In another recent work (Zhou, 2015), a similar zero-truncated Poisson construction, as ours, was proposed for *edge-partitioning* based network clustering, allowing the proposed model to scale in terms of the number of edges in the network. Our model, on the other hand, is more general and can be applied to multiway binary tensor data, with an optionally available binary network as a potential source of side-information. Moreover, the Dirichlet prior on the factor matrices, its reparametrizations (Section 3.2), and the online MCMC inference lead to a highly scalable framework for tensor decomposition with side-information.

Another line of work on scaling up tensor factorization methods involves developing distributed and parallel methods (Kang et al., 2012; Inah et al., 2015; Papalexakis et al., 2012; Beutel et al., 2014). Most of these methods, however, have one or more of the following limitations: (1) these methods lack a proper generative model of the data, which is simply assumed to be real-valued and the optimization objective is based on minimizing the Frobenius norm of the tensor reconstruction error, which may not be suitable for binary data; (2) these methods usually assume a parallel or distributed setting, and therefore are not feasible to run on a single machine; (3) missing data cannot be easily handled/predicted; and (4) the rank of the decomposition needs to be chosen via cross-validation.

Leveraging sources of side-information for tensor factorization has also been gaining a lot of attention recently. However, most of these methods cannot scale easily to massive tensors (Acar et al., 2011; Rai et al., 2015), or have to rely on parallel or distributed computing infrastructures (Beutel et al., 2014). In contrast, our model, by the virtue of its scalability that only depends on the number of nonzero entries in the tensor and/or the mode network, easily allows it to scale to massive binary tensors, with or without mode-network based side-information.

## 6 EXPERIMENTS

We report experimental results for our model on a wide range of real-world binary tensors (with and without mode-network based side-information), and compare it with several baselines for binary tensor factorization. We use the following data sets for our experiments:

- **Kinship:** This is a binary tensor of size  $104 \times 104 \times 26$ , representing 26 types of relationships between 104 members of a tribe (Nickel et al., 2011). The tensor has about 3.8% nonzeros.
- **UMLS:** This is a binary tensor of size  $135 \times 135 \times 49$  representing 56 types of verb relations between 135 high-level concepts (Nickel et al., 2011). The tensor has about 0.8% nonzeros.
- **MovieLens:** This is a binary *matrix* (two-way tensor) of size  $943 \times 1682$  representing the binary ratings (thumbs-up or thumbs-down) by 943 users on 1682 movies<sup>1</sup>. This data set has a total of 100,000 ones.
- **DBLP:** This is a binary tensor of size  $10,000 \times 200 \times 10,000$  representing (author-conference-keyword) relations (Zhe et al., 2015). This tensor has only about 0.001% nonzeros, and is an ideal example of a massive but sparse binary tensor.
- **Scholars:** This is a binary tensor of size  $2370 \times 8663 \times 4066$ , constructed from a database of research paper abstracts published by researchers at Duke University; the three tensor modes correspond to authors, words, and publication venues, respectively. Just like the DBLP data, this tensor is also massive but extremely sparse with only about 0.002% nonzeros. In addition, the co-authorship network (i.e., who has written papers with whom) is also available, which we use as a source of side-information, and use this network to experiment with the *cold-start* setting (i.e., when the main tensor has no information about some authors).
- **Facebook:** The Facebook data is a binary tensor of size  $63731 \times 63730 \times 1837$  with the three modes representing wall-owner, poster, and days (Papalexakis et al., 2013). This tensor has only 737498 nonzeros. In addition to the binary tensor, the social network (friendship-links) between users is also given in form of a symmetric binary matrix of size  $63731 \times 63731$ , which has 1634180 nonzeros. We use the network to experiment with the cold-start setting.

We use all the 6 data sets for the tensor completion experiments (Section 6.1). We also use the Scholars and Facebook data in the cold-start setting, where we experiment on the tensor completion task, leveraging the mode-network based side-information (Section 6.4).

<sup>1</sup><http://grouplens.org/datasets/movielens/>

The set of experiments we perform includes: (1) binary tensor completion (Section 6.1) using only the tensor data; (2) scalability behavior of our model (both batch as well as online MCMC) in terms of tensor completion accuracy vs run-time (Section 6.2); we compare our model with Bayesian CP based on logistic-likelihood (Rai et al., 2014); (3) a qualitative analysis of our results using a *multiway* topic modeling experiment (Section 6.3) on the Scholars data, with the entities being authors, words, and publication venues; and (4) leveraging the mode network for tensor completion in the cold-start setting (Section 6.4); for this experiment, we also demonstrate how leveraging the network leads to improved qualitative results in the multi-way topic modeling problem.

In the experiments, we refer to our model as **ZTP-CP** (Zero-Truncated Poisson based CP decomposition). We compare **ZTP-CP** (using both batch MCMC as well as online MCMC inference) with the following baselines: (1) the quadratic loss minimization (**Quad-App**) proposed in (Ermis and Bouchard, 2014); (2) the refined piecewise quadratic approximation algorithm (**PW-QuadApp**) (Ermis and Bouchard, 2014); and (3) **Bayesian CP** decomposition based on logistic likelihood for binary data (Rai et al., 2014).

**Experimental settings:** All experiments are done on a standard desktop computer with Intel i7 3.4GHz processor and 24GB RAM. Unless specified otherwise, the MCMC inference was run for 1000 iterations with 500 burn-in iterations. The online MCMC algorithm was also run for the same number of iterations, with minibatch size equal to one-tenth of the number of nonzeros in the training data. For all the data sets, except Scholars and Facebook, we use  $R = 20$  (also note that our model has the ability to prune the unnecessary factors by shrinking the corresponding  $\lambda_r$  to zero). For Scholars and Facebook data, we set  $R = 100$ . The hyperparameters  $g_r, f_r$  were set to 0.1, and  $\epsilon$  and  $\alpha$  are set to  $1/R$ , which worked well in our experiments.

### 6.1 TENSOR COMPLETION

In Table 1, we report the results on the tensor completion task (in terms of the AUC-ROC - the area under the ROC curve). For this experiment, although available, we do not use the mode network for the Scholars and the Facebook data; only the binary tensor is used (the results when also using the network are reported in Section 6.4). For each data set, we randomly select 90% of the tensor observations as the training data and evaluate each model on the remaining 10% observations used as the held-out data.

Since the code for **Quad-App** and **PW-QuadApp** baselines (both proposed in (Ermis and Bouchard, 2014)) is not publicly available, we are only able to report the results for the Kinship, UMLS, and MovieLens data set (using the results reported in (Ermis and Bouchard, 2014)). For Bayesian CP (Rai et al., 2014), we use the code provided

Table 1: Tensor completion accuracies in terms of AUC-ROC scores. Results are averaged over 10 splits of training and test data. Note: (1) Bayesian CP was infeasible to run on the Scholars and Facebook data; (2) Due to the lack of publicly available code for **Quad-App** and **PQ-QuadApp**, we only report its results on Kinship, UMLS, and MovieLens data (results taken from (Ermis and Bouchard, 2014)).

|  | Kinship       | UMLS          | MovieLens     | DBLP          | Scholars      | Facebook      |
|--|---------------|---------------|---------------|---------------|---------------|---------------|
| <b>Quad-App (Ermis and Bouchard, 2014)</b>     | 0.8193        | 0.8205        | 0.8511        | -             | -             | -             |
| <b>PW-QuadApp (Ermis and Bouchard, 2014)</b>   | 0.9213        | 0.9387        | 0.9490        | -             | -             | -             |
| <b>Bayesian-Logistic-CP (Rai et al., 2014)</b> | <b>0.9865</b> | <b>0.9965</b> | 0.9799        | 0.9307        | -             | -             |
| <b>ZTP-CP (Batch MCMC)</b>                     | 0.9674        | 0.9938        | <b>0.9895</b> | <b>0.9759</b> | <b>0.9959</b> | 0.9830        |
| <b>ZTP-CP (Online MCMC)</b>                    | 0.9628        | 0.9936        | 0.9841        | 0.9743        | 0.9958        | <b>0.9844</b> |

by the authors. Moreover, the Bayesian CP baseline was found infeasible to run on the Scholars and Facebook data (both of which are massive tensors), so we are unable to report those results. For fairness, on Kinship, UMLS, and MovieLens data, we use the same experimental settings for all the methods as used by (Ermis and Bouchard, 2014).

As shown in Table 1, our model outperforms **Quad-App** and **PW-QuadApp** in terms of the tensor-completion accuracies, and performs comparably or better than **Bayesian CP**, while being an order of magnitude faster (Section 6.2 shows the results on running times).

## 6.2 SCALABILITY

We next compare our model with Bayesian CP (Rai et al., 2014) in terms of the running times vs tensor completion accuracy on Kinship and UMLS data sets. As shown in Fig. 2 (top-row), our model (batch as well as online MCMC) runs/converges an order of magnitude faster than Bayesian CP in terms of running time. On Scholars and Facebook, since Bayesian CP was infeasible to run, we are only able to show the results (Fig. 2, bottom-row) for our model, with batch MCMC and online MCMC inference. On all the data sets, the online MCMC runs/converges faster than the batch MCMC.

We would like to note that, although the model proposed in (Ermis and Bouchard, 2014) also scales linearly <sup>2</sup> in the number of ones in the tensor, the per-iteration time-complexity of our model, which is linear in *both*  $\text{nnz}(\mathcal{B})$  as well as rank  $R$ , is better than the model proposed in (Ermis and Bouchard, 2014) (which has *quadratic* dependence on  $R$ ). Moreover, the tensor completion results of our model (shown in Table 1) on these data sets are better than the ones reported in (Ermis and Bouchard, 2014).

## 6.3 MULTIWAY TOPIC MODELING

We also apply our model for a *multiway* topic modeling task on the Scholars data. The binary tensor represents  $\text{AUTHORS} \times \text{WORDS} \times \text{VENUES}$  relationships. We apply our model (with batch MCMC) and examine the latent factors of each of the three dimensions. Since each factor is drawn from a Dirichlet, it is non-negative and naturally cor-

<sup>2</sup>Although (Ermis and Bouchard, 2014) reported run times on Kinship and UMLS data sets, those number are not directly comparable with our run times reported here (due to possibly different machine configuration, which they do not specify in the paper).

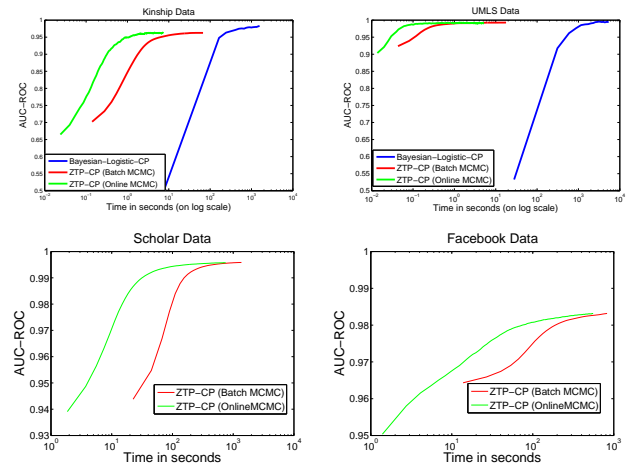

Figure 2: Running time (log-scale) comparison of various methods on Kinship (top left), UMLS (top right), Scholars (bottom left), and Facebook (bottom right) datasets.

responds to a “topic”. In Table 2, after examining the words factor matrix, we show the top-10 words for four of the factors (topics) inferred by our model; these factors seem to represent topics Evolutionary Biology, Medical Imaging, Machine Learning/Signal Processing, and Oncology. For the Machine Learning/Signal Processing topic, we also examine the corresponding topic in the venues factor matrix and show the top-10 venues in that topic (based on their factor scores in that factor). In Fig. 3, we also show the histograms of authors’ department affiliations for each of the four topics and the results make intuitive sense. The results in Table 2 and Fig. 3 demonstrate the usefulness of our model for scalable topic modeling of such multiway data.

## 6.4 LEVERAGING THE MODE NETWORK

Finally, to investigate the usefulness of leveraging the mode network, we experiment with using both the tensor *and* the mode network on Scholars and Facebook data sets. For each data set, we report the AUC-ROC (area under the ROC curve) and AUC-PR (area under the precision-recall curve) on the tensor completion task, with and without network. For both data sets, we experiment with the more challenging cold-start setting. In particular, for the Facebook data, we hold out all the entries of the tensor slices after the first 50,000 wall-owners and predict those entries (using only the rest of the tensor, and using the rest of the tensor as well as the friendship network). We run the experiment with  $R = 20$  and minibatch size of 50,000 for the online

Table 2: For the Scholars data, the most probable words in topics related to evolutionary biology (Evo Bio), medical imaging (Med Imag), machine learning/signal processing(ML/SP) and oncology, and top ranked venues in ML/SP

| EVO BIO      | MED IMAG   | ML/SP         | ONCOLOGY     | TOP VENUES IN ML/SP     |
|--------------|------------|---------------|--------------|-------------------------|
| SPECIES      | IMAGING    | BAYESIAN      | RADIATION    | ICASSP                  |
| SELECTION    | CONTRAST   | ALGORITHM     | RADIOTHERAPY | JASA                    |
| GENETIC      | COMPUTED   | SAMPLING      | STAGE        | ICML                    |
| EVOLUTION    | RESONANCE  | FEATURES      | TUMOR        | IEEE TRANS IMG PROC     |
| POPULATIONS  | DOSE       | PROCESS       | SURVIVAL     | NIPS                    |
| EVOLUTIONARY | TOMOGRAPHY | SPARSE        | LUNG         | COMPU STAT DATA ANALY   |
| GENE         | MAGNETIC   | NONPARAMETRIC | CHEMOTHERAPY | BIOMETRICS              |
| VARIATION    | IMAGE      | GIBBS         | TREATED      | BAYESIAN ANALYSIS       |
| PLANTS       | QUALITY    | PARAMETERS    | TOXICITY     | JMLR                    |
| NATURAL      | DIAGNOSTIC | INFERENCE     | ONCOLOGY     | IEEE TRANS. INF. THEORY |

Figure 3: Histogram of the department-affiliations for the top 20 authors in factors related to evolutionary biology (top left), medical imaging (top right), machine learning/signal processing(bottom left) and oncology (bottom right).

MCMC. The results in Table 3 show that using the network leads to better tensor completion accuracies.

We also perform a similar experiment on the Scholars data where we hold out all the entries in tensor slices after the first 1000 authors and predict those entries (using only the rest of the tensor, and using the rest of the tensor as well as the co-authorship network). We run the experiment with  $R = 100$  and minibatch size of 50,000 for the online MCMC. The results shown in Table 3 again demonstrate the benefit of using the network.

Table 3: Cold-start setting

|                        | Facebook      |               | Scholars      |               |
|------------------------|---------------|---------------|---------------|---------------|
|                        | AUC-ROC       | AUC-PR        | AUC-ROC       | AUC-PR        |
| <b>Without network</b> | 0.8897        | 0.6076        | 0.8051        | 0.5763        |
| <b>With network</b>    | <b>0.9075</b> | <b>0.7255</b> | <b>0.8124</b> | <b>0.6450</b> |

In Fig. 4, we show another result demonstrating the benefit of using the co-authorship network for the Scholars data. Note that in the cold-start setting, there is no information in the tensor for the *held-out* authors. Therefore the topics associated with such authors are expected to be roughly *uniformly random*. As shown in Fig. 4 (left column), the set of held-out authors assigned to the topics medical imaging and oncology seem very random and *arbitrary* (we only show the aggregate department-affiliations). Using side-information (in form of the co-authorship network), however, the model sensibly assigns authors who are indeed related to these topics, as shown in right column of Fig. 4.

Figure 4: Histogram of the department-affiliations of the top 15 held-out authors associated with the factors of medical imaging (top) and oncology (bottom). The left column is obtained using no co-authorship information, and the right column is obtained using co-authorship information.

## 7 CONCLUSION

We have presented a scalable Bayesian model for binary tensor factorization. In contrast to the models based on probit or logistic likelihood for binary tensor decomposition, the time-complexity of our model depends only in the number of ones in the tensor. This aspect of our model allows it to easily scale up to massive binary tensors. The simplicity of our model also leads to simple batch as well as on-line MCMC inference; the latter allows our model to scale up even when the number of ones could be massive. Our experimental results demonstrate that the model leads to speed-ups of an order of magnitude when compared to binary tensor factorization models based on the logistic likelihood, and also outperforms various other baselines. Our model also gives interpretable results which helps qualitative analysis of results. In addition, the ability to leverage mode networks (fully or partially observed) leads to improved tensor decomposition in cold-start problems.

## Abstract

We propose two efficient and general MCMC algorithms to compute optimal Bayesian decisions for Mallows’ model and Condorcet’s model w.r.t. any loss function and prior. We show that the mixing time of our Markov chain for Mallows’ model is polynomial in  $\varphi^{-k_{max}}$ ,  $d_{max}$ , and the input size, where  $\varphi$  is the dispersion of the model,  $k_{max}$  measures agents’ largest total bias in bipartitions of alternatives, and  $d_{max}$  is the maximum ratio between prior probabilities. We also show that in some cases the mixing time is at least  $\Theta(\varphi^{-k_{max}/2})$ . For Condorcet’s model, our Markov chain is rapid mixing for moderate prior distributions. Efficiency of our algorithms are illustrated by experiments on real-world datasets.

## 1 INTRODUCTION

In many social choice (a.k.a. rank aggregation) problems we want to compute an objectively optimal joint decision based on agents’ preferences. For example, the *Condorcet Jury Theorem* (Condorcet, 1785) studies how to select a “correct” leader in political elections when the votes are noisy perceptions of the ground truth. Principles and algorithms for social choice have also been used to aggregate rankings in meta-search engines (Dwork et al., 2001), recommender systems (Ghosh et al., 1999), crowdsourcing (Mao et al., 2013), semantic webs (Porello and Endriss, 2013), and peer grading for MOOC (Raman and Joachims, 2014).

In these social choice applications it is natural to take a Bayesian approach. Given a statistical model that describes agents’ noisy perception of the ground truth, a prior distribution, and a loss function that evaluates the joint decision w.r.t. the ground truth, we compute an optimal joint decision that has the minimum Bayesian expected loss w.r.t. the posterior distribution. This was recently formalized as a

*statistical decision-theoretic framework for social choice* by Azari Soufiani et al. (2014).

