial parameter learning BN model for each CPT column (shown schematically in Figure 1) to estimate parameters  $\theta_{ij1}, \dots, \theta_{ijr_i}$ .

**Figure 1:** Graphical model representation of MPL-C with  $M$  constraints. For the constraint nodes, their equations follow the representations in equation 3. The gray nodes are observed during the inference.

Specifically, we start by creating an integer node named  $N_{ijk}$  (corresponding to  $N_{ijk}$  as defined above) for each  $k$  that is *Binomial* distributed. This node has two parents

<sup>2</sup>Bayesian Dirichlet likelihood equivalent uniform prior.

<sup>3</sup>Note in some other works, e.g., Netica BN software, each CPT row represents a discrete probability distribution given a parent configuration.

$N_{ij}$  and  $\theta_{ijk}$  to model the total number of trials and success probability in the *Binomial* distribution. The  $N_{ij}$  has a *Normal* distribution<sup>4</sup>, which provides an infinite range for the total number of trials. The prior distribution of each  $\theta_{ijk}$  is uniform between 0 and 1. Finally, there is an integer node *sum*, which is a shared child of  $\theta_{ijk}$  ( $k = 1, \dots, r_i$ ). This node models the normalization constraint for the all success probabilities, i.e., that they should sum to 1.

### 4.2 INCORPORATING CONSTRAINTS

In real-world applications, many expert judgments can be described with linear inequality constraints and approximate equality constraints (Zhou et al., 2014a) having the following generic form:

$$\begin{cases} \beta_0 + \sum_{k=1}^{r_i} \beta_k \theta_{ijk} \leq 0 \\ |\theta_{ijk} - \theta_{ijk'}| \leq \varepsilon \quad (0 < \varepsilon < 1) \end{cases} \quad (3)$$

Here the coefficients  $\beta_0, \beta_k$  ( $1 \leq k \leq r_i$ ) are real numbers, and  $\varepsilon$  is an appropriate (small) positive value selected by the expert to represent  $\theta_{ijk} \approx \theta_{ijk'}$ .

Given that an expert has identified a number of constraints as defined above within a CPT column, then these constraints can be integrated as additional observed constraint nodes within the MPL model to generate a new model called MPL-C as shown in Figure 1.

Each constraint node  $C_m$  is a deterministic binary (*true/false*) node with expressions that specify the constraint relationships between its parents:

$$\begin{aligned} & \text{if}(\beta_0 + \sum_{k=1}^{r_i} \beta_k \theta_{ijk} \leq 0, \text{true}, \text{false}) \\ & \text{if}(\text{abs}(\theta_{ijk} - \theta_{ijk'}) \leq \varepsilon, \text{true}, \text{false}) \end{aligned}$$

When the constraint is between a single parameter and a constant (i.e.,  $\beta_0 + \beta_k \theta_{ijk} \leq 0$ ), the constraint node will only have a single parent. Inference for the unobserved  $\theta_{ijk}$  in this auxiliary model implements constrained MAP parameter learning for one CPT column of the target BN. In the next section we show how to generalise this framework to also take into account knowledge transfer from related source domains.

## 5 MPL-C MODEL WITH TRANSFERRED PRIOR

### 5.1 THE TRANSFER LEARNING MODEL

The idea behind transfer learning is to improve the accuracy of a target BN by making use of one or more related source BNs. For example, the target BN may be a model

<sup>4</sup>This can be replaced with *Poisson* distribution to only allow positive integers. Because this root node is always observed with a valid number of trials during the inference, using *Normal* or *Poisson* distribution will produce the same results.

for diagnosis of a particular disease based on limited data in one district or country. If there are other (source) BNs with similar variables and objectives but from a different district or country, then it make sense to exploit such models to improve the accuracy of the target BN. Transfer learning does this by providing methods for both determining suitability of the data in the source and its transfer to the target.