A major challenge in previous research, especially in the Bayesian approaches, is the high computational complexity of decision making. For example, the maximum likelihood estimator (MLE) of a popular ranking model called *Mallows’ model* (Mallows, 1957) is NP-hard to compute (Bartholdi et al., 1989). Computing optimal Bayesian decisions for rank aggregation is a hard combinatorial optimization problem because the parameter space is often discrete and its size is often exponential. Most previous work focused on designing efficient case-by-case algorithms for computing MLEs and MAPs of popular ranking models. However, the following question is left unanswered:

*Are there general and efficient algorithms that compute optimal Bayesian decisions for a wide range of rank aggregation problems?*

**Our contributions.** We give positive answers to this question for two popular ranking models: *Mallows’ model* (Mallows, 1957) and *Condorcet’s model* (Condorcet, 1785; Young, 1988) by proposing two general Markov chain Monte Carlo (MCMC) algorithms. Our algorithms work for any prior distribution, any decision space, and any loss function. In both algorithms, we first generate multiple samples by a Markov chain whose stationary distribution is the posterior distribution, which are used to compute the optimal decision that minimizes the empirical loss. Our Markov chains for both models are Metropolis-Hastings samplers (Metropolis et al., 1953; Hastings, 1970). For Mallows’ model, we apply a random transposition on adjacent pairs of alternatives in each step, and for Condorcet’s model, we adopt an *independent sampler*, which samples a candidate parameter with probability that is proportional to its likelihood in each step.

We prove that our Markov chains have good theoretical guarantees on the *mixing time*, which measures the rate of convergence to the stationary distribution and is closely related to the overall running time of the algorithms (Theorem 1). For Mallows’ model, we show that the mixing

time of our Markov chain is polynomial in  $\varphi^{-k_{max}}$ ,  $d_{max}$ , and the input size, where  $\varphi$  is the dispersion of the model,  $k_{max}$  measures agents’ largest total bias in bipartitions of alternatives (Theorem 3), and  $d_{max}$  is the maximum ratio between prior probabilities. We also show that in some cases the mixing time is at least  $\Theta(\varphi^{-k_{max}/2})$  (Proposition 1). For Condorcet’s model, our Markov chain is rapid mixing for moderate prior distributions—its mixing time is polynomial in the input size and  $(\ln \frac{d_{max}}{d_{max}-1})^{-1}$  (Theorem 5). Therefore, we can efficiently generate samples to estimate the Bayesian expected loss with high accuracy, for Mallows’ model when  $\varphi^{-k_{max}}$  and  $d_{max}$  are not too large, and for Condorcet’s model when  $d_{max}$  is not too large, for a wide range of social choice problems including those that are provably NP-hard to compute or even approximate (Theorem 2 and 4).

Computational and statistical efficiency of our algorithms are shown in preliminary experiments using real-world election data from Preflib (Mattei and Walsh, 2013) ([www.Preflib.org](http://www.Preflib.org)). The key observation is that for Mallows’ model, when the number of alternatives is at least 11 the brute-force search takes much more time than generating 10 million samples, based on which we can achieve a high precision for estimating the Bayesian loss and making the optimal Bayesian decision.

**Related Work and Discussions.** MCMC methods have been widely applied in Bayesian statistics (Smith and Roberts, 1993). However, obtaining non-trivial bounds on the mixing time is a “considerable challenge” (Jerrum and Sinclair, 1996). Our proofs involve novel applications of a wide range of analytical tools, which we believe to have independent interest. To the best of our knowledge, this is the first time that MCMC methods for Bayesian inference for ranking models have been analytically studied. The theoretical bounds on the mixing time of the proposed Markov chains are our main theoretical contribution.

Practically, the main advantage of our algorithms is their generality because they work for any decision space, any loss function, and any prior distribution. For many natural loss functions (e.g. those in Definition 4), no efficient algorithm was previously known. There have been much work on computing MLE and MAP for Mallows’ model and Condorcet’s model in (computational) social choice (Bartholdi et al., 1989; Hemaspaandra et al., 2005; Betzler et al., 2008), theory (Ailon et al., 2005; Kenyon-Mathieu and Schudy, 2007), and machine learning (Kuo et al., 2009; Long et al., 2010; Lu and Boutilier, 2011; Liu, 2011; Negahban et al., 2012; Azari Soufiani et al., 2012, 2013a,b; Raman and Joachims, 2015). Also see the experimental study by Ali and Meila (2012) for a comparison of 104 algorithms and combinations. Our algorithms are more general, as MLEs and MAPs are special combinations of decision space and loss function.

Specifically, we have not seen much work on MCMC algorithms for rank aggregation. The work that is closest to ours is by Raman and Joachims (2015), who proposed a different Markov chain for Mallows’ model and tested it on MOOC grading data. However, their paper did not analyze the mixing time. Diaconis and Hanlon (1992) proposed a Metropolis-Hastings algorithm to generate data according to a Mallows-like model that is based on the *Cayley distance*, which is different from both models studied in this paper. Moreover, it is not clear whether the algorithm by Diaconis and Hanlon can be leveraged to generate samples from the posterior distribution.

## 2 PRELIMINARIES

Let  $\mathcal{C}$  denote a set of  $m$  alternatives. Let  $\mathcal{L}(\mathcal{C})$  denote the set of *linear orders* over  $\mathcal{C}$ , that is, the set of all transitive, antisymmetric, and total binary relations. Let  $\mathcal{B}(\mathcal{C})$  denote the set of all possibly cyclic orders over  $\mathcal{C}$ , that is, all irreflexive, antisymmetric, and total binary relations over  $\mathcal{C}$ . Clearly  $\mathcal{L}(\mathcal{C}) \subseteq \mathcal{B}(\mathcal{C})$ . Each agent uses a (possibly cyclic) order over  $\mathcal{C}$  to represent her preferences. Let  $R$  denote the (*preference*) *profile* containing preferences from  $n$  agents. Given  $R$ , we want to make a joint decision from a decision space  $\mathcal{D}$ , which can be different from  $\mathcal{C}$ .

For any profile  $R$ , its *weighted majority graph*, denoted by  $\text{WMG}(R)$ , is a weighted directed graph whose vertices are  $\mathcal{C}$ , and there is an edge between each pair of alternatives  $(a, b)$  with weight  $w_R(a, b) = \#\{V \in R : a \succ_V b\} - \#\{V \in R : b \succ_V a\}$ . Clearly  $w_R(a, b) + w_R(b, a) = 0$ .

For any  $V, W \in \mathcal{B}(\mathcal{C})$ , we let  $\text{KT}(V, W)$  denote the *Kendall-tau distance* between  $V$  and  $W$ , that is, the number of different pairwise comparisons in  $V$  and  $W$ . In this paper, we focus on the following two ranking models.

**Definition 1** (Mallows’ model with fixed dispersion). *The parameter space is  $\Theta_M = \mathcal{L}(\mathcal{C})$ , the sample space  $\mathcal{S}_M$  is composed of  $n$  i.i.d. generated data in  $\mathcal{L}(\mathcal{C})$ , and for any  $W \in \mathcal{L}(\mathcal{C})$  and any profile  $R$ , we have  $\text{Pr}_M(R|W) = \prod_{V \in R} \left( \frac{1}{Z_M} \varphi^{\text{KT}(V, W)} \right)$ , where  $Z_M$  is the normalization factor such that  $Z_M = \sum_{U \in \mathcal{L}(\mathcal{C})} \varphi^{\text{KT}(U, W)}$ .*

**Definition 2** (Condorcet’s model with fixed dispersion). *The parameter space is  $\Theta_C = \mathcal{B}(\mathcal{C})$ , the sample space  $\mathcal{S}_C$  is composed of  $n$  i.i.d. generated data in  $\mathcal{B}(\mathcal{C})$ , and for any  $W \in \mathcal{B}(\mathcal{C})$  and any profile  $R$ , we have  $\text{Pr}_C(R|W) = \prod_{V \in R} \left( \frac{1}{Z_C} \varphi^{\text{KT}(V, W)} \right)$ , where  $Z_C$  is the normalization factor such that  $Z_C = \sum_{U \in \mathcal{B}(\mathcal{C})} \varphi^{\text{KT}(U, W)}$ .<sup>1</sup>*

In the above two definitions, the normalization factors  $Z_M$  and  $Z_C$  are independent of the selection of  $W$ . We now recall the *statistical decision-theoretic framework for social*

<sup>1</sup>Our results also work for the variant where the sample space is  $(\mathcal{L}(\mathcal{C}))^n$ .

choice defined by Azari Soufiani et al. (2014) to formulate the computational problem.

**Definition 3** ((Azari Soufiani et al., 2014)). A statistical decision-theoretic framework for social choice (SDT framework for short) is a tuple  $\mathcal{F} = (\mathcal{M}_C, \mathcal{D}, L)$ , where  $\mathcal{C}$  is the set of alternatives,  $\mathcal{M}_C = (\Theta, \text{Pr}, \mathcal{S})$  is a ranking model,  $\mathcal{D}$  is the decision space, and  $L : \Theta \times \mathcal{D} \rightarrow \mathbb{R}_{\geq 0}$  is a loss function that is easy to compute.

In this paper, we focus on computing the *Bayesian estimators*  $f_B$  of a SDT framework that minimizes the expected Bayesian loss for any prior and profile. More precisely, given a SDT framework  $\mathcal{F}$ , a prior over  $\Theta$ , and a profile  $R$ ,  $f_B(R) \in \min_{d \in \mathcal{D}} E_{\theta \sim \text{Pr}(\cdot | R)} L(\theta, d)$ . For example, the *maximum a posteriori (MAP)* is the Bayesian estimator for the SDT framework with  $\mathcal{D} = \Theta$  and the 0-1 loss function.

Natural choices of the decision space for ranking models are: (1)  $\mathcal{D} = \mathcal{C}$ , and  $f_B$  is called a *resolute voting rule*. (2)  $\mathcal{D} = 2^{\mathcal{C}} - \{\emptyset\}$ , and  $f_B$  is called a *irresolute voting rule*. (3)  $\mathcal{D} = \mathcal{L}(\mathcal{C})$ , and  $f_B$  is called a *preference function* or *social welfare function*.

In this paper, we focus on case (1)  $\mathcal{D} = \mathcal{C}$  and the exact Top- $k$  loss functions defined below. The proposed algorithms and theorems on the mixing time work for any SDT framework.

**Definition 4.** Let  $\mathcal{D} = \mathcal{C}$ . For any  $k \leq m - 1$ , the exact Top- $k$  loss function  $L_{E\text{Top-}k}$  is defined as: for any  $W \in \mathcal{B}(\mathcal{C})$  and  $d \in \mathcal{C}$ ,  $L_{E\text{Top-}k}(W, d) = 0$  if there exists  $A \subseteq \mathcal{C}$  such that  $|A| = k$ ,  $d \in A$ , and for all  $a \in A, b \in \mathcal{C} - A$  we have  $a \succ_W b$ ; otherwise  $L_{E\text{Top-}k}(W, d) = 1$ .

In words, the loss of an alternative  $d$  under the exact Top- $k$  loss function is 0 if  $d$  is clearly ranked within top  $k$  positions in the ground truth; otherwise the loss is 1.<sup>2</sup>

A Markov chain over a state space  $\Theta$  is characterized by a transition matrix  $P$  such that for any  $V, W \in \Theta$ ,  $P(V, W)$  is the probability for the next state to be  $W$  given that the current state is  $V$ . Therefore, for any  $V \in \Theta$ , we have  $\sum_{W \in \Theta} P(V, W) = 1$ . In this paper, the state space is the parameter space because we want to sample from the posterior distribution. The *stationary distribution*  $\pi$  of a Markov chain with transition matrix  $P$  is a probability distribution over  $\Theta$  such that for any  $V \in \Theta$  we have  $\sum_{W \in \Theta} \pi(W)P(W, V) = \pi(V)$ , that is,  $\pi$  (as a row vector) is a left eigenvector of  $P$  with eigenvalue 1.

Given a Markov chain with transition matrix  $P(V, W)$  and a unique stationary distribution  $\pi(\cdot)$ , the *variation distance* at time  $t$  w.r.t. starting state  $V$  is defined to be

$$\Delta_V(t) = \max_{S \subseteq \Theta} |P^t(V, S) - \pi(S)|$$

<sup>2</sup>We note that for some  $W \in \mathcal{B}(\mathcal{C})$  no alternative is clearly ranked within top  $k$ . For any  $W \in \mathcal{L}(\mathcal{C})$ , there are always  $k$  alternatives clearly ranked in top  $k$ .

where  $P^t(V, S)$  is the probability for the Markov chain starting at  $V$  to end in a state in  $S$  after  $t$  steps.

The convergence rate of a Markov chain to the stationary distribution is measured by its *mixing time*  $\tau_V(\epsilon)$ , which is the number of steps that guarantee a variation distance below  $\epsilon$ . Formally, we define

$$\tau_V(\epsilon) = \min\{t : \Delta_V(t') \leq \epsilon \text{ for all } t' \geq t\}$$

Let  $\tau(\epsilon)$  denote the maximum mixing time for all starting states, that is,  $\tau(\epsilon) = \max_V \tau_V(\epsilon)$ .

Our algorithms first use a Markov chain sampler  $\mathfrak{M}$  that runs a Markov chain for multiple steps to generate samples from the parameter space  $\Theta$ , then compute the optimal decision w.r.t. these samples. Formally, we use Algorithm 1 to estimate the expected Bayesian loss of all decisions, then choose one with minimum expected loss.

---

**Algorithm 1** CompBayesianLoss

---

- 1: **Input:** a profile  $R$ , a SDT framework  $\mathcal{F} = (\mathcal{M}_C, \mathcal{D}, L)$  with prior  $\text{Pr}(\cdot)$ , a Markov chain sampler  $\mathfrak{M}$  over  $\Theta$  whose stationary distribution is  $\text{Pr}(\cdot | R)$ , and a decision  $d \in \mathcal{D}$ .
  - 2: Use  $\mathfrak{M}$  to generate  $N$  independent samples, denoted by  $Q$ .
  - 3: **return**  $\sum_{W \in Q} L(W, d) / |Q|$ .
- 

It is well-known that the mixing time is closely related to the running time of approximate algorithms based on samples generated from the Markov chain. For SDT frameworks, this relation is formalized in Theorem 1. For completeness we include a short proof.

**Theorem 1.** For any  $d \in \mathcal{D}$  and any  $\epsilon > 0, \delta > 0$ , Algorithm 1 can compute the expected Bayesian loss of  $d$  with no more than  $\epsilon$  additive error with probability at least  $1 - \delta$  in  $O(\frac{l_{max}^2}{\epsilon^2} \ln \delta^{-1} \tau(\frac{\epsilon}{2l_{max}}) \eta)$  time, where  $l_{max}$  is the maximum loss in  $L$ ,  $\tau(\cdot)$  is the mixing time of the Markov chain used by  $\mathfrak{M}$ , and  $\eta$  is running time for one step in  $\mathfrak{M}$ .

**Proof:** Let  $\pi$  denote the posterior distribution over  $\Theta$  given  $R$  and let  $\pi^*$  denote the distribution by the Markov chain sampler. We first prove that using  $O(\frac{l_{max}^2}{\epsilon^2} \ln \delta^{-1})$  independent samples, the output of Algorithm 1 is no more than  $\epsilon/2$  away from  $E_{V \sim \pi^*} L(V, d)$ . We then choose a sampler  $\mathfrak{M}$  with mixing time  $\frac{\epsilon}{2l_{max}}$  and show that  $|E_{V \sim \pi^*} L(V, d) - E_{V \sim \pi} L(V, d)| \leq \frac{\epsilon}{2}$ .

Let  $X^1, \dots, X^N$  denote  $N$  i.i.d. random variables distributed as  $L(V, d)$ , where  $V$  is generated from  $\pi^*$ . Let  $Y^N = (\sum_{i=1}^N X^i) / N$ . Because for any  $\theta \in \Theta$  and  $d \in \mathcal{D}$ ,  $0 \leq L(\theta, d) \leq l_{max}$ , we have  $\text{Var}(X^1) \leq l_{max}^2$  and  $\text{Var}(Y^N) \leq l_{max}^2 / N$ . Also it is easy to check that  $E_{V \sim \pi^*} L(V, d) = E(X^1) = E(Y^N)$ . Therefore, by Chebyshev's inequality we have:  $\Pr(|Y^N - E(Y^N)| \geq$

$\frac{\epsilon}{2}) \leq \frac{4\text{Var}(Y^N)}{\epsilon^2} \leq \frac{4l_{max}^2}{\epsilon^2 N}$ . When  $N \geq \frac{16}{3} \frac{l_{max}^2}{\epsilon^2}$  we have  $\Pr(|Y^N - E(Y^N)| \geq \frac{\epsilon}{2}) \leq \frac{3}{4}$ . This can be leveraged to an algorithm that outputs an estimation to  $E(X^1)$  with no more than  $\frac{\epsilon}{2}$  additive error with probability at least  $1 - \delta$ , using  $O(\frac{l_{max}^2}{\epsilon^2} \ln \delta^{-1})$  calls to the sampler  $\mathfrak{M}$ . For any  $\mathfrak{M}$  with mixing time  $\tau(\frac{\epsilon}{2l_{max}})$ , we have  $|E_{V \sim \pi^*} L(V, d) - E_{V \sim \pi} L(V, d)| \leq \sum_{V \in \Theta} L(V, d) |\pi(V) - \pi^*(V)| \leq l_{max} \frac{\epsilon}{2l_{max}} = \frac{\epsilon}{2}$ .

Therefore, the total running time of Algorithm 1 is  $O(\frac{l_{max}^2}{\epsilon^2} \ln \delta^{-1} \tau(\frac{\epsilon}{2l_{max}}) \eta)$ .  $\square$

In the remainder of this paper we focus on the Markov chains for Mallows' model and Condorcet's model. For both models, we will design *Metropolis-Hastings sampling algorithms* (Metropolis et al., 1953; Hastings, 1970), which work as follows. For each state  $V$  we first generate a candidate  $W$  for the next state from a proposal distribution  $p_V(\cdot)$ . Then, with probability  $\min\{1, \frac{\pi(W)p_W(V)}{\pi(V)p_V(W)}\}$  the next state is  $W$ ; otherwise the next state remains at  $V$ .

### 3 MARKOV CHAIN FOR MALLOWS' MODEL

To motivate the study, we first prove that the expected Bayesian loss is hard to approximate for Mallows' model w.r.t. the exact Top-1 loss function and uniform prior. In the BAYESIANLOSS problem, we are given a SDT framework, a prior, and a decision  $d \in \mathcal{D}$ . We are asked to compute the expected Bayesian loss of  $d$ .<sup>3</sup>

**Theorem 2.** *If BAYESIANLOSS for Mallows' model w.r.t. the exact Top-1 loss function and the uniform prior has a polynomial-time approximation algorithm with constant approximation ratio, then  $\mathbf{P} = \mathbf{NP} = \mathbf{P}_{||}^{\mathbf{NP}}$ .*

$\mathbf{P}_{||}^{\mathbf{NP}}$  is the class of problems that can be computed by a  $\mathbf{P}$  oracle machine using polynomial number of parallel access to  $\mathbf{NP}$  oracles.  $\mathbf{P}_{||}^{\mathbf{NP}}$  contains  $\mathbf{NP}$  and  $\mathbf{co-NP}$ .