The obvious practical limitation of transfer learning – which limits the applicability of all work in this area including this paper – is that the relatedness is never truly known. The necessary assumptions to overcome this introduce inevitable bias into the results. In this paper we assume there is at least one source domain that is sampled from similar distributions as the target, and that this can be transferred to help learn the target BN parameters. However determining relatedness in a data driven way means there is an inevitable confirmation bias in the sense that the source BNs most likely to be selected are those that most closely match the current target estimate. This limits the extent that the source can ‘change’ the target when it is more ‘correct’ than the current noisy target estimates.

If the chosen source and target are not sampled from similar distributions, directly applying parameters learned in another domain may be impossible or result in negative transfer: the underlying tasks may have major quantitative or qualitative differences (e.g., care procedures vary across hospitals). This limits the effectiveness of existing methods such as CPTAgg in (Luis et al., 2010). Our framework will address this by robustly measuring piecewise relatedness.

Given the scarce data for parameter estimation in the target domain  $\mathcal{D}^t = \{V^t, G^t, D^t\}$ , the knowledge in available source domains should be mined to help the learning in the target domain. We aim to learn a target domain  $\mathcal{D}^t$  leveraging sources  $\{\mathcal{D}^s\}$  with potentially *piecewise* relatedness. Typically relatedness is computed at domain or instance level granularity, but for more flexible transfer we model relevance as varying within-domain. Thus transfer can still be exploited when different subsets of features/variables are relevant to different source domains. Thus we allow the heterogeneity  $V^t \neq V^s$  and  $G^t \neq G^s$ , and transfer at the level of BN *fragments*.

**Definition 1 BN fragment.** A Bayesian network of domain  $\mathcal{D}$  can be divided into a set of sub-networks (denoted *fragments*)  $\mathcal{D} = \{\mathcal{D}_i\}$  by considering the graph  $G$ . Each fragment  $\mathcal{D}_i = \{V_i, G_i, D_i\}$  is a single root node or a node with its direct parents in the original BN, and encodes a single CPT from the original BN. The number of fragments is the number of variables in the original BN.

To achieve flexible BN parameter transfer, the target domain and source domains are all broken into fragments  $\mathcal{D}^t = \{\mathcal{D}_i^t\}$ ,  $\{\mathcal{D}^s\} = \{\{\mathcal{D}_{i'}^s\}\}$ . Assuming for now no latent variables in the target domain, then each target fragment  $i$  can be learned independently  $\hat{\theta}_i^t =$

$\arg \max_{\theta_i^t} p(\theta_i^t | C_i^t, \mathcal{D}_i^t, \{\{\mathcal{D}_{i'}^s\}\})$ . To leverage the bag of source domain fragments  $\{\{\mathcal{D}_{i'}^s\}\}$  in learning each  $\theta_i^t$ , we consider each source fragment  $\mathcal{D}_{i'}^s$  as potentially relevant. Specifically, for each target fragment, every source fragment is evaluated for relatedness and the best fragment mapping is chosen. Once the best source fragment is chosen for each target, it will be used as parameter priors in the target MPL-C model. This auxiliary model can then be updated to infer the parameter posteriors given target data  $D_i^t$ , target constraints  $C_i^t$  and source networks  $\{\mathcal{D}^s\}$ .

To realize this strategy, three issues must be addressed: 1) which source fragments are transferrable, 2) how to deal with variable name mapping, 3) how to quantify the relatedness of each transferrable source fragment in order to find the best one. We next address each of these issues in turn:

**Fragment Compatibility** For a target fragment  $i$  and putative source fragment  $i'$ , we say they are *compatible* if they have the same structure and state space. That is, the same number of states and parents states. Additionally, if the target fragment contains parameter constraints  $C_i^t$ , the associated source parameter  $\theta_{i'}^s$  should fall in the constrained value ranges  $\Omega_{C_i^t}$ , so

$$compatible(\mathcal{D}_i^t, \mathcal{D}_{i'}^s) = \begin{cases} 1 & \text{if } G_i^t = G_{i'}^s \ \& \ \theta_{i'}^s \in \Omega_{C_i^t} \\ & \ \& \ dim(\theta_i^t) = dim(\theta_{i'}^s) \\ 0 & \text{otherwise} \end{cases}$$

where  $dim(\theta_i^t) = dim(\theta_{i'}^s)$  means  $r_i^t = r_{i'}^s$  and  $|\pi_i^t| = |\pi_{i'}^s|$ . This assumption could be relaxed quite straightforwardly at the expense of additional computational cost. For example, if the target variable contains 2 states (*true* and *false*), and one source variable contains 3 states (*high*, *medium* and *low*), we can try multiple aggregations of the source states to generate three mappings to the target: 1) *true* – *high* and *false* – *medium, low*; 2) *true* – *medium* and *false* – *high, low*; 3) *true* – *low* and *false* – *high, medium*.

**Fragment Permutation Mapping** For two fragments  $i$  and  $i'$  determined to be compatible, we still may not know the mapping between variable names. For example, if  $i$  has parents  $[a, b]$  and  $i'$  has parents  $[d, c]$ , the correspondence could be  $a - d, b - c$  or  $b - d, a - c$ . The function *permutations*( $G_i^t, G_{i'}^s$ ) returns an exhaustive list of possible mappings  $P_m$  that map states of  $i'$  to states of  $i$ .

**Fitness Measurement** To measure the relatedness between compatible target and source fragments  $\mathcal{D}_i^t$  and  $\mathcal{D}_{i'}^s$ , we use Bayesian model comparison for two hypotheses:  $H_1$  is the relevance hypothesis<sup>5</sup> that the source and target data share a common CPT, and  $H_0$  (not  $H_1$ ) is the indepen-

<sup>5</sup>Simplifying the fragment notation, so  $H_1$  only refers the dependent hypothesis between  $\mathcal{D}_i^t$  and  $\mathcal{D}_{i'}^s$ .

dent hypothesis that the source and target data have distinct CPTs. These two hypotheses are the outputs of our function  $fitness(\mathcal{D}_i^t, \mathcal{D}_{i'}^s, p(H))$ , and can be computed with:

$$\begin{aligned} p(H_1|D_{i'}^s, D_i^t) &\propto \int p(D_i^t|\theta_i)p(\theta_i|D_{i'}^s, H_1)p(H_1)d\theta_i, \\ p(H_0|D_{i'}^s, D_i^t) &\propto \int p(D_i^t|\theta_i^t)p(\theta_i^t|H_0)p(H_0)d\theta_i^t. \end{aligned} \quad (4)$$

For discrete data, the likelihood of  $H_1$ , integrating out the unknown CPTs  $\theta_i$ , is the Dirichlet compound multinomial (DCM) or *Pólya* distribution:

$$p(D_i^t|D_{i'}^s, H_1) = \sum_{j=1}^{|\pi_i|} \left( \frac{\Gamma(\alpha_{i'j}^s)}{\Gamma(N_{ij}^t + \alpha_{i'j}^s)} \prod_{k=1}^{r_i} \frac{\Gamma(N_{ijk}^t + \alpha_{i'jk}^s)}{\Gamma(\alpha_{i'jk}^s)} \right) \quad (5)$$

where  $\alpha_{i'jk}^s$  indicates the aggregate counts from the source domain and distribution prior, and  $\alpha_{i'j}^s = \sum_k \alpha_{i'jk}^s$ . Maximising  $p(H_1|D_{i'}^s, D_i^t)$  over source networks  $s$  and fragment  $i'$  finds the fragment most likely to share the same generating distribution as the target, and thus the best source to transfer. Next we will discuss how to use the selected source data to help learn the target parameters.

## 5.2 THE MPL-TC MODEL

Given a target fragment and selected source fragment, the challenge is to fuse them in a robust manner. We solve this fusion problem in a Bayesian way – treating the transferred information as the target parameter priors. We refer to this framework as MPL-TC, which contains three main steps: 1) for each BN fragment in the target domain, find its closest source fragment and permutation in the source domain; 2) transfer the selected source fragment by converting the source data statistics into prior distributions of parameters in the target MPL-C model (see Section 4) and 3) perform the inference in this auxiliary model to learn the target parameters. The detail can be found in Algorithm 1.