**Proof:** The hardness is proved by a reduction from the KEMENYWINNER problem, which is  $\mathbf{NP}$ -hard (Bartholdi et al., 1989) and  $\mathbf{P}_{||}^{\mathbf{NP}}$ -complete (Hemaspaandra et al., 2005). Given a profile  $R$ , for any alternative  $c$ , the *Kemeny score* of  $c$  is the smallest Kendall-tau distance between the profile and any linear order where  $c$  is ranked at the top. An alternative with the minimum Kemeny score is called a *Kemeny winner*. In a KEMENYWINNER problem, we are given a profile  $R$  and an alternative  $c$ , and we are asked if  $c$  is a Kemeny winner.

Given a KEMENYWINNER instance  $(R, c)$ , we construct a BAYESIANLOSS instance where there is a new alternative  $d$  and the profile  $R'$  satisfies that  $\text{WMG}(R')$  equals to  $\text{WMG}(R)$  plus the edges  $d \rightarrow a$  for all  $a \neq c$ , whose

<sup>3</sup>This problem is known to be  $\mathbf{NP}$ -hard and  $\mathbf{P}_{||}^{\mathbf{NP}}$ -hard to compute exactly (Procaccia et al., 2012; Azari Soufiani et al., 2014).

weights are 1 (if weights on edges in  $\text{WMG}(R)$  are odd) or 2 (if weights on edges in  $\text{WMG}(R)$  are even). Given any constant  $\alpha > 1$ , we let  $\varphi = \frac{\alpha^2}{2(m!)^2}$ . We note that  $\varphi$  can be represented using polynomial number of bits. This instance can be constructed in polynomial time using McGarvey's trick (McGarvey, 1953).

Clearly  $d$  is a Kemeny winner in  $R'$ . If the KEMENYWINNER is a "yes" instance, then  $c$  is also a Kemeny winner in  $R'$  (where  $d$  is ranked in the second place in the winning ranking). The Bayesian expected loss of  $d$  is at least  $\frac{1}{m!}$  because in at least one ranking  $d$  is not at the top.

If the KEMENYWINNER is a "no" instance, then  $d$  is the unique Kemeny winner. Let  $V$  denote a ranking where  $d$  is ranked in the top and  $\text{KT}(V, R')$  equals to the Kemeny score of  $d$ . It is easy to check that for any ranking  $W$  where  $d$  is not ranked in the top,  $\text{KT}(V, R') \leq \text{KT}(W, R') - 1$ , which means that  $\frac{\Pr(W|R')}{\Pr(V|R')} \leq \varphi$ . Therefore, the posterior probability that  $d$  is not ranked in the top, which equals to the expected Bayesian loss of  $d$ , is at most  $\frac{(m!-1)\varphi}{1+(m!-1)\varphi}$ .

When  $\varphi = \frac{\alpha^2}{2(m!)^2}$ , we have  $\frac{(m!-1)\varphi}{1+(m!-1)\varphi} < \frac{\alpha^2}{m!}$ .

It follows that if there exists a polynomial-time  $\alpha$ -approximation algorithm for BAYESIANLOSS, then we can use this algorithm to solve KEMENYWINNER in polynomial time: if the output of the algorithm is no more than  $\frac{\alpha}{m!}$  then the KEMENYWINNER instance is a "no" instance; otherwise the KEMENYWINNER instance is a "yes" instance. This means that  $\mathbf{P} = \mathbf{NP} = \mathbf{P}_{||}^{\mathbf{NP}}$ .  $\square$

We now present the Markov chain  $\mathfrak{M}_M$  for Mallows' model in Algorithm 2, which runs  $\mathfrak{M}_M$  for  $N$  steps. In each step, we first apply a random transposition of adjacent alternatives in the current state  $V$  (changing  $d \succ c$  to  $c \succ d$ ) to obtain a candidate ranking  $W$ , then with probability  $\frac{1}{2} \min\{\frac{\Pr_M(W)}{\Pr_M(V)} \varphi^{R[d \succ c] - R[c \succ d]}, 1\}$  we let  $V = W$ , otherwise the next state stays at  $V$ , where  $R[c \succ d]$  is the number of times  $c \succ d$  in  $R$ . The  $\frac{1}{2}$  factor is a popular trick to prove bounds on the mixing time in Lemma 2.

---

#### Algorithm 2 Markov chain $\mathfrak{M}_M$ for Mallows' model.

---

- 1: **Inputs:** a profile  $R$ , a prior  $\Pr_M$ , an initial ranking  $V$ , and the number of iterations  $N$ .
  - 2: **for**  $t=1$  **to**  $N$  **do**
  - 3:   Switch a pair of adjacent alternatives uniformly at random (from  $d \succ c$  to  $c \succ d$ ). Let  $W$  denote the new ranking.
  - 4:   With probability  $\frac{1}{2} \min\{\frac{\Pr_M(W)}{\Pr_M(V)} \varphi^{R[d \succ c] - R[c \succ d]}, 1\}$  let  $V = W$ .
  - 5: **end for**
  - 6: **return**  $V$ .
- 

For any profile  $R$ , let  $k_{max}$  denote the max cut of the undirected  $\text{WMG}(R)$ . That is,  $k_{max} = \max_{A \subseteq C} \sum_{a \in A, b \in C-A} |w_R(a, b)|$ . Let  $d_{max}$  denote the

maximum ratio between prior probabilities. That is,  $d_{max} = \max_{V, W \in \Theta} \frac{\text{Pr}_M(V)}{\text{Pr}_M(W)}$ .

**Theorem 3.** *The mixing time of the Markov chain in Algorithm 2 for any starting state is  $O(m^4 d_{max}^3 \varphi^{-k_{max}} (nm^3 \log m \ln \varphi^{-1} + \ln \epsilon^{-1}))$ .*

**Proof:** It is easy to check that the Markov chain  $\mathfrak{M}_M$  in Algorithm 2 is finite, ergodic, reversible and the transition matrix  $P_M(V, W)$  is diagonally dominant. Therefore, all eigenvalues of  $P_M(V, W)$  are real and positive, and the largest one is 1. The following lemma shows that the mixing time is closely related to the *spectral gap*  $1 - \lambda_{max}$ , where  $\lambda_{max}$  is the second largest eigenvalue of  $P_M(V, W)$ . It is easy to verify that the stationary distribution  $\pi_M$  equals to the posterior distribution  $\text{Pr}_M(\cdot | R)$ .

**Lemma 1** (e.g. (Sinclair, 1992)).

$$(i) \tau_V(\epsilon) \leq (1 - \lambda_{max})^{-1} (\ln \pi(V)^{-1} + \ln \epsilon^{-1});$$

$$(ii) \max_{V \in \Theta} \tau_V(\epsilon) \geq \frac{1}{2} (1 - \lambda_{max})^{-1} \ln(2\epsilon)^{-1}.$$

It is often hard to directly obtain lower bounds on the spectral gap. We will take the *canonical path* approach, whose idea is the following. Any reversible Markov chain can be visualized as an undirected graph  $G$  where the vertices are  $\Theta$  and the weight on the edge between  $V$  and  $W$  is  $Q(V, W) = \pi(V)P(V, W)$ . For each pair of states  $V, W \in \Theta$ , we fix a directed path (canonical path) from  $V$  to  $W$  in  $G$ , denoted by  $\gamma_{VW}$ . Let  $|\gamma_{VW}|$  denote the length of  $\gamma_{VW}$ . Let  $\Gamma$  denote the set of all canonical paths defined above, one for each pair  $(V, W)$ . The maximum *loading* of a single edge in  $\Gamma$  provides a lower bound on the spectral gap, thus it can be used to upper-bound the mixing time. Formally, this was proved by Sinclair (1992) in the following Lemma.

**Lemma 2** ((Sinclair, 1992; Jerrum and Sinclair, 1996)). *Let  $\mathfrak{M}$  be a finite, reversible, and ergodic Markov chain with loop probabilities  $P(V, V) \geq \frac{1}{2}$  for all states  $V$ . Let  $\Gamma$  be a set of canonical paths with maximum edge loading*

$$\rho = \max_e \frac{1}{Q(e)} \sum_{\gamma_{VW} \ni e} \pi(V)\pi(W)|\gamma_{VW}|$$

*Then the mixing time satisfies  $\tau_V(\epsilon) \leq \rho(\ln \pi(V)^{-1} + \ln \epsilon^{-1})$  for all  $V \in \Theta$ .*

To apply Lemma 2, we consider the following canonical paths  $\Gamma_M$  for  $\mathfrak{M}_M$ . We note that the graph  $G$  for canonical paths, whose vertices are rankings over alternatives, is different from the weighted majority graph, whose vertices are the alternatives.

**Definition 5.** *In the canonical paths  $\Gamma_M$ , for any pair of different rankings  $V, W \in \mathcal{L}(\mathcal{C})$ ,  $\gamma_{VW}$  contains the rankings obtained in  $m - 1$  stages of adjacent transpositions, where in stage  $k$ , the alternative ranked at the  $k$ -th position in  $W$  is moved up to the  $k$ -th position in  $V$ .*

W.l.o.g. let  $W = [a_1 \succ \dots \succ a_m]$ . In stage 1, we apply the minimum number of adjacent transpositions on  $V$  to move  $a_1$  to the top position. This process passes through no more than  $m - 1$  rankings, and let  $V_1$  denote the ranking at the end of the process, where  $a_1$  is ranked at the top position and the other part of  $V_1$  is the same as in  $V$ . In stage 2, if  $a_2$  is not already ranked at the second position of  $V_1$ , then we apply the minimum number of adjacent transpositions on  $V_1$  to move  $a_2$  to the second position. The process continues until we reach  $W$ . For example, when  $m = 4$ ,  $V = [a_4 \succ a_1 \succ a_3 \succ a_2]$ , and  $W = [a_1 \succ a_2 \succ a_3 \succ a_4]$ , we have  $\gamma_{VW} = V \rightarrow [a_1 \succ a_4 \succ a_3 \succ a_2] \rightarrow [a_1 \succ a_4 \succ a_2 \succ a_3] \rightarrow [a_1 \succ a_2 \succ a_4 \succ a_3] \rightarrow W$ .

It is not hard to see that  $|\gamma_{VW}| \leq m^2$ . For any edge  $e = E \rightarrow E'$  in a canonical path, we have  $Q_M(E, E') = \pi_M(E)P_M(E, E') = \pi_M(E')P_M(E', E) \geq \frac{1}{2(m-1)} \min\{\pi_M(E), \pi_M(E')\}$ . Therefore, we have

$$\rho \leq \max_{e = E \rightarrow E'} \left( \frac{2m^2(m-1)}{\min\{\pi_M(E), \pi_M(E')\}} \sum_{\gamma_{VW} \ni e} \pi_M(V)\pi_M(W) \right) \quad (1)$$

**Lemma 3.** *Given the canonical paths  $\Gamma_M$  defined in Definition 5 and any edge  $e = E \rightarrow E'$ , we have:*

- (i)  $\sum_{V, W: \gamma_{VW} \ni e} \pi_M(V)\pi_M(W)/\pi_M(E) \leq m\varphi^{-k_{max}}$ , and
- (ii)  $\sum_{V, W: \gamma_{VW} \ni e} \pi_M(V)\pi_M(W)/\pi_M(E') \leq m\varphi^{-k_{max}}$ .

**Proof:** Let  $E = [T \succ d \succ c \succ B]$  and  $E' = [T \succ c \succ d \succ B]$ . For any  $0 \leq k \leq |T|$ , we let  $T_k$  denote the top  $k$  ordering of  $T$  and let  $T_k^*$  denote the remaining ordering. That is, for any  $k \leq |T|$  we have  $T = [T_k \succ T_k^*]$ . It is easy to check that  $e \in \gamma_{VW}$  if and only if there exists  $0 \leq k \leq |T| \leq m - 2$  such that the following conditions hold.

- (1)  $T_k^* \succ d \succ B$  and  $d \succ c$  hold in  $V$ . Let  $\mathcal{V}_k$  denote the set of all such  $V$ 's.
- (2) The top  $k + 1$  alternatives in  $W$  are ranked as  $[T_k \succ c]$ . Let  $\mathcal{W}_k$  denote the set of all such  $W$ 's.

We first prove the inequality for  $E$ . Let  $A_k$  denote the alternatives in  $T_k$ , let  $A_k^*$  denote the alternatives in  $T_k^*$  plus  $d$ , let  $S$  denote the alternatives in  $B$ , and let  $\bar{A}_k = \mathcal{C} - A_k$ . For each pairwise comparison  $a \succ_E b$  in  $E$ , either we have (1)  $a \succ_V b$  for all  $V \in \mathcal{V}_K$  or (2)  $a \succ_W b$  for all  $W \in \mathcal{W}_K$ . This relationship is shown in Table 1.

For example, “ $W$ ” at  $(A_k, A_k)$  in Table 1 means that for all  $W \in \mathcal{W}_k$ ,  $(a, b) \in A_k \times A_k$ ,  $a \succ_W b$  if and only if  $a \succ_E b$ .  $(c, c)$  is marked N/A because the pairwise comparison between  $c$  and  $c$  is not well defined.

For any  $J \subseteq \mathcal{L}(\mathcal{C}) \times \mathcal{L}(\mathcal{C})$  and  $V, W \in \mathcal{L}(\mathcal{C})$ , we let  $D_J(V, W)$  denote the number of different pairwise comparisons between  $V$  and  $W$  for all pairs  $\{a, b\}$  such that

|         | $A_k$ | $A_k^*$ | $c$ | $S$ |
|---------|-------|---------|-----|-----|
| $A_k$   | $W$   | $W$     | $W$ | $W$ |
| $A_k^*$ | $W$   | $V$     | $V$ | $V$ |
| $c$     | $W$   | $V$     | N/A | $W$ |
| $S$     | $W$   | $V$     | $W$ | $V$ |

Table 1: Pairwise comparisons in  $E$  that are the same as in  $V \in \mathcal{V}_k$  or  $W \in \mathcal{W}_k$ .

$(a, b) \in J$  or  $(b, a) \in J$ . Formally,  $D_J(V, W) = \#\{\{a, b\} : [(a, b) \in J \text{ or } (b, a) \in J] \text{ and } [[a \succ_V b \text{ and } b \succ_W a] \text{ or } [a \succ_W b \text{ and } b \succ_V a]]\}$ . In other words,  $D_J(V, W)$  is the Kendall-tau distance between the restriction of  $V$  on  $J$  and the restriction of  $W$  on  $J$ . We note that any unordered pair of alternatives  $\{a, b\}$  is counted only once in  $J$ . In particular, for any  $a \in \mathcal{C}$  and  $A \subset \mathcal{C}$ ,  $D_{\{a\} \times \{a\}}(V, W) = 0$  and  $D_{(\{a\} \cup A) \times (\{a\} \cup A)}(V, W) = D_{A \times (\{a\} \cup A)}(V, W) = D_{(\{a\} \cup A) \times A}(V, W)$ . We have

$$\begin{aligned}
& \sum_{V, W: \gamma_V W \ni e} \pi_M(V) \pi_M(W) / \pi_M(E) \\
&= \sum_{0 \leq k \leq |T|} \sum_{V \in \mathcal{V}_k, W \in \mathcal{W}_k} \pi_M(V) \pi_M(W) / \pi_M(E) \\
&\leq \sum_{0 \leq k \leq |T|} \sum_{V \in \mathcal{V}_k, W \in \mathcal{W}_k} d_{max}^3 \frac{\Pr_M(R|V) \Pr_M(R|W)}{\Pr_M(R|E) \sum_{U \in \mathcal{L}(\mathcal{C})} \Pr_M(R|U)} \\
&= \sum_{0 \leq k \leq |T|} \sum_{V \in \mathcal{V}_k, W \in \mathcal{W}_k} \frac{d_{max}^3 f_1(V, E) f_2(W, E)}{\sum_{U \in \mathcal{L}(\mathcal{C})} \varphi^{KT(U, R)}} \quad (3)
\end{aligned}$$

where  $f_1(V, E) = \varphi^{D_{A_k \times \mathcal{C}}(V, R) + D_{\{c\} \times S}(V, R)}$  and  $f_2(W, E) = \varphi^{D_{A_k^* \times \bar{A}_k}(W, R) + D_{S \times S}(W, R)}$ . (2) is due to the following lemma.

**Lemma 4.** For any ranking model, any  $V \in \Theta$ , and any profile  $R$ , we have  $\frac{\Pr(V|R)}{d_{max}} \leq \frac{\Pr(R|V)}{\sum_{U \in \Theta} \Pr(R|U)} \leq d_{max} \Pr(V|R)$ .

For (3), according to Table 1, we have (for all grids with “V” in Table 1)

$$\begin{aligned}
& D_{A_k^* \times \bar{A}_k}(E, R) + D_{S \times S}(E, R) \\
&= D_{A_k^* \times \bar{A}_k}(V, R) + D_{S \times S}(V, R)
\end{aligned}$$

and (for all grids with “W” in Table 1)

$$\begin{aligned}
& D_{A_k \times \mathcal{C}}(E, R) + D_{\{c\} \times S}(E, R) \\
&= D_{A_k \times \mathcal{C}}(W, R) + D_{\{c\} \times S}(W, R)
\end{aligned}$$

We note that for any  $U \in \mathcal{L}(\mathcal{C})$ ,  $\Pr(R|U) \propto \varphi^{KT(U, R)}$  and

$$\begin{aligned}
KT(U, R) &= D_{A_k \times \mathcal{C}}(U, R) + D_{A_k^* \times \bar{A}_k}(U, R) \\
&\quad + D_{\{c\} \times S}(U, R) + D_{S \times S}(U, R)
\end{aligned}$$

Therefore,

$$\begin{aligned}
KT(E, R) &= D_{A_k^* \times \bar{A}_k}(V, R) + D_{S \times S}(V, R) \\
&\quad + D_{A_k \times \mathcal{C}}(W, R) + D_{\{c\} \times S}(W, R) \quad (4)
\end{aligned}$$

(3) follows after substituting (4) into (2).

We next prove that  $\sum_{V \in \mathcal{V}_k, W \in \mathcal{W}_k} \frac{f_1(V, E) f_2(W, E)}{\sum_{U \in \mathcal{L}(\mathcal{C})} \varphi^{KT(U, R)}} \leq \varphi^{-k_{max}}$ . To do so, we define a function  $g : \mathcal{V}_k \times \mathcal{W}_k \rightarrow \mathcal{L}(\mathcal{C})$  as follows: for any  $(V, W) \in \mathcal{V}_k \times \mathcal{W}_k$ ,  $g(V, W)$  is obtained from  $V$  by applying a permutation over  $A_k^* \cup S$  so that the preferences of  $g(V, W)$  over  $A_k^* \cup S$  become the preferences of  $W$  over  $A_k^* \cup S$ , while the other pairwise comparisons stay the same as in  $V$ . This means that the positions of  $A_k \cup \{c\}$  in  $g(V, W)$  are the same as in  $V$ . It is not hard to verify that for all pairs  $(V_1, W_1) \neq (V_2, W_2)$ , we have  $g(V_1, W_1) \neq g(V_2, W_2)$ , which means that  $\{g(V, W) : V \in \mathcal{V}_k, W \in \mathcal{W}_k\} \subseteq \mathcal{L}(\mathcal{C})$ .