**Fragment Fusion** To fuse the selected source fragment with the target fragment in the second step of our algorithm, we perform the bootstrap approach in the source to generate the priors of target parameters. Bootstrap is a resampling method to measure the quality of true samples (Duval, 1993). In this paper, we are interested in the quality of selected source parameters. We cannot access infinite training samples of selected source, instead we only have a sample of it (the selected best mapping source sample  $D_{i'j}^s$ ), which means the MLE of  $\theta_{i'jk}^s$  is not accurate.

From a specific subset of source samples, i.e.,  $D_{i'j}^s$ , only one estimate of the MLE for a parameter of interest  $\theta_{i'jk}^s$  can be obtained. In order to reason about the population, we need some sense of the variability of the estimated MLE. Thus, we apply the simplest bootstrap method – sam-

**INPUT** : Target domain  $\mathcal{D}^t$ , source domains  $\{\mathcal{D}^s\}$  and target constraints  $C^t$ .

**OUTPUT**: The target parameters  $\hat{\theta}^t$ .

**for each target fragment  $i$  do**

**for each source network  $s$  and fragment  $i'$  do**

**if compatible**( $\mathcal{D}_i^t, \mathcal{D}_{i'}^s$ ) **then**

$P = \text{permutations}(G_{i'}^t, G_{i'}^s)$ ;

**for permutation  $m = 1$  to  $M$  do**

Measure relatedness:

$fitness(\mathcal{D}_i^t, P_m(\mathcal{D}_{i'}^s)) =$

$p(H_1|D_i^t, P_m(D_{i'}^s))$

**end**

**end**

**end**

Find the best source fragment and permutation:

$\arg \max_{i', s, m} p(H_1|D_i^t, P_m(D_{i'}^s))$

**for each parent state configuration  $j$  do**

**for each state value  $k$  do**

$\{\theta_{i'jk}^s\} =$

$\text{bootstrap}(100, @MLE, P_m(D_{i'j}^s))$

Fit the  $\{\theta_{i'jk}^s\}$  with

$\zeta_{i'jk}^s = TNormal(\mu_{ijk}, \sigma_{ijk}, 0, 1)$

**end**

Generate the auxiliary model in the target:

$\Psi_{ij}^t = \text{mpltc}(D_{ij}^t, C_{ij}^t, \zeta_{i'jk}^s)$

Inference to get the parameters estimation:

$\hat{\theta}_{ij}^t = \text{inference}(\Psi_{ij}^t)$

**end**

**end**

**return**  $\hat{\theta}^t = \{\hat{\theta}_{ij}^t\}$

**Algorithm 1:** Multinomial Parameter Learning with Transferred Prior and Constraints

pling from the  $D_{i'j}^s$  to form a new sample (called a “resample” or bootstrap sample) that is also of size  $|D_{i'j}^s|$ . The bootstrap sample is taken from the original using sampling with replacement. This process is repeated multiple times (100 or 1000), and for each of these bootstrap samples we compute the MLE of  $\theta_{i'jk}^s$  (each of these are called bootstrap estimates). We now have a set of bootstrap estimates, which are used to fit a *TNormal* distribution to encode how much the source MLE varies.

In our MPL-TC approach, these *TNormal* distributions ( $\{\zeta_{i'jk}^s\}$ ) are used to replace the uniform parameter priors on  $\theta_{i'jk}^s$  (Figure 1) of MPL-C models in the target domain. Thus the transferred prior, target training samples and constraints are now all encoded in the target MPL-TC models (referred to as  $\Psi_{ij}^t$  in Algorithm 1). After observing the sources, the target data statistics ( $N_{ij}^t, N_{ij1}^t, \dots, N_{ijr_i}^t$ ) and available constraints (The constraint nodes are all observed

with ‘true’ values), we can update (by *inference*( $\cdot$ ) function in Algorithm 1) these auxiliary models to get the target parameter posteriors:

$$p(\hat{\theta}_{ij1}^t, \dots, \hat{\theta}_{ijr_t}^t | N_{ij}^t, N_{ij1}^t, \dots, N_{ijr_t}^t, \dots, C_1^t, \dots, C_M^t, \zeta_{i'jk}^s, \dots, \zeta_{i'jr_t}^s, sum)$$

Because the auxiliary BNs are hybrid models, the update/inference is performed via a state-of-the-art dynamic discretization junction tree (DDJT) algorithm (Neil et al., 2007) that is implemented in AgenaRisk<sup>6</sup>. The time complexity of the inference is exponential in model treewidth, which restricts the applicability at some point. However, approximate inference could be used with dynamic discretization to improve the time efficiency.

### 5.3 ILLUSTRATIVE EXAMPLES

**Bootstrap Fitting of TNormal Priors** Figure 2 demonstrates an example of fitted *TNormal* distributions for MLE estimation  $\theta_{i'jk}^s = 0.2$  learned from sample sizes 10 and 100. As we can see, although the parameter estimations of two source samples are the same, the estimation from the large sample are definitely more reliable than the estimation from the small sample, where the fitted *TNormal* distribution in  $|D_{i'j}^s| = 100$  is much sharper than the distribution in  $|D_{i'j}^s| = 10$ . Moreover, the number of bootstrap replicates does not change the results much, and we use 100 replicates in all subsequent experiments.

**Figure 2:** The fitted *TNormal* distributions for a parameter of interest with different source sample sizes 10 and 100. The original source MLE estimation of this parameter is 0.2, which means there are 2 and 20 appearances of this parameter in sample sizes 10 and 100 respectively. The bootstrap process in each case is repeated 100 and 1000 times.

**Fragment Transfer** Here we provide an illustrative example of our framework for fragment-based parameter transfer and the target parameter estimation: the target is a three node BN shown in the left part of Figure 3(a), and

the source is an eight node BN shown in the right part of Figure 3(a). We aim to estimate the CPT of  $S^t$ , which has four parent state configurations –  $\pi_1^t, \pi_2^t, \pi_3^t$  and  $\pi_4^t$ . As we can see, there are two source fragments ( $\{T^s, L^s, E^s\}$  and  $\{E^s, B^s, S^s\}$ ) which are *compatible* with target fragment (shown with dashed triangle in Figure 3(a)). Thus, there are four *permutations* of compatible source fragments (assuming binary parent nodes). All four of these options are then evaluated for *fitness*, and the best fragment and permutation is picked ( $\{B^s, E^s, S^s\}$ ). In Figure 3(b), we generate four auxiliary BNs (MPL-TC model) for each target parameter column, the right part of Figure 3(b) shows the MPL-TC model of the first parameter column, which is used to estimate  $\theta_{11}^t$  and  $\theta_{12}^t$ . The constraints and data statistics in the target domain are modelled by nodes with gray color. The parameter priors (nodes with white color) are *TNormal* distributions fitted from source bootstrap samples. Finally, these priors are updated by observing the target data statistics and constraints to get the posterior parameter estimates.

**Figure 3:** A simple example to show the framework of multinomial parameter learning with transferred prior and constraints. (a) The dashed triangle represents source fragments  $\{T^s, L^s, E^s\}$  and  $\{E^s, B^s, S^s\}$ , which are *compatible* to the target fragment. (b) The structure representation of the MPL-TC model for estimating  $\theta_{11}^t$  and  $\theta_{12}^t$  is in the first target parameter column, whose parameter priors ( $\theta_{11}^s$  and  $\theta_{12}^s$ ) are converted from the most fit source fragment  $\{B^s, E^s, S^s\}$  via bootstrap.

## 6 EXPERIMENTS

### 6.1 EXPERIMENT SETTING

In all cases, we assume that the structure of the model is known and that the ‘true’ CPTs that we are trying to learn

<sup>6</sup><http://www.agenarisk.com/>

are those that are provided as standard with benchmark BN models. For the purpose of the experiment we are not given these true CPTs but instead are given a limited number of sample observations which are randomly generated based on the true target CPTs. To introduce noise between the target and source for simulating varying relatedness, the source datasets are also sampled from the true CPTs but with ‘soft’ and ‘hard’ noise conditions: (1) soft: generate three source domains with 200, 300 and 400 sample sizes to simulate continuously varying relatedness among a set of sources; (2) hard: choose a portion (20%) of each source’s fragments uniformly at random and randomise their data/CPTs to make them irrelevant. This results in a different subset of compatible but (un)related fragments in each source. Introducing these two types of sampling noise makes the sources similar but different to the target, and hence simulates the kind of source-target relations that may exist in practice.