**Claim 1.** For any  $(V, W) \in \mathcal{V}_k \times \mathcal{W}_k$ ,  $f_1(V, E) f_2(W, E) \leq \varphi^{KT(g(V, W), R) - k_{max}}$ .

**Proof:** By the definition of  $g(V, W)$  we have  $D_{A_k \times (A_k \cup \{c\})}(V, R) = D_{A_k \times (A_k \cup \{c\})}(g(V, W), R)$  and  $D_{A_k^* \times (A_k^* \cup S)}(W, R) = D_{A_k^* \times (A_k^* \cup S)}(g(V, W), R)$ . Therefore,

$$\begin{aligned}
& f_1(V, E) f_2(W, E) / \varphi^{g(V, W)} \\
&= \frac{\varphi^{D_{A_k \times (A_k^* \cup S)}(V, R) + D_{\{c\} \times S}(V, R) + D_{\{c\} \times A_k^*}(W, R)}}{\varphi^{D_{(A_k \cup \{c\}) \times (A_k^* \cup S)}(g(V, W), R)}} \\
&\leq \varphi^{-\sum_{a \in A_k \cup \{c\}, b \in A_k^* \cup S} |w_R(a, b)|} \leq \varphi^{-k_{max}}
\end{aligned}$$

□

By Claim 1 we have

$$\begin{aligned}
& \sum_{0 \leq k \leq |T|} \sum_{V \in \mathcal{V}_k, W \in \mathcal{W}_k} \frac{f_1(V, E) f_2(W, E)}{\sum_{U \in \mathcal{L}(\mathcal{C})} \varphi^{KT(U, R)}} \\
&\leq \sum_{0 \leq k \leq |T|} \frac{\sum_{V \in \mathcal{V}_k, W \in \mathcal{W}_k} f_1(V, E) f_2(W, E)}{\sum_{V \in \mathcal{V}_k, W \in \mathcal{W}_k} \varphi^{KT(g(V, W), R)}} \\
&\leq \sum_{0 \leq k \leq |T|} \max_{V \in \mathcal{V}_k, W \in \mathcal{W}_k} f_1(V, E) f_2(W, E) / \varphi^{KT(g(V, W), R)} \\
&\leq m \varphi^{-k_{max}}
\end{aligned}$$

This proves the inequality for  $E$ . The inequality for  $E'$  is proved similarly by letting  $A_k^*$  denote the alternatives in  $T_k^*$  and letting  $S$  denote the alternatives in  $B$  plus  $d$ . □

Combining Lemma 3 and inequality (1), we have  $\rho \leq 2m^4 d_{max}^3 \varphi^{-k_{max}}$ . We also note that for any state  $V$ ,  $\pi(V) \geq \varphi^{nm^2} / m!$ , which means that  $\ln \pi(V)^{-1}$  is  $O(nm^3 \log m \ln \varphi^{-1})$ . The theorem follows after applying Lemma 2. □

**Remarks:** The upper bound proved in Theorem 3 is polynomial in  $m, n, d_{max}, \ln \epsilon^{-1}$ , and is exponential in  $k_{max}$  (with base  $\varphi^{-1}$ ). Therefore, the algorithm is efficient if  $d_{max}$  and  $\varphi^{-k_{max}}$  are small, that is, either  $\varphi$  is close to 1 or  $k_{max}$  is small. The next proposition shows that the mixing time of  $\mathfrak{M}_M$  is sometimes  $\Omega(m\varphi^{-k_{max}/2})$ .

**Proposition 1.** *There exists a constant  $\alpha$  so that for any  $m \geq 3$ , there exists a profile  $R$  and the mixing time of  $\mathfrak{M}_M$  is at least  $\alpha m \varphi^{-k_{max}/2} \ln(2\epsilon)^{-1}$ .*

**Proof:** For any  $m \geq 3$  and any even number  $l$  we can construct a profile  $R^l$  with polynomial many votes using McGarvey’s trick (McGarvey, 1953) such that the  $\text{WMG}(R^l)$  contains only three edges:  $a_1 \rightarrow a_2, a_2 \rightarrow a_3, a_3 \rightarrow a_1$ , and the weight on all three edges is  $l$ .

It is easy to check that  $k_{max} = 2l$ . We prove the lower bound on the mixing time by applying Lemma 2(ii) and the conductance approach.

**Definition 6** (Sinclair and Jerrum (1989)). *The conductance of a Markov chain  $\mathfrak{M}$  is defined as*

$$\Phi(\mathfrak{M}) = \min_{S \subseteq \Theta: \pi(S) \leq 1/2} \frac{Q(S, \bar{S})}{\pi(S)},$$

where  $Q(S, \bar{S}) = \sum_{V \in S, W \in \bar{S}} Q(V, W)$ .

The spectral gap is related to the conductance in the following lemma proved by Sinclair and Jerrum (1989).

**Lemma 5** ((Sinclair and Jerrum, 1989)). *For any reversible Markov chain whose conductance is  $\Phi$ , the second eigenvalue  $\lambda_1$  satisfies  $1 - 2\Phi \leq \lambda_1 \leq 1 - \frac{\Phi^2}{2}$ .*

We recall that all eigenvalues of  $\mathfrak{M}_M$  are non-negative. Therefore, the spectral gap of  $\mathfrak{M}_M$  is  $1 - \lambda_1$ , which is at most  $2\Phi$ . The following claim gives an upper bound on the conductance for all  $R^l$ .

**Claim 2.** *There exists  $\beta > 0$  so that for all even number  $l$ ,  $\Phi(\mathfrak{M}_M) \leq \beta \frac{1}{m} \varphi^{k_{max}/2}$  for all  $R^l$ .*

**Proof:** We let  $S \subseteq \Theta$  denote the set of rankings where  $a_1 \succ a_2 \succ a_3$ . For any  $V \in S$  and  $W \in \bar{S}$ , if  $P(V, W) > 0$  then either  $a_2 \succ_W a_1 \succ_W a_3$  or  $a_1 \succ_W a_3 \succ_W a_2$ , which means that  $Q(V, \bar{S})/\pi(V) \leq \frac{1}{m-1} \varphi^{k_{max}/2}$ . Therefore,  $\frac{Q(S, \bar{S})}{\pi(S)} = \frac{\sum_{V \in S} Q(V, \bar{S})}{\sum_{V \in S} \pi(V)} \leq \frac{1}{m-1} \varphi^{k_{max}/2}$ . It is easy to check that  $1/6 \leq \pi(S) \leq 1/3$ , which means that there exists  $\beta > 0$  so that  $\Phi(\mathfrak{M}_M) \leq \frac{Q(S, \bar{S})}{\pi(S)} \leq \beta \frac{1}{m} \varphi^{k_{max}/2}$ .  $\square$

Combining Lemma 5 and Claim 2 we have  $1 - \lambda_{max} = 1 - \lambda_1 \leq \beta \frac{1}{m} \varphi^{k_{max}/2}$ . It follows from Lemma 1(ii) that  $\max_V \tau_V(\epsilon) \geq \frac{\beta}{2} m \varphi^{-k_{max}/2} \ln(2\epsilon)^{-1}$ .  $\square$

## 4 MARKOV CHAIN FOR CONDORCET’S MODEL

For Condorcet’s model it has been shown by Young (1988) that for any  $W \in \mathcal{B}(\mathcal{C})$  and any profile  $R$ ,  $\Pr_{\mathcal{C}}(R|W) \propto$

$\prod_{a \succ_W b} \left(\frac{\varphi}{1-\varphi}\right)^{R[a \succ b]}$ , where we recall that  $R[a \succ b]$  is the number of times  $a \succ b$  in  $R$ . This leads to the following observation.

**Proposition 2.** *Let  $R$  denote a profile of binary relations.  $V \in \mathcal{B}(\mathcal{C})$  maximizes the likelihood if and only if for any pair of alternatives  $(a, b)$ , we have  $(R[a \succ b] > R[b \succ a]) \Rightarrow (a \succ_V b)$ .*

An immediate corollary is that for any profile  $R$ , computing the MLE is in  $\mathbf{P}$ . While computing the expected Bayesian loss w.r.t. the exact Top-1 loss function is in  $\mathbf{P}$  (Young, 1988; Elkind and Shah, 2014; Azari Soufiani et al., 2014), for some natural loss functions computing the minimum expected Bayesian loss is  $\mathbf{NP}$ -hard. Formally, in a  $\text{MIN-BAYESIANLOSS}$  problem, we are given a SDT framework, a prior, a decision  $d \in \mathcal{D}$ , and a number  $l$ . We are asked whether there exists a decision whose expected Bayesian loss is no more than  $l$ .

**Theorem 4.**  *$\text{MINBAYESIANLOSS}$  can be computed in polynomial time for Condorcet’s model w.r.t.  $L_{\text{ETop-}k}$  and the uniform prior for any fixed  $k$ . It is  $\mathbf{NP}$ -hard to compute  $\text{MINBAYESIANLOSS}$  for Condorcet’s model w.r.t.  $L_{\text{ETop-}\frac{m}{2}}$  and the uniform prior for even  $m$ .*

**Proof:** For any fixed  $k$ , the Bayesian loss of any decision can be computed by enumerating all combinations of alternatives ranked at top  $k$  positions in the ground truth, the probability of which can be computed by Claim 3 below.

We prove the  $\mathbf{NP}$ -hardness of  $\text{MINBAYESIANLOSS}$  for Condorcet’s model w.r.t.  $L_{\text{ETop-}\frac{m}{2}}$  by a reduction from an  $\mathbf{NP}$ -hard problem called  $\text{ONEWAYBISECTION}$  (Feige and Yahalom, 2003). In a  $\text{ONEWAYBISECTION}$  instance, we are given an oriented graph  $G = (\mathcal{V}, \mathcal{E})$  with  $m$  vertices, where  $m$  is even, and we are asked whether there exists a partition of  $\mathcal{V} = \mathcal{S} \cup \mathcal{T}$  so that  $|\mathcal{S}| = |\mathcal{T}| = \frac{m}{2}$  and there is no edge from  $\mathcal{T}$  to  $\mathcal{S}$ . For any  $\text{ONEWAYBISECTION}$  instance, we construct a  $\text{MINBAYESIANLOSS}$  instance as follows.

The alternatives are the vertices. The preferences  $R$  are obtained by McGarvey’s trick (McGarvey, 1953) so that the positive edges in  $\text{WMG}(R)$  are the same as in  $G$ , and all positive weights are 2.  $\varphi = 2^{-m^2}$ .  $l = 1 - 2^{-m^2/4}$ .

For any  $A \subseteq \mathcal{C}$ , we let  $\Pr(A \succ \bar{A}|R)$  denote the posterior probability that all alternatives in  $A$  are preferred to all alternatives in  $\bar{A}$ . That is,  $h(A) = \sum_{W: A \succ_W \bar{A}} \Pr(W|R)$ . The next claim follows after calculations in (Elkind and Shah, 2014; Azari Soufiani et al., 2014).

**Claim 3.**  $\Pr(A \succ \bar{A}|R) = \prod_{a \in A, b \in \bar{A}} F(a, b)$ , where

$$F(a, b) = \begin{cases} \frac{1}{1+\varphi^2} & \text{if } w_R(a, b) = 2 \\ \frac{\varphi}{1+\varphi^2} & \text{if } w_R(a, b) = -2 \\ 1/2 & \text{if } w_R(a, b) = 0 \end{cases}$$

Therefore, if the  $\text{ONEWAYBISECTION}$  instance has a solution  $A$ , then the expected Bayesian loss for any alternative in  $A$  is at most  $1 - \Pr(A \succ \bar{A}|R) \leq 1 - 2^{-m^2/4}$ ,

which means that the MINBAYESIANLOSS instance is a “yes” instance. If the ONEWAYBISECTION instance does not have a solution, then for any alternative  $a \in \mathcal{C}$ , the expected Bayesian loss is at least  $1 - \binom{m}{m/2} \frac{\varphi^2}{1+\varphi^2} > 1 - 2^{m \log m} \frac{\varphi^2}{1+\varphi^2} > 1 - 2^{-m^2/4}$ , which means that the MINBAYESIANLOSS instance is a “no” instance.  $\square$

We now present the Markov chain  $\mathfrak{M}_C$  for Condorcet’s model in Algorithm 3, which runs  $\mathfrak{M}_C$  for  $N$  steps.  $\mathfrak{M}_C$  is an *independent sampler* and starts at an arbitrary state that maximizes the likelihood. In each step, a candidate next state is drawn independent of the current state, which means that  $p_X(\cdot)$  is the same for all  $X$ . We let  $p(\cdot)$  denote this proposal distribution.

In  $\mathfrak{M}_C$ ,  $p(\cdot)$  is the posterior probability *assuming that the prior is uniform*. In other words, for any  $W \in \mathcal{B}(\mathcal{C})$ ,  $p(W)$  is proportional to  $\Pr(R|W)$ . A binary relation in  $\mathcal{B}(\mathcal{C})$  can be efficiently generated from  $p(\cdot)$  by generating pairwise comparisons between alternatives independently, such that for each pair of alternatives  $(a, b)$ ,  $\frac{\Pr(a \succ_W b)}{\Pr(b \succ_W a)} = \frac{\varphi^{R[b \succ a]}}{\varphi^{R[a \succ b]}} = \varphi^{R[b \succ a] - R[a \succ b]}$ .

---

**Algorithm 3** Markov chain  $\mathfrak{M}_C$  for Condorcet’s model.

---

- 1: **Inputs:** a profile  $R$ , a prior  $\Pr_C$  over  $\mathcal{L}(\mathcal{C})$ , and the number of iterations  $N$ .
  - 2: Let  $V \in \mathcal{B}(\mathcal{C})$  denote a binary relation with the maximum likelihood computed by Proposition 2.
  - 3: **for**  $t=1$  **to**  $N$  **do**
  - 4:   Generate  $W \in \mathcal{B}(\mathcal{C})$  where all pairwise comparisons are generated independently such that for any  $(a, b)$ ,  $\frac{\Pr(a \succ b)}{\Pr(b \succ a)} = \varphi^{R[b \succ a] - R[a \succ b]}$ .
  - 5:   With probability  $\min\{\frac{\Pr_C(W)}{\Pr_C(V)}, 1\}$  let  $V = W$ .
  - 6: **end for**
  - 7: **return**  $V$ .
- 

**Theorem 5.** *The mixing time of  $\mathfrak{M}_C$  in Algorithm 3 is  $O((\ln \frac{d_{max}}{d_{max}-1})^{-1} (\ln d_{max} + m \ln m + \ln \epsilon^{-1}))$ .*

**Proof:** We apply a result by Liu (1996) to prove the upper bound on the variation distance.

**Lemma 6** ((Liu, 1996)). *For any independent sampler starting at  $V$ , we have*

$$\Delta_V(t) \leq \frac{(1 - \min_W \{p(W)/\pi(W)\})^t}{2\sqrt{\pi(V)}}$$

For any  $W$ , we have  $p(W) = \frac{\Pr(R|W)}{\sum_{U \in \mathcal{B}(\mathcal{C})} \Pr(R|U)}$  and  $\pi(W) = \Pr(W|R) = \frac{\Pr(R|W) \cdot \Pr(W)}{\sum_{U \in \mathcal{B}(\mathcal{C})} \Pr(R|U) \cdot \Pr(U)}$ . Therefore  $\frac{p(W)}{\pi(W)} = \frac{1}{\Pr(W)} \cdot \frac{\sum_{U \in \mathcal{B}(\mathcal{C})} \Pr(R|U) \cdot \Pr(U)}{\sum_{U \in \mathcal{B}(\mathcal{C})} \Pr(R|U)} \geq \min_U \{\frac{\Pr(U)}{\Pr(Y)}\} \geq \frac{1}{d_{max}}$ . By Lemma 6 we have  $\Delta_V(t) \leq \frac{1}{2\sqrt{\pi(V)}} \cdot (1 - \frac{1}{d_{max}})^t$ . Therefore,  $\tau_V(\epsilon)$  is  $O((\ln \frac{d_{max}}{d_{max}-1})^{-1} (\ln \pi(V)^{-1} + \ln \epsilon^{-1}))$ . When  $V$  maxi-

mizes the likelihood, we have  $\pi(V) \geq \frac{1}{d_{max} m!}$ . Applying Stirling’s formula we have  $\ln \pi(V)^{-1}$  is  $O(\ln d_{max} + m \ln m)$ , which proves the theorem.  $\square$

## 5 EXPERIMENTS

Most theoretical results in this paper are based on worst-case analysis. In this section we present some preliminary experimental results to illustrate the efficiency of our algorithms for real-world ranking data.

**Dataset:** We use the weighted majority graph dataset from Preflib (Mattei and Walsh, 2013) ([www.Preflib.org](http://www.Preflib.org)). Most of these datasets are collected from political elections. For each WMG, we normalize the weights to  $[-1, 1]$  by dividing all weights by the heaviest one. This is without loss of generality because we can set  $\varphi$  appropriately.

All experiments were run on a laptop with Intel i7-4600U processor, 8GB memory, and 256 GB SSD hard drive, running Windows 8.1 (64bit) and Python 2.7.9 (32bit).

### 5.1 MALLOWS’ MODEL

We tested Algorithm 1 with Algorithm 2 for the decision problem with Mallows’ model,  $\varphi = 0.9$ ,  $\mathcal{D} = \mathcal{C}$ , uniform prior, and the exact Top-1 loss function for  $m = 5$  through 11. We use brute-force enumeration to compute the optimal decision and discard the first 1/8 samples in our MCMC algorithm as burn-in. The average running time and convergence of Bayesian loss computed for all datasets with the same number of alternatives are shown in Figure 1.<sup>4</sup>

In Figure 1 (a) we observe that the running time of brute-force search grows exponentially in  $m$  (because the number of parameters is  $m!$ ) while the running time for our MCMC algorithm grows linearly in  $m$ . Figure 1 (b) shows the reduction of the total difference between the estimated Bayesian loss via MCMC and the ground truth computed by brute-force search w.r.t. the number of samples. We note that this is *not* the variance distance. The average is taken over all datasets with the same number of alternatives. We observe that the total difference can be effectively reduced by increasing the number of samples. Moreover, when we use 10 million samples, the optimal Bayesian decision is correct in 109 out of 115 datasets ( $\approx 95\%$ ) as shown in Table 2.

| $m =$     | 5  | 6  | 7  | 8  | 9  | 10 | 11 | Total |
|-----------|----|----|----|----|----|----|----|-------|
| correct   | 18 | 13 | 18 | 11 | 17 | 20 | 12 | 109   |
| incorrect | 0  | 0  | 2  | 1  | 3  | 0  | 0  | 6     |

Table 2: The number of correct and incorrect Bayesian decisions for Mallows’ model.

<sup>4</sup>We have also tested the efficiency of the algorithm with larger  $N$  in Algorithm 2, and observe that the efficiency is in general lower than the efficiency when all samples are used.

(a) Average running time.

(b) Average total difference.

Figure 1: The average running time and average total difference of our algorithm for Mallows' model.