The constraints are elicited from the true CPTs (so they are certainly correct) and randomly assigned to parameters in the network. Following the method of constraints generation in (Liao and Ji, 2009), for each true parameter  $\theta_{ijk}$ , we create a constraint:

$$\min((1 + \varepsilon)\theta_{ijk}, 1) \geq \theta_{ijk}^t \geq \max((1 - \varepsilon)\theta_{ijk}, 0)$$

where the  $\varepsilon = 0.05$  in the experiments. These elicited constraints are encoded in the MPL-TC auxiliary models, which are built with BN software AgenaRisk.

We compare our MPL-TC<sup>+5</sup> against following algorithms and settings (the upper right superscript value associated with learning algorithms represents the number of constraints used in these algorithms):

- MLE and MAP, conventional BN parameter learning algorithms.
- MPL-C<sup>+5</sup>, state-of-the-art parameter learning algorithm with five constraints (Zhou et al., 2014a).
- CPTAgg, state-of-the-art parameter transfer learning algorithm (Luis et al., 2010).
- MPL-TC<sup>+0</sup>, our MPL-TC algorithm with zero constraints.

The resulting learned CPTs are evaluated against the true CPTs by using the K-L divergence measure (Kullback and Leibler, 1951). The smaller the K-L divergence is, the closer the estimated CPT is to the true CPT. Here the K-L divergence is locally measured for each CPT column and averaged over the whole model. This is to ensure that the fit of each distribution is equally weighted in the overall metric. Each experiment is repeated 10 times, and the results are reported with the mean and standard deviation of the K-L divergences between estimated and true CPTs.

**Figure 4:** Parameter learning performance in the Cancer BN under different levels of data sparsity. Lower is better.

## 6.2 EXPERIMENTS ON CANCER BN

The Cancer BN (Korb and Nicholson, 2010) models the interaction between risk factors and symptoms for the purpose of diagnosing the most likely condition for a patient getting lung cancer. This BN contains 5 *Boolean* nodes, so each CPT column has just 2 parameters to learn; since the parameters sum to 1, each column has only one independent parameter. Hence there are 10 independent parameters to learn in the model. In the target domain, training samples under different sparsity levels (10 to 100 samples) are drawn from the ground-truth Cancer BN.

**Overall** Figure 4 presents the results of all learning algorithms under varying data volumes in the target Cancer BN. It is clear that the average K-L divergence of all learning algorithms decreases with increasing target sample size. With increasing sample sizes, the performance gap between the algorithms decreases<sup>7</sup>. Moreover, our MPL-TC<sup>+5</sup> always outperforms all the other competitors, which demonstrates the effectiveness of our framework.

Considering models without parameter constraints (MLE, CPTAgg, MAP and MPL-TC<sup>+0</sup>): MPL-TC<sup>+0</sup> provides overall K-L divergence reductions (performance improvements) of 93.4%, 84.1% and 52.3% compared with MLE, CPTAgg and MAP respectively, thus demonstrating the efficacy of knowledge transfer.

After introducing 5 sampled constraints, MPL-TC<sup>+5</sup> achieves even greater reductions in comparison with MLE, CPTAgg and MAP, which are 97.1%, 93.0% and 79.1% respectively. Due to the benefit of introducing parameter constraints, MPL-C<sup>+5</sup> algorithm also outperforms MLE, CPTAgg and MAP. However, MPL-TC<sup>+5</sup> still outperforms MPL-C<sup>+5</sup> with 42.0% average K-L divergence reduction.

According to the results, the MPL-TC<sup>+5</sup> greatly outperforms the conventional MLE and MAP algorithms, and the

<sup>7</sup>Given enough target training samples, the learning performance of all algorithms converge.

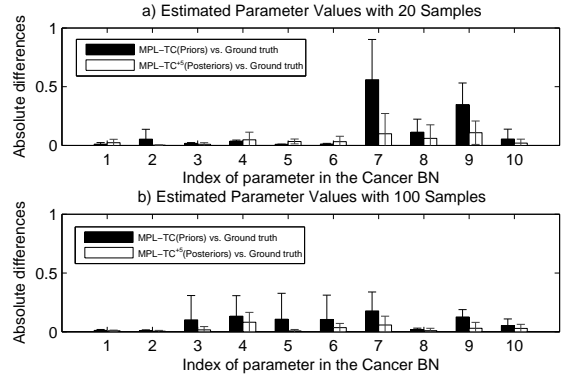

**Figure 5:** Performance of MPL-C and MPL-TC when varying the number of constraints ( $m = 1, \dots, 10$ ).

CPTAgg and MPL-C<sup>+5</sup> that only use transfer or constraints alone. This demonstrates the complementarity of both constraints and sources of external knowledge when learning with scarce target data.

**Varying Number of Constraints** To investigate how the number of introduced constraints affect the learning performance of MPL-C and MPL-TC, we vary the number of sampled constraints in parameter learning (shown in Figure 5). As we can see, K-L divergence decreases with more constraints for both MPL-C and MPL-TC in both data sparsity settings. However, when the number of constraints is small, our MPL-TC greatly outperforms MPL-C due to the benefit of transferred parameter priors. When the number of constraints increases to 10 (every parameter is constrained), the learning results of MPL-C and MPL-TC both converge to zero in both settings.

**Priors vs. Posteriors** To provide insight into the mechanisms of our framework, we investigate the differences between MPL-TC(Priors) (transferred  $TNormal$  mean values) and MPL-TC<sup>+5</sup>(Posteriors) (the updated parameter posteriors after inference given the target data and parameter constraints) for each parameter in the Cancer BN. The results are presented in Figure 6, where the heights of the bars represent the absolute differences between estimated values and true CPT values.

As we can see, the MPL-TC(Priors) shows inaccurate transfer in both two settings: parameters 7–9 in Figure 6(a) and parameters 3–7 and 9 in Figure 6(b). This is caused by the bias in target samples and noise in source domains. Therefore, the estimates of MPL-TC(Priors) are far from the true values, (average K-L divergence of 0.65 and 0.40 for sample sizes 20 and 100 respectively). However, after performing MAP learning in the MPL-TC<sup>+5</sup> model, the MPL-TC<sup>+5</sup>(Posteriors) reduces the average K-L divergence between the estimated values and true values to 0.09 and 0.03 respectively. These results demonstrate the robustness of the Bayesian learning in MPL-TC<sup>+5</sup>, and the importance of systematically inferring the new parameters

**Figure 6:** The differences between estimated probability values (MPL-TC(Priors) and MPL-TC<sup>+5</sup>(Posteriors)) and ground truth for all parameters in the Cancer BN.

given available data and constraints. Next, we will compare the performance of all these algorithms in different BN parameter learning problems.

### 6.3 EXPERIMENTS ON STANDARD BNS

We evaluate the algorithms on 12 standard BNs<sup>8</sup> (details in Table 1). For each BN, 100 training samples and 5 constraints are drawn from the true CPTs in the target domain.

**Overall** Table 1 summarises the average K-L divergence per parameter. The best results are presented in bold. The statistically significant improvements of the best result over competitors are indicated with asterisks \* (two-sample t-test at the default 5% significance level). In summary, the MPL-C<sup>+5</sup> and MPL-TC<sup>+5</sup> methods outperform conventional MLE and MAP in 11 out of 12 settings, the only exception is the learning performance in Weather BN, where the learning results of these methods converge with enough training samples<sup>9</sup>. These results demonstrate the benefit of learning with both sources of external knowledge. Compared with the state-of-the-art MPL-C<sup>+5</sup>, MPL-TC<sup>+5</sup> wins in every setting (including the Weather BN, where MPL-TC<sup>+5</sup> achieves even smaller average K-L divergence – 0.018 of MPL-TC<sup>+5</sup> vs. 0.020 of MPL-C<sup>+5</sup>). Over all BNs, MPL-TC<sup>+5</sup> gets 83.2%, 33.5% and 26.9% average reduction of K-L divergence compared with MLE, MAP and MPL-C<sup>+5</sup> respectively.