## 5.2 CONDORCET'S MODEL

We tested Algorithm 1 with Algorithm 3 for the decision problem with Condorcet's model,  $\varphi = 0.9$ ,  $\mathcal{D} = \mathcal{C}$ , uniform prior, and the exact Top- $\lfloor \frac{m}{2} \rfloor$  loss function for  $m = 5$  through 11. Given a binary relation  $W \in \mathcal{B}(\mathcal{C})$  and an alternative  $d$ , the exact Top- $k$  loss can be computed by the following polynomial-time algorithm. We say an alternative  $a$  dominates another alternative  $b$  in  $W$ , if there is a directed path from  $a$  to  $b$  in  $W$ . For each alternative  $c$ , we first compute the set of all alternatives that dominate  $c$ , denoted by  $D_c$ . By definition we have  $c \in D_c$ . Then, the loss of  $d$  is 0 if and only if there exists an alternative  $c$  such that (1)  $|D_c| = k$  and (2)  $d \in D_c$ ; otherwise the loss of  $d$  is 1.

By Theorem 4, when  $k$  is small there exists a polynomial-time algorithm to compute the Bayesian losses. This makes experiments on Preflib data hard because the algorithm can efficiently compute the optimal Bayesian losses for reasonably large  $m$  (for example  $m = 20$ ), and there are not enough datasets with  $m > 20$ . Therefore, we only show the reduction in average total difference in Figure 2. Extensive experimental studies on real-world datasets are left for future work.

In Figure 2 we observe that (i) for the same number of samples the total difference for Condorcet's model is smaller than the total difference for Mallows' model, and (ii) with the same number of samples, larger  $m$  corresponds to smaller total difference. (The total difference for  $m = 11$  is too small to be seen clearly in Figure 2.) This may be due to two reasons. First,  $\mathfrak{M}_C$  has a better theoretical guarantee (that it is fast mixing) than  $\mathfrak{M}_M$ . Second, for Condorcet's model the probability for the loss of any decision (alternative) to be 0 w.r.t. the exact Top- $\lfloor \frac{m}{2} \rfloor$  loss function is small, which means that for most generated samples the loss of all alternatives is 1.

Figure 2: The average total difference for Condorcet's model.

## 6 SUMMARY AND FUTURE WORK

We have proposed and analyzed two MCMC algorithms for making optimal Bayesian decisions for two popular ranking models w.r.t. any prior and loss function. There are many open questions and future directions. Can we improve the analysis to show that the Markov chain for Mallows' model is rapid mixing or prove that the Bayesian decision problems are hard to approximate by efficient randomized algorithms? Can we design and analyze other Markov chain samplers? How to further improve the performance of the Markov chain sampler in practice? How does the Markov chain approach compare to other popular statistical and machine learning techniques, for example importance sampling?

## Abstract

One of the basic tasks of causal discovery is to estimate the causal effect of some set of variables on another given a statistical data set. In this article we bridge the gap between causal structure discovery and the *do*-calculus by proposing a method for the identification of causal effects on the basis of arbitrary (equivalence) classes of semi-Markovian causal models. The approach uses a general logical representation of the equivalence class of graphs obtained from a causal structure discovery algorithm, the properties of which can then be queried by procedures implementing the *do*-calculus inference for causal effects. We show that the method is more efficient than determining causal effects using a naive enumeration of graphs in the equivalence class. Moreover, the method is complete with respect to the identifiability of causal effects for settings, in which extant methods that do not require knowledge of the true graph, offer only incomplete results. The method is entirely modular and easily adapted for different background settings.

## 1 INTRODUCTION

The theory of causal learning is aimed at finding ways to estimate causal effects in a variety of different settings. In the most basic setting the starting point is a statistical data set of measurements over the variables of interest. In this article we explore how quantitative causal effects can be estimated from such data alone, that is, without the additional knowledge of the causal structure.

When the true causal structure (the causal graph) *is* known, the well-known *do*-calculus enables the complete inference (i.e., the identification) of causal effects from the passive observational distribution over the variables (Pearl, 2000;

Shpitser and Pearl, 2006b). However, full knowledge of the true graph requires a rather extensive understanding of the system under investigation. Data alone is in general insufficient to uniquely determine the true causal graph. Even complete discovery methods will usually leave the graph underdetermined (Spirtes et al., 1993).

Here we develop a general method for the combined task of causal structure discovery and the inference about causal effects.<sup>1</sup> Leveraging a constraint satisfaction approach to connect the output of causal discovery algorithms to the *do*-calculus, our method enables the identification of causal effects for arbitrary (equivalence) classes of semi-Markovian causal models (DAGs with latent variables). The primary advantages of the approach are that (i) it does not assume a unique true causal structure, (ii) it is not restricted to particular types of equivalence classes of causal structures, such as partial ancestral graphs (PAGs), (iii) it provides an algorithm that outputs (when possible) at least one estimator of the causal effect, rather than only specifying rules of a calculus, (iv) it considers all *do*-calculus inferences, not just e.g. the so-called backdoor conditions, and (v) it gives the user flexibility e.g. in how statistical conflicts in the data are handled and how the possibility of multiple estimators of a causal effect is addressed. To simplify notation we will, throughout this article, describe our method using a single observational data set as input. However, we emphasize that the method is extremely general, so, where relevant, we will indicate how the approach is extended or adapted to other scenarios.

Figure 1 gives an overview of the computational flow of the proposed method. The method determines whether a causal effect of the form  $P(y \mid do(x), w)$  is identified given a data set as input, and if so, provides a numerical estimate. We use a (complete) causal discovery method to extract from the data as much information as possible about the true causal graph in terms of so-called *d-separation/connection constraints*. We encode these constraints in the language of propositional logic for the constraint solving component, thereby *implicitly* representing the equivalence class

---

<sup>1</sup>See Section 5 for a discussion of related approaches.

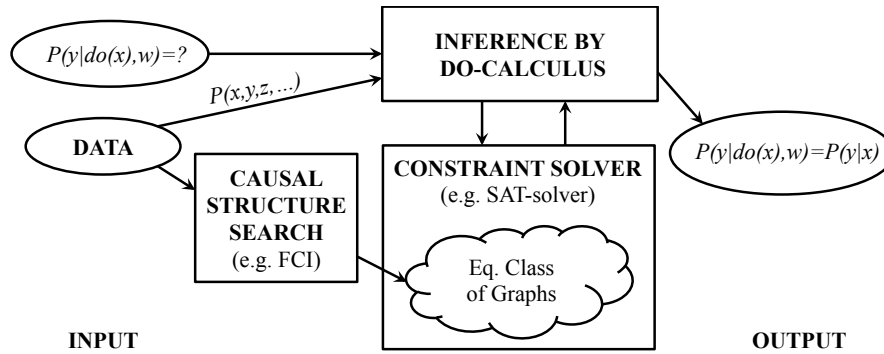

Figure 1: Overall structure of the system.

of causal structures (Hyttinen et al., 2013, 2014). This enables the application of modern constraint solving techniques, such as Boolean satisfiability (SAT) solvers (Biere et al., 2009). We can then use the *do*-calculus to determine whether the causal effect  $P(y | do(x), w)$  is identified by alternating between *do*-calculus inferences and constraining the equivalence class to graphs for which no estimator of the causal effect has been found yet. If the causal effect is identifiable, we obtain a formula and a numerical estimate of the causal effect from the joint probability distribution over the variables.

Our method enables considerable flexibility in addressing the identification problem: The representation of the candidate causal structures in terms of a logical formula frees us from the restriction to settings where standard graphical representations of equivalence classes of causal graphs apply. We can include a wide variety of background constraints or additional knowledge, e.g., from experiments. We can leverage the full inferential power of the *do*-calculus without having to explicitly enumerate every causal structure consistent with the data. Nevertheless, we can (and do) instantiate an implicit exhaustive search that ensures that we preserve the completeness guarantees of *both* the causal discovery procedure and the *do*-calculus.

The paper is structured as follows: In Section 2 we describe the model space and assumptions used and give a concise problem statement. Section 3 explains the inference algorithms, whose completeness properties are discussed in Section 4. In Section 5 we describe known results and approaches that are closely related to ours or that provide context. Section 6 provides simulated results illustrating our main points.

## 2 PROBLEM SETUP

Following the standard set-up of the *do*-calculus, we assume that the causal system can be represented by a semi-Markovian causal model (SMCM). In other words, the un-

Figure 2: a) Example of a SMCM graph for which the causal effect  $P(y|do(x))$  is identifiable even when the graph is unknown. b) Example of a SMCM graph for which the causal effect  $P(y|do(x))$  is not identifiable even when the graph is known (since the graph includes a *hedge*).

derlying causal structure over a set of causal variables  $\mathbf{V}$  is described by a directed acyclic graph  $G$ , in which the directed edges correspond to direct causal relations between the variables (relative to  $\mathbf{V}$ ), and confounding of any two observed variables by some unobserved common cause  $U$  is represented by a bi-directed edge between the variables (thereby omitting  $U$  for simplicity in the graph; see Figure 2). The causal structure gives rise to a probability distribution that is assumed to be Markov and faithful to the graph. No further parametric assumption about the distribution is made. Importantly, Markov and faithfulness ensure that the probabilistic (in)dependencies of the distribution correspond to *d*-separation/connection relations in the causal graph.<sup>2</sup>

Under specific *d*-separation conditions on the underlying causal structure, the rules of the *do*-calculus (see Figure 3) license inferences between the passive observational distribution  $P(\mathbf{V})$  and the corresponding (conditional) interventional distributions  $P(y | w, do(x))$ , where one or more variables  $x \subset \mathbf{V}$  have been subject to intervention and variables  $w \subset \mathbf{V}$  are conditioned on. By using an additional exogenous intervention variable  $I_X$  with  $I_X \rightarrow X$  for each variable  $X$ , the *d*-separation conditions of the *do*-calculus can be stated as in Figure 3 (see Pearl (1995, p. 686) for the

<sup>2</sup>See Spirtes et al. (1993) for a precise statement of the assumptions and for a definition of *d*-separation.

**Rule 1** (Insertion/deletion of observations):

$$P(y|do(x), z, w) = P(y|do(x), w) \text{ if } Y \perp\!\!\!\perp Z|X, W||X$$

**Rule 2** (Action/observation exchange):

$$P(y|do(x), do(z), w) = P(y|do(x), z, w) \text{ if } Y \perp\!\!\!\perp I_Z|X, Z, W||X$$

**Rule 3** (Insertion/deletion of actions):

$$P(y|do(x), do(z), w) = P(y|do(x), w) \text{ if } Y \perp\!\!\!\perp I_Z|X, W||X$$

**Rule 4** (Marginalization/sum-rule):

$$P(y|do(x), w) = \sum_z P(y, z|do(x), w)$$

**Rule 5** (Conditioning):

$$P(y|do(x), z, w) = \frac{P(y, z|do(x), w)}{\sum_y P(y, z|do(x), w)}$$

**Rule 6** (product/chain-rule):

$$P(y, z|do(x), w) = P(y|do(x), w, z)P(z|do(x), w)$$

Figure 3: Rules of the do-calculus.

proof of equivalence to the standard conditions; see also Spirtes et al. (1993, p. 79)). The d-separation conditions of each rule have the general form of ‘ $Y \perp\!\!\!\perp Z | X, W || X$ ’, where  $W, X, Y, Z$  are disjoint sets of variables in the graph (including intervention variables), and ‘ $|| X$ ’ denotes an intervention on  $X$ : any edges with arrowheads into the variables in  $X$  are cut.

Given a graph  $G$ , the identifiability of a causal effect is now defined as follows (see Pearl (2000), Def. 3.2.4, p. 77): a causal effect is identifiable if and only if it can be uniquely computed from  $G$  and any positive input distribution  $P()$  that is Markov to  $G$ , i.e., there are no two causal models with structure  $G$  that are Markov to  $P()$  but have different numerical values for the causal effect.

An algorithm to apply the do-calculus when the true graph is known was developed by Tian and Pearl (2002), which with some modifications was shown to be complete for the identification of (conditional) causal effects by Shpitser and Pearl (2006b) (see also Huang and Valtorta (2006)). The *Shpitser algorithm* provides (given the graph and the observational distribution) one estimator of the causal effect, if such an estimator exists. When the causal effect is non-identifiable, it returns a feature of the graph, known as a *hedge*, that proves non-identifiability (see Figure 2b for an example; see Shpitser and Pearl (2006b) for the exact definition).

Since we do not assume that the true graph  $G$  is known, we take a causal effect to be identifiable given the equivalence class of causal structures deemed consistent with the input data if and only if the causal effect is (Pearl-) identifiable by the same estimator for each member of the equivalence class.

As shown in the simulations in Section 6, the causal effect is very often not uniquely identifiable from data when the true graph is unknown. So, instead of outputting only whether an effect is identifiable, and the estimate if it is, we follow Maathuis et al. (2009), who output a (multi)set of causal effect estimates that in some cases can be used to obtain bounds on the true causal effect. This leads to the following problem statement.

### Problem Statement

**INPUT:** Data set  $D$  generated from an SMCM over variables  $\mathbf{V}$  and a query about a causal effect  $P(y | do(x), w)$ .

**TASK:** Output a set of causal effect estimates  $S$  such that it includes an estimate for  $P(y | do(x), w)$  for any causal structure that is consistent with  $D$ . Include ‘NA’ in  $S$ , if the causal effect is not identifiable for some causal structure consistent with  $D$ .

## 3 THE APPROACH

We proceed by describing the main contribution of this work: a general method for the estimation of causal effects. In the following, we will specify the main components (recall Figure 1) of our approach. First, we give details on how we connect the causal structure discovery algorithm of choice with the constraint solving component that maintains a logical representation of the equivalence class of models under consideration. Then, we describe the do-calculus inference component and its iterative interactions with the constraint solver.

### 3.1 Querying the Equivalence Class

We use (for purposes of illustration) the FCI-algorithm (Spirtes et al., 1993) to determine the equivalence class of candidate causal structures from the data set. The FCI-algorithm considers the same class of causal models as the do-calculus: acyclic causal structures with latent variables. It is complete with respect to knowledge about the underlying causal structure that can be obtained from conditional independence tests. Most importantly, FCI achieves this d-separation completeness while performing very few redundant tests. It thus also lends itself to the efficient characterization of the equivalence class in terms of a small set of d-separation constraints that can be fed to the constraint solver.

---

**Algorithm 1** Do-calculus Inference.

---

Input:  $P(y|do(x), w)$ , an equivalence class  $E$  of SMCM graphs.

Initialize the set  $S$  of causal effect estimates as empty.

While  $E$  is nonempty:

Find a graph  $G$  from the equivalence class  $E$ .

Find a formula  $F$  by calling Shpitser’s algorithm for graph  $G$ . If the algorithm does not find a formula but returns a hedge  $H$ , restrict eq. class  $E$  not to include  $H$ , add NA to  $S$  and continue the loop from the beginning.

Find a derivation for  $F$  by calling Algorithm 2 for graph  $G$  and the input distributions used in  $F$ .

Using  $F$  and the (estimated)  $P(\mathbf{V})$ , compute the estimate for the causal effect and add it to  $S$ .

Restrict the eq. class  $E$  to not satisfy at least one of the required d-separations in derivation  $D$ .

Return a set  $S$  of numerical causal effect estimates.

---

We translate the d-separation constraints of the equivalence class into a logical representation using the ASP-encoding of Hyttinen et al. (2014). We can then query the constraint solver to obtain graphs from the equivalence class or to check whether any graphical conditions, such as d-separations or ancestral relations, apply to all, some or none of the members in the equivalence class, and we can further restrict the equivalence class with additional constraints.

For other settings or different background assumptions, the FCI algorithm can be substituted with any other structure discovery method. If one has reason to think that there are no latent variables, we would recommend using an exact Bayesian search algorithm, or the PC- or GES-algorithms if something more scalable is required (Spirtes et al., 1993; Chickering, 2002). If the causal constraints are to be obtained from heterogeneous data sets, possibly including experimental data or background knowledge, then a search algorithm such as GIES, IOD or a SAT-based procedure may be better (Hauser and Bühlmann, 2012; Tillman and Spirtes, 2011; Triantafillou and Tsamardinos, 2014; Hyttinen et al., 2014). The overall completeness of our method depends in part, of course, on whether the causal discovery method is complete.

### 3.2 Identifying Causal Effects

Algorithm 1 instantiates the *do*-calculus inference on a given equivalence class. It queries the constraint solver for a graph  $G$  in the equivalence class (one truth-value assignment to the logical formula) and calls Shpitser’s algorithm on  $G$  to identify the desired causal effect.

If Shpitser’s algorithm fails to identify the effect and returns a hedge  $H$ , then the causal effect is non-identifiable for  $G$ . Consequently, Algorithm 1 adds ‘NA’ to the set

---

**Algorithm 2** Do-calculus Derivation.

---

Input:  $P(y|do(x), w)$ , a SMCM graph  $G$ , and a set of distributions  $P = \{P_1, \dots\}$ .

For each  $P_i$  in  $P$ :

Derive the distributions computable from  $P_i$  using the rules of the do-calculus such that:

- The required d-separation conditions are satisfied by  $G$ .
- All variables appearing in the derived distributions are ancestors of  $Y \cup W$  (see Shpitser and Pearl (2006a)).
- For an application of the product rule, both required distributions are in  $P$ .

Add the new distributions to  $P$  and record the used rules and the required d-separations.

If  $P(y|do(x), w)$  was derived, return the formula, the rules, and the d-separations used on the way.

Return “the effect is not identifiable”.

---

$S$  of causal effect estimates to mark the non-identifiability. In addition, we restrict the equivalence class to not include any graphs that have the hedge  $H$ , as the causal effect is unidentifiable for such graphs as well.

If Shpitser’s algorithm returns a formula  $F$ , then the causal effect is identifiable on the basis of the (marginal conditional) distributions  $\{P_1, \dots\}$  used in  $F$ . Algorithm 2 is then called with the causal effect query, the graph  $G$  and the list of distributions  $\{P_1, \dots\}$  to obtain a ‘derivation’ for the formula. This derivation specifies the rules of the do-calculus used to derive the formula  $F$  and consequently the set of d-separation constraints  $C$  that warrant the use of this estimate. The numerical estimate is added to  $S$ . This estimate is now valid for all graphs that satisfy the d-separation constraints in  $C$ . Then, the equivalence class is again restricted to disregard such graphs by ensuring that at least one of the constraints in  $C$  is no longer satisfied, i.e., we add the negation of the conjunction of constraints in  $C$  to the constraint solver. We repeatedly solve for a new graph  $G$  from the restricted equivalence class until the class becomes empty, at which time we have the solution to the Problem Statement. Note that the repeated restrictions of the equivalence class avoid an explicit enumeration of all the members of the equivalence class, allowing for faster operation.