**Transfer vs. No Transfer** Considering transfer learning only, both CPTAgg and MPL-TC<sup>+0</sup> outperform conventional MLE, which demonstrate the benefit of introducing source domain knowledge. However, due to a simplistic relatedness model and CPT fusion heuristic, CPTAgg even fails to outperform MAP in some settings. In contrast, our MPL-TC<sup>+0</sup> outperforms CPTAgg and MAP with 74.1%

<sup>8</sup><http://www.bnlearn.com/bnrepository/>

<sup>9</sup>As shown in Table 1, the Weather BN only contains 9 parameters to learn, therefore 100 training samples are already enough to train a good model.

**Table 1:** Parameter learning performance (average K-L divergence) in 12 standard Bayesian networks.

| Name       | Nodes | Edges | Para | MLE               | MAP        | MPL-C <sup>+5</sup> | CPTAgg            | MPL-TC <sup>+0</sup> | MPL-TC <sup>+5</sup> |

and 31.2% average reduction of K-L divergence over all the settings. In addition, after introducing both transferred parameter priors and target constraints, our MPL-TC<sup>+5</sup> shows additional improved learning performance over CPTAgg and MPL-TC<sup>+0</sup> (75.0% and 3.5% average reduction of K-L divergence).

**Importance of Transfer vs. Constraints** As we can see, our MPL-TC<sup>+0</sup> outperforms MPL-C<sup>+5</sup>, which indicates the transferred prior is more helpful than a moderate number (i.e., 5) of constraints in improving parameter learning performance in these experiments. Given the burden of constraint elicitation in the real world, we used a realistic limited number of constraints. Of course if sufficient constraints were available, MPL-C would perform better (cf Figure 5) and this result would be reversed. But in this case, the transferred prior makes a greater contribution in improving performance – despite the noise process between source and target domain, and the imperfect estimation of relevance. This is especially in the larger BNs, where the constraints are scarcer relative to the number of parameters to learn. This also explains why MPL-TC<sup>+0</sup> and MPL-TC<sup>+5</sup> have similar results in the Alarm, Andes, Hailfinder, Insurance and Sachs BNs.

## 7 DISCUSSION AND CONCLUSIONS

When data is scarce, purely data driven BN parameter learning is inaccurate. The broad goal of this paper was to introduce a new method (MPL-TC) that is the first attempt at BN parameter learning incorporating both transfer learning and qualitative constraints in a complementary way. Using the public BN repository, we showed that learning performance was greatly improved in MPL-TC across a range of networks. In particular, we demonstrated that MPL-TC worked well in every data and constraint sparsity in the Cancer BN, and achieved the best performance in all BNs in the repository compared with other state-of-the-art algorithms.

We currently assume there is at least one relevant source. For each target fragment, we find the most relevant source fragment to generate target parameter priors. Transferring to a target fragment using information from >1 sources would be a straightforward modification of the current framework. However it would increase the risk of ‘negative transfer’ (Torrey and Shavlik, 2009) that could be detrimental to performance (if some apparently relevant sources used for transfer are actually false positives). This trade off between maximum exploitable transfer, and robustness to negative transfer is pervasive in transfer learning.

We discussed the limitations of all BN transfer learning approaches with respect to the fact that, in practice relatedness is hard to guarantee or estimate. Thus data-driven transfer (source selection) may be biased by inaccurate target data (resulting in bad choice of source and thus negative transfer) in extremely scarce settings. In the spirit of synergistically combining source data and constraints, available target constraints clearly provide an opportunity to guide and disambiguate transfer. In this paper, we only used target parameter constraints to exclude individual incompatible source fragments. Richer models for guiding transfer with constraints including cross-node constraints, source-domain constraints, and cross-domain constraints should be investigated in future.