Algorithm 2 implements the search for a valid do-calculus derivation for a formula. We need such a derivation as Shpitser’s algorithm does not output the set of d-separations needed for the validity of the formula. Algorithm 2 does an exhaustive breadth-first-search, producing computable distributions that are warranted by the input graph and do-calculus. It stops when a derivation for the causal effect is found. The algorithm can be made sufficiently efficient because 1) we only input the distributions that are used in

the formula given by Shpitser’s algorithm, 2) we use the fact that only variables that are ancestors of  $Y \cup W$  can be helpful in determining the causal effect (Shpitser and Pearl, 2006b), and 3) causal structures usually permit the identification of fairly few distributions.

Figure 9 at the end of the paper shows an example run of Algorithm 1 for one particular equivalence class.

## 4 COMPLETENESS RESULTS

The completeness properties of our method are derivative of the completeness properties of the causal discovery algorithm of choice and the *do*-calculus. Given a complete structure search algorithm, such as FCI, we obtain in the large sample limit the Markov equivalence class of the true causal structure. If the causal effect in this equivalence class is non-identifiable, it is either because one graph in the equivalence class contains a *hedge*, which proves non-identifiability, or because there are two graphs which have different estimators for the causal effect. Algorithm 1 repeatedly performs the (complete) Shpitser algorithm on members of the equivalence class, each time restricting the equivalence class to graphs for which the discovered derivations of an estimator do not hold. Consequently, its output must eventually identify a graph with a hedge if there is one, since implicitly the entire set of graphs in the equivalence class is enumerated. If no graph with a hedge is found, then Algorithm 1 only terminates once there is a derivation of an estimator of the causal effect for each graph in the equivalence class. A check whether these formulas are the same determines the identifiability. (In the presented version of the algorithms we only output the numerical estimates, but the formulas could easily be added to avoid any formal concern that there could be coincidentally identical numerical values of the causal effect derived from two different estimators.)

We note that the FCI algorithm is not complete with regard to so-called *Verma constraints* that can further restrict the equivalence class of causal structures (Shpitser and Pearl, 2008). We are not aware of any search algorithm that is complete in this regard. However, any specific Verma constraint that may be established for a particular case, can easily be included and the set of estimators our method returns will be complete with regard to that additional constraint.

For settings involving multiple data sets or experimental data sets, there exist d-separation complete structure search algorithms, but it is not known whether the *do*-calculus is complete for these settings. Certainly, Shpitser’s algorithm is restricted to the passive observational distribution. For the restricted experimental settings described in Bareinboim and Pearl (2012), we could replace Shpitser’s algorithm with Bareinboim’s method in Algorithm 1 and retain completeness, since Bareinboim shows completeness for the identification problem in these so-called “surrogate

experiments”. In the future, we hope our approach can aid the identification of causal effects from multiple data sets of non-identical populations (Bareinboim and Pearl, 2013).

## 5 RELATED WORK

Building the connection between causal structure discovery and causal effect inference seems essential if one wants to complete the aim of causal learning from data sets to causal effects. We consider it all the more important given that significant parts of the causal literature regard the problem of identifying the causal effect *given* the causal structure as entirely separate from the problem of discovering the causal structure in the first place. For example, the entire literature on algorithms applying the *do*-calculus assumes — generally without further discussion — that the causal graph is known (Tian and Pearl, 2002; Huang and Valtorta, 2006; Shpitser and Pearl, 2006b; Bareinboim and Pearl, 2012). In the general model space that the *do*-calculus allows for, the causal structure can hardly ever be uniquely determined from the passive observational distribution or even from the experimental distributions that Bareinboim and Pearl (2012) consider. Still, the algorithms rely on being able to check complicated features of the causal structure. Similarly, the methods of causal structure discovery often remain silent on how exactly one should determine the causal effects given their output equivalence class.<sup>3</sup> There need not be any harm in this division of labor if there is an obvious and satisfactory answer of how to connect the two. We assume that the standard proposal would be to take the equivalence class of causal structures output by a search algorithm, enumerate each member of the equivalence class, and perform the *do*-calculus algorithm on each member to determine (the identifiability of) the causal effect. Effectively, this is what is done in the IDA-algorithm which returns (multi-sets of) estimates of the causal effects of variables from an equivalence class of causal structures under the assumption that there are no latent variables (Maathuis et al., 2009). However, such an explicit enumeration of the members of an equivalence class can very quickly become unwieldy (see also (Malinsky, 2015)). In our simulations (Section 6) we show that our approach is more efficient than a naive enumeration combined with the *do*-calculus inference.

Zhang (2008), instead, developed a *do*-calculus directly for the equivalence classes represented by partial ancestral graphs (PAGs; see also Richardson and Spirtes (2003)). As he explains, the calculus is not complete and no inference algorithm to apply the calculus is given (although Zhang notes that his results could be used to improve on the ear-

<sup>3</sup>The same is not true for methods of causal discovery that include a parametric assumption (e.g. linearity, additive noise, non-Gaussianity, etc), since in these cases the identification of the qualitative causal effect generally corresponds to providing a quantitative estimate of it.

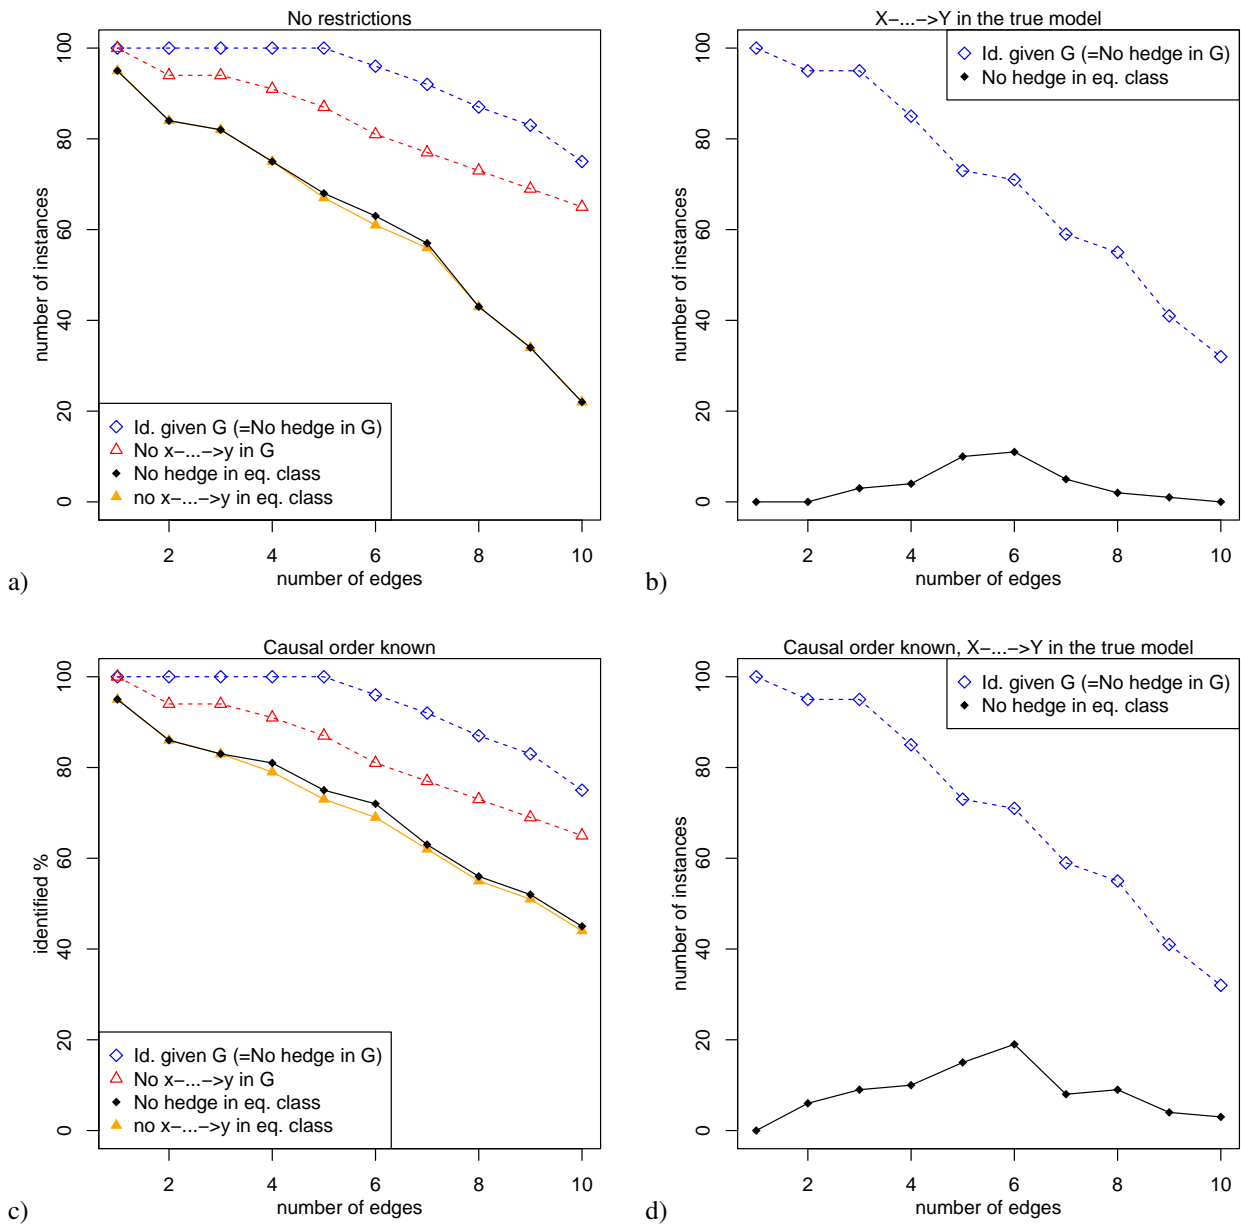

Figure 4: Identifiability of the causal effect  $P(y|do(x))$  over random 5-variable graphs.

lier Prediction Algorithm by Spirtes et al. (1993)). His approach is closely related to ours, with the main difference that we do not restrict ourselves to equivalence classes of SMCMs that are PAGs and that our procedure is complete for his setting.

Also relying on PAGs, Maathuis and Colombo (2015) focus on a subset of Zhang’s invariance principles (which themselves are implied by the *do*-calculus) in order to specify conditions on a PAG that allow for the identification of an *adjustment set*, i.e., a set of variables  $W$  that block all so-called “backdoor paths” between  $X$  and  $Y$ , and allow for the causal effect  $P(y | do(x))$  to be estimated using  $P(y | w, x)$ . In our approach their “generalized backdoor criterion” corresponds to the simple and intuitive d-separation conditions that are required for the estimation of the causal effect ( $w \perp\!\!\!\perp I_x$  and  $y \perp\!\!\!\perp I_x | x, w$ ). These we can directly query on *any* class of SMCMs, not just on PAGs (or MAGs or DAGs).

More data-driven methods to find adjustment sets have also been developed (De Luna et al., 2011; Entner et al., 2013; VanderWeele and Shpitser, 2011). These do not rely explicitly on a graphical representation of the causal knowledge, but specify independence conditions that can be directly checked in the data. This is a very attractive direction of research, since it cuts out the graph from the inference procedure altogether. However, extant methods rely on a variety of general background assumptions about how the causal variables may be related (e.g. order assumptions) that we do not require. More generally, methods for the identification of adjustment sets obviously do not exhaust the identifiability conditions for causal effects for which the *do*-calculus was shown to be complete. Most prominently, the so-called “front-door” criterion for identifiability is not considered. Thus, one of the contributions of our method is to enable the full identification power of the *do*-calculus in settings when the causal structure is underdetermined.

## 6 SIMULATIONS

These simulations explore the identifiability of the causal effects when the true causal graph is unknown, the scalability of the methods presented in this paper, and, finally, the accuracy of different causal effect estimates when multiple estimators can be calculated. We implemented the algorithms using R with various packages (Tikka, 2014; Kalisch et al., 2012). Following Hyttinen et al. (2014) for the implementation of the constraint solving component, we employed the off-the-shelf state-of-the-art answer set programming (ASP) solver Clingo version 4.4.0, which at its core uses modern SAT solving techniques to perform a complete search for solutions, and at the same time allows for a natural high-level representation of the structural constraints in logical form (Gebser et al., 2011).

Figure 4 compares the identifiability of the basic causal ef-

fect  $P(y|do(x))$  when the graph is known vs. when only its equivalence class is known. Figure 4a shows the number of identified causal effects in random 5-variable graphs without any restrictions, as density increases. When only the equivalence class is known, the causal effect is almost always either trivially identified as  $X$  is discovered not to be an ancestor of  $Y$  in any member of the equivalence class, or trivially unidentifiable due to a possible hedge in the equivalence class. When the graph is known, a significant number of causal effects are identified even when  $X$  is an ancestor of  $Y$ . This is further highlighted in Figure 4b where  $X$  is required to be an ancestor of  $Y$  in the true graph. Almost no causal effects are identified when only the equivalence class is known. Only in very rare cases can one orient enough edges to deduce the absence of hedges from the equivalence class. This seems to happen when 4-7 edges are present; additional edges often prevent the determination of the orientation. Figure 4c and 4d consider the same comparison with the modification that the true causal order is known by the causal discovery algorithm, and thus fixed in the equivalence class. A few more effects are identified, but since the fixed causal order does not prevent bidirected edges, the improvement on non-trivial instances is limited in Figure 4d.

Figure 5 shows equivalence classes of graphs for which the causal effect is identified even when the true graph is unknown. In each case, we are able to deduce enough edge orientations to prevent the presence of a hedge, and to fix the orientation of the paths from  $X$  to  $Y$ . Note that Figure 5d shows an example for which the *do*-calculus formulation of Zhang (2008) over PAGs is incomplete. Our approach is complete here and can hence identify the conditional causal effect.

We also compared the running times of Algorithm 1 against

Figure 6: Algorithm 1 vs. Enumeration approach.

trivially enumerating all graphs in the equivalence class and running Shpitser’s algorithm on all of them. Figure 6 shows the median times spent by the different parts of the algorithms. Algorithm 1 is much faster. In addition to the time spent on enumerating the whole equivalence class by the ASP constraint solver used here, running Shpitser’s algorithm on so many graphs also takes a considerable amount of time.

Figure 7 shows the median of the time spent during the different operations of Algorithm 1 on larger instances. FCI was run using an independence oracle. Algorithm 1 spends the majority of its time finding graphs for which the formulas obtained in previous iteration rounds are not warranted. For some outlier instances not visible in the median here, Algorithm 2 also needs a considerable amount of time when finding the derivation for a particularly complicated formula. Note that we undergo here a rather heavy task of finding estimates for all graphs in the equivalence class. If we were content to just decide whether the effect is identifiable, the total running times would be considerably lower. However, as shown in Figure 4, the results of that kind of an algorithm would be quite uninformative.

Finally, we examined the benefits of finding more estimators for the causal effect using Algorithm 2 in cases where multiple different estimators exist. We drew random parameters for a binary SMCM with the graph in Figure 2. Given the equivalence class (shown in Figure 5c), the causal effect  $P(y|do(x = 0))$  can be calculated from the passively observed distribution  $P(h, w, x, y, z)$  either by the backdoor formula adjusting for  $h$ , or by the front-door formula relative to  $z$  (see Figure 5c). We also estimated the causal effect by directly sampling from the model when  $x$  is surgically fixed to 0. Figure 8 shows the average KL-divergence of the different estimators. The distributions

Figure 7: Time spent by Algorithm 1.

needed for the estimators were estimated directly (with regularization to avoid zero probabilities). In these simulations the front-door estimator seems to offer better accuracy than the backdoor estimator. By intervention we can obtain still higher accuracy than either of the estimates obtained from passively observed data. Shpitser’s algorithm gives here only the backdoor formula. This simulation shows that it may be beneficial to consider many estimators of a causal effect instead of using only a single consistent formula.

## 7 CONCLUSION

In this work we explored the possibilities of estimating causal effects from data. We have considerably relaxed the assumption of the known true graph, which has been standard in the literature on the *do*-calculus. Although causal effects are rarely identified when the true graph is unknown, our approach can still generate informative output in terms of a set of estimates. Unlike other approaches that perform only a limited set of causal effect inferences, our method retains the completeness properties of the used causal discovery algorithm and the *do*-calculus inference. We hope that the flexible machinery presented in this paper can be used to obtain further graphical criteria for identifiability, and will help in achieving more completeness results.

## Abstract

We propose an efficient nonparametric strategy for learning a message operator in expectation propagation (EP), which takes as input the set of incoming messages to a factor node, and produces an outgoing message as output. This learned operator replaces the multivariate integral required in classical EP, which may not have an analytic expression. We use kernel-based regression, which is trained on a set of probability distributions representing the incoming messages, and the associated outgoing messages. The kernel approach has two main advantages: first, it is fast, as it is implemented using a novel two-layer random feature representation of the input message distributions; second, it has principled uncertainty estimates, and can be cheaply updated online, meaning it can request and incorporate new training data when it encounters inputs on which it is uncertain. In experiments, our approach is able to solve learning problems where a single message operator is required for multiple, substantially different data sets (logistic regression for a variety of classification problems), where it is essential to accurately assess uncertainty and to efficiently and robustly update the message operator.

## 1 INTRODUCTION

An increasing priority in Bayesian modelling is to make inference accessible and implementable for practitioners, without requiring specialist knowledge. This is a goal

sought, for instance, in probabilistic programming languages (Wingate et al., 2011; Goodman et al., 2008), as well as in more granular, component-based systems (Stan Development Team, 2014; Minka et al., 2014). In all cases, the user should be able to freely specify what they wish their model to express, without having to deal with the complexities of sampling, variational approximation, or distribution conjugacy. In reality, however, model convenience and simplicity can limit or undermine intended models, sometimes in ways the users might not expect. To take one example, the inverse gamma prior, which is widely used as a convenient conjugate prior for the variance, has quite pathological behaviour (Gelman, 2006). In general, more expressive, freely chosen models are more likely to require expensive sampling or quadrature approaches, which can make them challenging to implement or impractical to run.

We address the particular setting of expectation propagation (Minka, 2001), a message passing algorithm wherein messages are confined to being members of a particular parametric family. The process of integrating incoming messages over a factor potential, and projecting the result onto the required output family, can be difficult, and in some cases not achievable in closed form. Thus, a number of approaches have been proposed to implement EP updates numerically, independent of the details of the factor potential being used. One approach, due to Barthelmé and Chopin (2011), is to compute the message update via importance sampling. While these estimates converge to the desired integrals for a sufficient number of importance samples, the sampling procedure must be run at every iteration during inference, hence it is not viable for large-scale problems.

An improvement on this approach is to use importance sampled instances of input/output message pairs to train a regression algorithm, which can then be used in place

of the sampler. Heess et al. (2013) use neural networks to learn the mapping from incoming to outgoing messages, and the learned mappings perform well on a variety of practical problems. This approach comes with a disadvantage: it requires training data that cover the entire set of possible input messages for a given type of problem (e.g., datasets representative of all classification problems the user proposes to solve), and it has no way of assessing the uncertainty of its prediction, or of updating the model online in the event that a prediction is uncertain.

The disadvantages of the neural network approach were the basis for work by Eslami et al. (2014), who replaced the neural networks with random forests. The random forests provide uncertainty estimates for each prediction. This allows them to be trained ‘just-in-time’, during EP inference, whenever the predictor decides it is uncertain. Uncertainty estimation for random forests relies on unproven heuristics, however: we demonstrate empirically that such heuristics can become highly misleading as we move away from the initial training data. Moreover, online updating can result in unbalanced trees, resulting in a cost of prediction of  $O(N)$  for training data of size  $N$ , rather than the ideal of  $O(\log(N))$ .

We propose a novel, kernel-based approach to learning a message operator nonparametrically for expectation propagation. The learning algorithm takes the form of a distribution regression problem, where the inputs are probability measures represented as embeddings of the distributions to a reproducing kernel Hilbert space (RKHS), and the outputs are vectors of message parameters (Szabó et al., 2014). A first advantage of this approach is that one does not need to pre-specify customized features of the distributions, as in (Eslami et al., 2014; Heess et al., 2013). Rather, we use a general characteristic kernel on input distributions (Christmann and Steinwart, 2010, eq. 9). To make the algorithm computationally tractable, we regress directly in the primal from random Fourier features of the data (Rahimi and Recht, 2007; Le et al., 2013; Yang et al., 2015). In particular, we establish a novel random feature representation for when inputs are distributions, via a two-level random feature approach. This gives us both fast prediction (linear in the number of random features), and fast online updates (quadratic in the number of random features).

A second advantage of our approach is that, being an instance of Gaussian process regression, there are well established estimates of predictive uncertainty (Rasmussen and Williams, 2006, Ch. 2). We use these uncertainty estimates so as to determine when to query the importance sampler for additional input/output pairs, i.e., the uncertain predictions trigger just-in-time updates of the regressor. We demonstrate empirically that our uncertainty estimates are more robust and informative than those for random forests, especially as we move away from the training data.

Figure 1: Distributions of incoming messages to logistic factor in four different UCI datasets.

Our paper proceeds as follows. In Section 2, we introduce the notation for expectation propagation, and indicate how an importance sampling procedure can be used as an oracle to provide training data for the message operator. We also give a brief overview of previous learning approaches to the problem, with a focus on that of Eslami et al. (2014). Next, in Section 3, we describe our kernel regression approach, and the form of an efficient kernel message operator mapping the input messages (distributions embedded in an RKHS) to outgoing messages (sets of parameters of the outgoing messages). Finally, in Section 4, we describe our experiments, which cover three topics: a benchmark of our uncertainty estimates, a demonstration of factor learning on artificial data with well-controlled statistical properties, and a logistic regression experiment on four different real-world datasets, demonstrating that our just-in-time learner can correctly evaluate its uncertainty and update the regression function as the incoming messages change (see Fig. 1). Code to implement our method is available online at <https://github.com/wittawatj/kernel-ep>.

## 2 BACKGROUND

We assume that distributions (or densities)  $p$  over a set of variables  $\mathbf{x} = (x_1, \dots, x_d)$  of interest can be represented as factor graphs, i.e.  $p(\mathbf{x}) = \frac{1}{Z} \prod_{j=1}^J f_j(\mathbf{x}_{\text{ne}(f_j)})$ . The factors  $f_j$  are non-negative functions which are defined over subsets  $\mathbf{x}_{\text{ne}(f_j)}$  of the full set of variables  $\mathbf{x}$ . These variables form the neighbors of the factor node  $f_j$  in the factor graph, and we use  $\text{ne}(f_j)$  to denote the corresponding set of indices.  $Z$  is the normalization constant.

We deal with models in which some of the factors have a non-standard form, or may not have a known analytic expression (i.e. ‘‘black box’’ factors). Although our approach applies to any such factor in principle, in this paper we focus on *directed* factors  $f(\mathbf{x}_{\text{out}}|\mathbf{x}_{\text{in}})$  which specify a conditional distribution over variables  $\mathbf{x}_{\text{out}}$  given  $\mathbf{x}_{\text{in}}$  (and thus  $\mathbf{x}_{\text{ne}(f)} = (\mathbf{x}_{\text{out}}, \mathbf{x}_{\text{in}})$ ). The only assumption we make is that we are provided with a forward sampling function  $f : \mathbf{x}_{\text{in}} \mapsto \mathbf{x}_{\text{out}}$ , i.e., a function that maps (stochastically or deterministically) a setting of the input variables  $\mathbf{x}_{\text{in}}$  to a sample from the conditional distribution

over  $\mathbf{x}_{\text{out}} \sim f(\cdot|\mathbf{x}_{\text{in}})$ . In particular, the ability to evaluate the value of  $f(\mathbf{x}_{\text{out}}|\mathbf{x}_{\text{in}})$  is not assumed. A natural way to specify  $f$  is as code in a probabilistic program.

## 2.1 EXPECTATION PROPAGATION

Expectation Propagation (EP) is an approximate iterative procedure for computing marginal beliefs of variables by iteratively passing messages between variables and factors until convergence (Minka, 2001). It can be seen as an alternative to belief propagation, where the marginals are projected onto a member of some class of known parametric distributions. The message  $m_{f \rightarrow V}(x_V)$  from factor  $f$  to variable  $V \in \text{ne}(f)$  is

$$\frac{\text{proj} \left[ \int f(\mathbf{x}_{\text{ne}(f)}) \prod_{V' \in \text{ne}(f)} m_{V' \rightarrow f}(x_{V'}) d\mathbf{x}_{\text{ne}(f) \setminus V} \right]}{m_{V \rightarrow f}(x_V)}, \quad (1)$$

where  $m_{V' \rightarrow f}$  are the messages sent to factor  $f$  from all of its neighboring variables  $x_{V'}$ ,  $\text{proj}[p] = \text{argmin}_{q \in \mathcal{Q}} \text{KL}[p||q]$ , and  $\mathcal{Q}$  is typically in the exponential family, e.g. the set of Gaussian or Beta distributions.

Computing the numerator of (1) can be challenging, as it requires evaluating a high-dimensional integral as well as minimization of the Kullback-Leibler divergence to some non-standard distribution. Even for factors with known analytic form this often requires hand-crafted approximations, or the use of expensive numerical integration techniques; for “black-box” factors implemented as forward sampling functions, fully nonparametric techniques are needed.

Barthelmé and Chopin (2011); Heess et al. (2013); Eslami et al. (2014) propose an alternative, stochastic approach to the integration and projection step. When the projection is to a member  $q(x|\eta) = h(x) \exp(\eta^\top u(x) - A(\eta))$  of an exponential family, one simply computes the expectation of the sufficient statistic  $u(\cdot)$  under the numerator of (1). A sample based approximation of this expectation can be obtained via Monte Carlo simulation. Given a forward-sampling function  $f$  as described above, one especially simple approach is importance sampling,

$$\mathbb{E}_{\mathbf{x}_{\text{ne}(f)} \sim b} [u(x_V)] \approx \frac{1}{M} \sum_{l=1}^M w(\mathbf{x}_{\text{ne}(f)}^l) u(x_V^l), \quad (2)$$

where  $\mathbf{x}_{\text{ne}(f)}^l \sim \tilde{b}$ , for  $l = 1, \dots, M$  and on the left hand side,

$$b(\mathbf{x}_{\text{ne}(f)}) = f(\mathbf{x}_{\text{ne}(f)}) \prod_{W \in \text{ne}(f)} m_{W \rightarrow f}(x_W).$$

On the right hand side we draw samples  $\mathbf{x}_{\text{ne}(f)}^l$  from some proposal distribution  $\tilde{b}$  which we choose to be  $\tilde{b}(\mathbf{x}_{\text{ne}(f)}) = r(\mathbf{x}_{\text{in}})f(\mathbf{x}_{\text{out}}|\mathbf{x}_{\text{in}})$  for some distribution  $r$  with appropriate

support, and compute importance weights

$$w(\mathbf{x}_{\text{ne}(f)}) = \frac{\prod_{W \in \text{ne}(f)} m_{W \rightarrow f}(x_W)}{r(\mathbf{x}_{\text{in}})}.$$

Thus the estimated expected sufficient statistics provide us with an estimate of the parameters  $\eta$  of the result  $q$  of the projection  $\text{proj}[p]$ , from which the message is readily computed.

## 2.2 JUST-IN-TIME LEARNING OF MESSAGES

Message approximations as in the previous section could be used directly when running the EP algorithm, as in Barthelmé and Chopin (2011), but this approach can suffer when the number of samples  $M$  is small, and the importance sampling estimate is not reliable. On the other hand, for large  $M$  the computational cost of running EP with approximate messages can be very high, as importance sampling must be performed for sending each outgoing message. To obtain low-variance message approximations at lower computational cost, Heess et al. (2013) and Eslami et al. (2014) both amortize previously computed approximate messages by training a function approximator to directly map a tuple of incoming variable-to-factor messages  $(m_{V' \rightarrow f})_{V' \in \text{ne}(f)}$  to an approximate factor to variable message  $m_{f \rightarrow V}$ , i.e. they learn a mapping

$$M_{f \rightarrow V}^\theta : (m_{V' \rightarrow f})_{V' \in \text{ne}(f)} \mapsto m_{f \rightarrow V}, \quad (3)$$

where  $\theta$  are the parameters of the approximator.

Heess et al. (2013) use neural networks and a large, fixed training set to learn their approximate message operator prior to running EP. By contrast, Eslami et al. (2014) employ random forests as their class of learning functions, and update their approximate message operator on the fly during inference, depending on the predictive uncertainty of the current message operator. Specifically, they endow their function approximator with an uncertainty estimate

$$\mathfrak{V}_{f \rightarrow V}^\theta : (m_{V' \rightarrow f})_{V' \in \text{ne}(f)} \mapsto \mathbf{v}, \quad (4)$$

where  $\mathbf{v}$  indicates the expected unreliability of the predicted, approximate message  $m_{f \rightarrow V}$  returned by  $M_{f \rightarrow V}^\theta$ . If  $\mathbf{v} = \mathfrak{V}_{f \rightarrow V}^\theta((m_{V' \rightarrow f})_{V' \in \text{ne}(f)})$  exceeds a predefined threshold, the required message is approximated via importance sampling (cf. (2)) and  $M_{f \rightarrow V}^\theta$  is updated on this new datapoint (leading to a new set of parameters  $\theta'$  with  $\mathfrak{V}_{f \rightarrow V}^{\theta'}((m_{V' \rightarrow f})_{V' \in \text{ne}(f)}) < \mathfrak{V}_{f \rightarrow V}^\theta((m_{V' \rightarrow f})_{V' \in \text{ne}(f)})$ ).

Eslami et al. (2014) estimate the predictive uncertainty  $\mathfrak{V}_{f \rightarrow V}^\theta$  via the heuristic of looking at the variability of the forest predictions for each point (Criminisi and Shotton, 2013). They implement their online updates by splitting the trees at their leaves. Both these mechanisms can be problematic, however. First, the heuristic used in computing uncertainty has no guarantees: indeed, uncertainty estimation

for random forests remains a challenging topic of current research (Hutter, 2009). This is not merely a theoretical consideration: in our experiments in Section 4, we demonstrate that uncertainty heuristics for random forests become unstable and inaccurate as we move away from the initial training data. Second, online updates of random forests may not work well when the newly observed data are from a very different distribution to the initial training sample (e.g. Lakshminarayanan et al., 2014, Fig. 3). For large amounts of training set drift, the leaf-splitting approach of Eslami et al. can result in a decision tree in the form of a long chain, giving a worst case cost of prediction (computational and storage) of  $O(N)$  for training data of size  $N$ , vs the ideal of  $O(\log(N))$  for balanced trees. Finally, note that the approach of Eslami et al. uses certain bespoke features of the factors when specifying tree traversal in the random forests, notably the value of the factor potentials at the mean and mode of the incoming messages. These features require expert knowledge of the model on the part of the practitioner, and are not available in the “forward sampling” setting. The present work does not employ such features.

In terms of computational cost, prediction for the random forest of Eslami et al. costs  $O(KD_r D_t \log(N))$ , and updating following a new observation costs  $O(KD_r^3 D_t \log(N))$ , where  $K$  is the number of trees in the random forest,  $D_t$  is the number of features used in tree traversal,  $D_r$  is the number of features used in making predictions at the leaves, and  $N$  is the number of training messages. Representative values are  $K = 64$ ,  $D_t = D_r \approx 15$ , and  $N$  in the range of 1,000 to 5,000.

### 3 KERNEL LEARNING OF OPERATORS

We now propose a kernel regression method for jointly learning the message operator  $M_{f \rightarrow V}^\theta$  and uncertainty estimate  $\mathfrak{A}_{f \rightarrow V}^\theta$ . We regress from the tuple of incoming messages, which are probability distributions, to the parameters of the outgoing message. To this end we apply a kernel over distributions from (Christmann and Steinwart, 2010) to the case where the input consists of more than one distribution.

We note that Song et al. (2010, 2011) propose a related regression approach for predicting outgoing messages from incoming messages, for the purpose of belief propagation. Their setting is different from ours, however, as their messages are smoothed conditional density functions rather than parametric distributions of known form.

To achieve fast predictions and factor updates, we follow Rahimi and Recht (2007); Le et al. (2013); Yang et al. (2015), and express the kernel regression in terms of random features whose expected inner product is equal to the kernel function; i.e. we perform regression directly in the primal on these random features. In Section 3.1, we de-

fine our kernel on tuples of distributions, and then derive the corresponding random feature representation in Section 3.2. Section 3.3 describes the regression algorithm, as well as our strategy for uncertainty evaluation and online updates.

#### 3.1 KERNELS ON TUPLES OF DISTRIBUTIONS

In the following, we consider only a single factor, and therefore drop the factor identity from our notation. We write the set of  $c$  incoming messages to a factor node as a tuple of probability distributions  $R := (r^{(l)})_{l=1}^c$  of random variables  $X^{(l)}$  on respective domains  $\mathcal{X}^{(l)}$ . Our goal is to define a kernel between one such tuple, and a second one, which we will write  $S := (s^{(l)})_{l=1}^c$ .

We define our kernel in terms of embeddings of the tuples  $R, S$  into a reproducing kernel Hilbert space (RKHS). We first consider the embedding of a single distribution in the tuple: Let us define an RKHS  $\mathcal{H}^{(l)}$  on each domain, with respective kernel  $k^{(l)}(x_1^{(l)}, x_2^{(l)})$ . We may embed individual probability distributions to these RKHSs, following (Smola et al., 2007). The *mean embedding* of  $r^{(l)}$  is written

$$\mu_{r^{(l)}}(\cdot) := \int k^{(l)}(x^{(l)}, \cdot) dr^{(l)}(x^{(l)}). \quad (5)$$

Similarly, a mean embedding may be defined on the product of messages in a tuple  $r = \times_{l=1}^c r^{(l)}$  as

$$\mu_r := \int k([x^{(1)}, \dots, x^{(c)}], \cdot) dr(x^{(1)}, \dots, x^{(c)}), \quad (6)$$

where we have defined the joint kernel  $k$  on the product space  $\mathcal{X}^{(1)} \times \dots \times \mathcal{X}^{(c)}$ . Finally, a kernel on two such embeddings  $\mu_r, \mu_s$  of tuples  $R, S$  can be obtained as in Christmann and Steinwart (2010, eq. 9),

$$\kappa(r, s) = \exp\left(-\frac{\|\mu_r - \mu_s\|_{\mathcal{H}}^2}{2\gamma^2}\right). \quad (7)$$

This kernel has two parameters:  $\gamma^2$ , and the width parameter of the kernel  $k$  defining  $\mu_r = \mathbb{E}_{x \sim r} k(x, \cdot)$ .

We have considered several alternative kernels on tuples of messages, including kernels on the message parameters, kernels on a tensor feature space of the distribution embeddings in the tuple, and dot products of the features (6). We have found these alternatives to have worse empirical performance than the approach described above. We give details of these experiments in Section C of the supplementary material.

#### 3.2 RANDOM FEATURE APPROXIMATIONS

One approach to learning the mapping  $M_{f \rightarrow V}^\theta$  from incoming to outgoing messages would be to employ Gaussian process regression, using the kernel (7). This approach is

not suited to just-in-time (JIT) learning, however, as both prediction and storage costs grow with the size of the training set; thus, inference on even moderately sized datasets rapidly becomes computationally prohibitive. Instead, we define a finite-dimensional random feature map  $\hat{\psi} \in \mathbb{R}^{D_{\text{out}}}$  such that  $\kappa(r, s) \approx \hat{\psi}(r)^\top \hat{\psi}(s)$ , and regress directly on these feature maps in the primal (see next section): storage and computation are then a function of the dimension of the feature map  $D_{\text{out}}$ , yet performance is close to that obtained using a kernel.

In [Rahimi and Recht \(2007\)](#), a method based on Fourier transforms was proposed for computing a vector of random features  $\hat{\varphi}$  for a translation invariant kernel  $k(x, y) = k(x - y)$  such that  $k(x, y) \approx \hat{\varphi}(x)^\top \hat{\varphi}(y)$  where  $x, y \in \mathbb{R}^d$  and  $\hat{\varphi}(x), \hat{\varphi}(y) \in \mathbb{R}^{D_{\text{in}}}$ . This is possible because of Bochner’s theorem ([Rudin, 2013](#)), which states that a continuous, translation-invariant kernel  $k$  can be written in the form of an inverse Fourier transform:

$$k(x - y) = \int \hat{k}(\omega) e^{j\omega^\top (x-y)} d\omega,$$

where  $j = \sqrt{-1}$  and the Fourier transform  $\hat{k}$  of the kernel can be treated as a distribution. The inverse Fourier transform can thus be seen as an expectation of the complex exponential, which can be approximated with a Monte Carlo average by drawing random frequencies from the Fourier transform. We will follow a similar approach, and derive a two-stage set of random Fourier features for (7).

We start by expanding the exponent of (7) as

$$\exp\left(-\frac{1}{2\gamma^2} \langle \mu_r, \mu_r \rangle + \frac{1}{\gamma^2} \langle \mu_r, \mu_s \rangle - \frac{1}{2\gamma^2} \langle \mu_s, \mu_s \rangle\right).$$

Assume that the embedding kernel  $k$  used to define the embeddings  $\mu_r$  and  $\mu_s$  is translation invariant. Since  $\langle \mu_r, \mu_s \rangle = \mathbb{E}_{x \sim r} \mathbb{E}_{y \sim s} k(x - y)$ , one can use the result of [Rahimi and Recht \(2007\)](#) to write

$$\begin{aligned} \langle \mu_r, \mu_s \rangle &\approx \mathbb{E}_{x \sim r} \mathbb{E}_{y \sim s} \hat{\varphi}(x)^\top \hat{\varphi}(y) \\ &= \mathbb{E}_{x \sim r} \hat{\varphi}(x)^\top \mathbb{E}_{y \sim s} \hat{\varphi}(y) := \hat{\varphi}(r)^\top \hat{\varphi}(s), \end{aligned}$$

where the mappings  $\hat{\varphi}$  are  $D_{\text{in}}$  standard Rahimi-Recht random features, shown in Steps 1-3 of Algorithm 1.

With the approximation of  $\langle \mu_r, \mu_s \rangle$ , we have

$$\kappa(r, s) \approx \exp\left(-\frac{\|\hat{\varphi}(r) - \hat{\varphi}(s)\|_{D_{\text{in}}}^2}{2\gamma^2}\right), \quad (8)$$

which is a standard Gaussian kernel on  $\mathbb{R}^{D_{\text{in}}}$ . We can thus further approximate this Gaussian kernel by the random Fourier features of [Rahimi and Recht](#), to obtain a vector of random features  $\hat{\psi}$  such that  $\kappa(r, s) \approx \hat{\psi}(r)^\top \hat{\psi}(s)$  where  $\hat{\psi}(r), \hat{\psi}(s) \in \mathbb{R}^{D_{\text{out}}}$ . Pseudocode for generating the random features  $\hat{\psi}$  is given in Algorithm 1. Note that the sine

**Algorithm 1** Construction of two-stage random features for  $\kappa$

---

**Input:** Input distribution  $r$ , Fourier transform  $\hat{k}$  of the embedding translation-invariant kernel  $k$ , number of inner features  $D_{\text{in}}$ , number of outer features  $D_{\text{out}}$ , outer Gaussian width  $\gamma^2$ .

**Output:** Random features  $\hat{\psi}(r) \in \mathbb{R}^{D_{\text{out}}}$ .

- 1: Sample  $\{\omega_i\}_{i=1}^{D_{\text{in}}} \stackrel{i.i.d.}{\sim} \hat{k}$ .
- 2: Sample  $\{b_i\}_{i=1}^{D_{\text{in}}} \stackrel{i.i.d.}{\sim} \text{Uniform}[0, 2\pi]$ .
- 3:  $\hat{\phi}(r) = \sqrt{\frac{2}{D_{\text{in}}}} \left( \mathbb{E}_{x \sim r} \cos(\omega_i^\top x + b_i) \right)_{i=1}^{D_{\text{in}}} \in \mathbb{R}^{D_{\text{in}}}$   
If  $r(x) = \mathcal{N}(x; m, \Sigma)$ ,

$$\hat{\phi}(r) = \sqrt{\frac{2}{D_{\text{in}}}} \left( \cos(\omega_i^\top m + b_i) \exp\left(-\frac{1}{2} \omega_i^\top \Sigma \omega_i\right) \right)_{i=1}^{D_{\text{in}}}.$$

- 4: Sample  $\{\nu_i\}_{i=1}^{D_{\text{out}}} \stackrel{i.i.d.}{\sim} \hat{k}_{\text{gauss}}(\gamma^2)$  i.e., Fourier transform of a Gaussian kernel with width  $\gamma^2$ .
  - 5: Sample  $\{c_i\}_{i=1}^{D_{\text{out}}} \stackrel{i.i.d.}{\sim} \text{Uniform}[0, 2\pi]$ .
  - 6:  $\hat{\psi}(r) = \sqrt{\frac{2}{D_{\text{out}}}} \left( \cos(\nu_i^\top \hat{\phi}(r) + c_i) \right)_{i=1}^{D_{\text{out}}} \in \mathbb{R}^{D_{\text{out}}}$
- 

component in the complex exponential vanishes due to the translation invariance property (analogous to an even function), i.e., only the cosine term remains. We refer to Section B.3 in the supplementary material for more details.

For the implementation, we need to pre-compute  $\{\omega_i\}_{i=1}^{D_{\text{in}}}, \{b_i\}_{i=1}^{D_{\text{in}}}, \{\nu_i\}_{i=1}^{D_{\text{out}}}$  and  $\{c_i\}_{i=1}^{D_{\text{out}}}$ , where  $D_{\text{in}}$  and  $D_{\text{out}}$  are the number of random features used. A more efficient way to support a large number of random features is to store only the random seed used to generate the features, and to generate the coefficients on-the-fly as needed ([Dai et al., 2014](#)). In our implementation, we use a Gaussian kernel for  $k$ .

### 3.3 REGRESSION FOR OPERATOR PREDICTION

Let  $\mathbf{X} = (x_1 | \dots | x_N)$  be the  $N$  training samples of incoming messages to a factor node, and let  $\mathbf{Y} = \left( \mathbb{E}_{x_V \sim q_{f \rightarrow V}^1} u(x_V) | \dots | \mathbb{E}_{x_V \sim q_{f \rightarrow V}^N} u(x_V) \right) \in \mathbb{R}^{D_y \times N}$  be the expected sufficient statistics of the corresponding output messages, where  $q_{f \rightarrow V}^i$  is the numerator of (1). We write  $x_i = \hat{\psi}(r_i)$  as a more compact notation for the random feature vector representing the  $i^{\text{th}}$  training tuple of incoming messages, as computed via Algorithm 1.

Since we require uncertainty estimates on our predictions, we perform Bayesian linear regression from the random features to the output messages, which yields predictions close to those obtained by Gaussian process regression with the kernel in (7). The uncertainty estimate in this case will

be the predictive variance. We assume prior and likelihood

$$w \sim \mathcal{N}(w; 0, I_{D_{\text{out}}}\sigma_0^2), \quad (9)$$

$$Y | X, w \sim \mathcal{N}(Y; w^\top X, \sigma_y^2 I_N), \quad (10)$$

where the output noise variance  $\sigma_y^2$  captures the intrinsic stochasticity of the importance sampler used to generate  $Y$ . It follows that the posterior of  $w$  is given by (Bishop, 2006)

$$p(w|Y) = \mathcal{N}(w; \mu_w, \Sigma_w), \quad (11)$$

$$\Sigma_w = (\mathbf{X}\mathbf{X}^\top \sigma_y^{-2} + \sigma_0^{-2}I)^{-1}, \quad (12)$$

$$\mu_w = \Sigma_w \mathbf{X}Y^\top \sigma_y^{-2}. \quad (13)$$

The predictive distribution on the output  $y^*$  given an observation  $x^*$  is

$$p(y^*|x^*, Y) = \int p(y^*|w, x^*, Y)p(w|Y) dw \quad (14)$$

$$= \mathcal{N}(y^*; x^{*\top} \mu_w, x^{*\top} \Sigma_w x^* + \sigma_y^2). \quad (15)$$

For simplicity, we treat each output (expected sufficient statistic) as a separate regression problem. Treating all outputs jointly can be achieved with a multi-output kernel (Alvarez et al., 2011).

**Online Update** We describe an online update for  $\Sigma_w$  and  $\mu_w$  when observations (i.e., random features representing incoming messages)  $x_i$  arrive sequentially. We use  $\cdot^{(N)}$  to denote a quantity constructed from  $N$  samples. Recall that  $\Sigma_w^{-1(N)} = \mathbf{X}\mathbf{X}^\top \sigma_y^{-2} + \sigma_0^{-2}I$ . The posterior covariance matrix at time  $N + 1$  is

$$\Sigma_w^{(N+1)} = \Sigma_w^{(N)} - \frac{\Sigma_w^{(N)} x_{N+1} x_{N+1}^\top \Sigma_w^{(N)} \sigma_y^{-2}}{1 + x_{N+1}^\top \Sigma_w^{(N)} x_{N+1} \sigma_y^{-2}}, \quad (16)$$

meaning it can be expressed as an inexpensive update of the covariance at time  $N$ . Updating  $\Sigma_w$  for all the  $D_y$  outputs costs  $O((D_{\text{in}}D_{\text{out}} + D_{\text{out}}^2)D_y)$  per new observation. For  $\mu_w = \Sigma_w \mathbf{X}Y^\top \sigma_y^{-2}$ , we maintain  $\mathbf{X}Y^\top \in \mathbb{R}^{D_{\text{out}} \times D_y}$ , and update it at cost  $O(D_{\text{in}}D_{\text{out}}D_y)$  as

$$(\mathbf{X}Y^\top)^{(N+1)} = (\mathbf{X}Y^\top + x_{N+1}y_{N+1}^\top). \quad (17)$$

Since we have  $D_y$  regression functions, for each tuple of incoming messages  $x^*$ , there are  $D_y$  predictive variances,  $v_1^*, \dots, v_{D_y}^*$ , one for each output. Let  $\{\tau_i\}_{i=1}^{D_y}$  be pre-specified predictive variance thresholds. Given a new input  $x^*$ , if  $v_1^* > \tau_1$  or  $\dots$  or  $v_{D_y}^* > \tau_{D_y}$  (the operator is uncertain), a query is made to the oracle to obtain a ground truth  $y^*$ . The pair  $(x^*, y^*)$  is then used to update  $\Sigma_w$  and  $\mu_w$ .

## 4 EXPERIMENTS

We evaluate our learned message operator using two different factors: the logistic factor, and the compound gamma

factor. In the first and second experiment we demonstrate that the proposed operator is capable of learning high-quality mappings from incoming to outgoing messages, and that the associated uncertainty estimates are reliable. The third and fourth experiments assess the performance of the operator as part of the full EP inference loop in two different models: approximating the logistic, and the compound gamma factor. Our final experiment demonstrates the ability of our learning process to reliably and quickly adapt to large shifts in the message distribution, as encountered during inference in a sequence of several real-world regression problems.

For all experiments we used Infer.NET (Minka et al., 2014) with its extensible factor interface for our own operator. We used the default settings of Infer.NET unless stated otherwise. The regression target is the marginal belief (numerator of (1)) in experiment 1,2,3 and 5. We set the regression target to the outgoing message in experiment 4. Given a marginal belief, the outgoing message can be calculated straightforwardly.

Figure 2: Factor graph for binary logistic regression. The kernel-based message operator learns to approximate the logistic factor highlighted in red. The two incoming messages are  $m_{z_i \rightarrow f} = \mathcal{N}(z_i; \mu, \sigma^2)$  and  $m_{p_i \rightarrow f} = \text{Beta}(p_i; \alpha, \beta)$ .

**Experiment 1: Batch Learning** As in (Heess et al., 2013; Eslami et al., 2014), we study the logistic factor  $f(p|z) = \delta\left(p - \frac{1}{1+\exp(-z)}\right)$ , where  $\delta$  is the Dirac delta function, in the context of a binary logistic regression model (Fig. 2). The factor is deterministic and there are two incoming messages:  $m_{p_i \rightarrow f} = \text{Beta}(p_i; \alpha, \beta)$  and  $m_{z_i \rightarrow f} = \mathcal{N}(z_i; \mu, \sigma^2)$ , where  $z_i = w^\top x_i$  represents the dot product between an observation  $x_i \in \mathbb{R}^d$  and the coefficient vector  $w$  whose posterior is to be inferred.

In this first experiment we simply learn a kernel-based operator to send the message  $m_{f \rightarrow z_i}$ . Following Eslami et al. (2014), we set  $d$  to 20, and generated 20 different datasets, sampling a different  $w \sim \mathcal{N}(0, I)$  and then a set of  $\{(x_i, y_i)\}_{i=1}^n$  ( $n = 300$ ) observations according to the model. For each dataset we ran EP for 10 iterations, and collected incoming-outgoing message pairs in the first five iterations of EP from Infer.NET’s implementation of the logistic factor. We partitioned the messages randomly into 5,000 training and 3,000 test messages, and learned a message operator to predict  $m_{f \rightarrow z_i}$  as described in Section 3. Regularization and kernel parameters were chosen

by leave-one-out cross validation. We set the number of random features to  $D_{in} = 500$  and  $D_{out} = 1,000$ ; empirically, we observed no significant improvements beyond 1,000 random features.

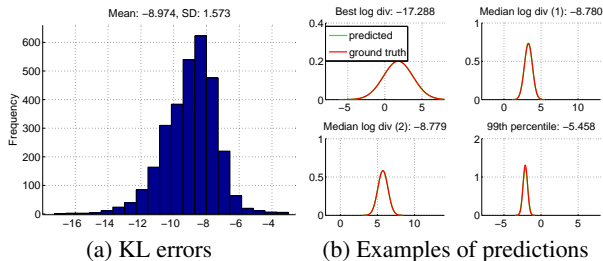

Figure 3: Prediction errors for predicting the projected beliefs to  $z_i$ , and examples of predicted messages at different error levels.

We report  $\log \text{KL}[q_{f \rightarrow z_i} || \hat{q}_{f \rightarrow z_i}]$  where  $q_{f \rightarrow z_i}$  is the ground truth projected belief (numerator of (1)) and  $\hat{q}_{f \rightarrow z_i}$  is the prediction. The histogram of the log KL errors is shown in Fig. 3a; Fig. 3b shows examples of predicted messages for different log KL errors. It is evident that the kernel-based operator does well in capturing the relationship between incoming and outgoing messages. The discrepancy with respect to the ground truth is barely visible even at the 99th percentile. See Section C in the supplementary material for a comparison with other methods.

**Experiment 2: Uncertainty Estimates** For the approximate message operator to perform well in a JIT learning setting, it is crucial to have reliable estimates of operator’s predictive uncertainty in different parts of the space of incoming messages. To assess this property we compute the predictive variance using the same learned operator as used in Fig. 3. The forward incoming messages  $m_{z_i \rightarrow f}$  in the previously used training set are shown in Fig. 4a. The backward incoming messages  $m_{p_i \rightarrow f}$  are not displayed. Shown in the same plot are two curves (a blue line, and a pink parabola) representing two “uncertainty test sets”: these are the sets of parameter pairs on which we wish to evaluate the uncertainty of the predictor, and pass through regions with both high and low densities of training samples. Fig. 4b shows uncertainty estimates of our kernel-based operator and of random forests, where we fix  $m_{p_i \rightarrow f} := \text{Beta}(p_i; 1, 2)$  for testing. The implementation of the random forests closely follows Eslami et al. (2014).

From the figure, as the mean of the test message moves away from the region densely sampled by the training data, the predictive variance reported by the kernel method increases much more smoothly than that of the random forests. Further, our method clearly exhibits a higher uncertainty on the test set #1 than on the test set #2. This

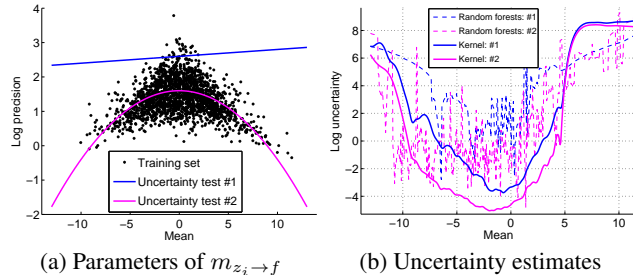

Figure 4: (a) Incoming messages from  $z$  to  $f$  from 20 EP runs of binary logistic regression, as shown in Fig. 2. (b) Uncertainty estimates of the proposed kernel-based method (predictive variance) and Eslami et al.’s random forests (KL-based agreement of predictions of different trees) on the two uncertainty test sets shown. For testing, we fix the other incoming message  $m_{p_i \rightarrow f}$  to  $\text{Beta}(p_i; 1, 2)$ .

behaviour is desirable, as most of the points in test set #1 are either in a low density region or an unexplored region. These results suggest that the predictive variance is a robust criterion for querying the importance sampling oracle. One key observation is that the uncertainty estimates of the random forests are highly non-smooth; i.e., uncertainty on nearby points may vary wildly. As a result, a random forest-based JIT learner may still query the importance sampler oracle when presented with incoming messages similar to those in the training set, thereby wasting computation.

We have further checked that the predictive uncertainty of the regression function is a reliable indication of the error in KL divergence of the predicted outgoing messages. These results are given in Figure 10 of Appendix C.

**Experiment 3: Just-In-Time Learning** In this experiment we test the approximate operator in the logistic regression model as part of the full EP inference loop in a just-in-time learning setting (KJIT). We now learn two kernel-based message operators, one for each outgoing direction from the logistic factor. The data generation is the same as in the batch learning experiment. We sequentially presented the operator with 30 related problems, where a new set of observations  $\{(x_i, y_i)\}_{i=1}^n$  was generated at the beginning of each problem from the model, while keeping  $w$  fixed. This scenario is common in practice: one is often given several sets of observations which share the same model parameter (Eslami et al., 2014). As before, the inference target was  $p(w | \{(x_i, y_i)\}_{i=1}^n)$ . We set the maximum number of EP iterations to 10 in each problem.

We employed a “mini-batch” learning approach in which the operator always consults the oracle in the first few hundred factor invocations for initial batch training. In principle, during the initial batch training, the operator can perform cross validation or type-II maximum likelihood esti-

Figure 5: Uncertainty estimate of KJIT in its prediction of outgoing messages at each factor invocation, for the binary regression problem. The black dashed lines indicate the start of a new inference problem.

mation for parameter selection; however for computational simplicity we set the kernel parameters according to the median heuristic (Schölkopf and Smola, 2002). Full detail of the heuristic is given in Section A in the supplementary material. The numbers of random features were  $D_{\text{in}} = 300$  and  $D_{\text{out}} = 500$ . The output noise variance  $\sigma_y^2$  was fixed to  $10^{-4}$  and the uncertainty threshold on the log predictive variance was set to  $-8.5$ . To simulate a black-box setup, we used an importance sampler as the oracle rather than Infer.NET’s factor implementation, where the proposal distribution was fixed to  $\mathcal{N}(z; 0, 200)$  with  $5 \times 10^5$  particles.

Fig. 5 shows a trace of the predictive variance of KJIT in predicting the mean of each  $m_{f \rightarrow z_i}$  upon each factor invocation. The black dashed lines indicate the start of a new inference problem. Since the first 300 factor invocations are for the initial training, no uncertainty estimate is shown. From the trace, we observe that the uncertainty rapidly drops down to a stable point at roughly  $-8.8$  and levels off after the operator sees about 1,000 incoming-outgoing message pairs, which is relatively low compared to approximately 3,000 message passings (i.e., 10 iterations  $\times$  300 observations) required for one problem. The uncertainty trace displays a periodic structure, repeating itself in every 300 factor invocations, corresponding to a full sweep over all 300 observations to collect incoming messages  $m_{z_i \rightarrow f}$ . The abrupt drop in uncertainty in the first EP iteration of each new problem is due to the fact that Infer.NET’s inference engine initializes the message from  $w$  to have zero mean, leading to  $m_{z_i \rightarrow f}$  also having a zero mean. Repeated encounters of such a zero mean incoming message reinforce the operator’s confidence; hence the drop in uncertainty.

Fig. 6a shows binary classification errors obtained by using the inferred posterior mean of  $w$  on a test set of size 10000 generated from the true underlying parameter. Included in the plot are the errors obtained by using only the importance sampler for inference (“Sampling”), and using the Infer.NET’s hand-crafted logistic factor. The loss of KJIT matches well with that of the importance sampler and Infer.NET, suggesting that the inference accuracy is as good as these alternatives. Fig. 6b shows the inference time required by all methods in each problem. While the inference quality is equally good, KJIT is orders of magnitude faster

Figure 6: Classification performance and inference times of all methods in the binary logistic regression problem.

than the importance sampler.

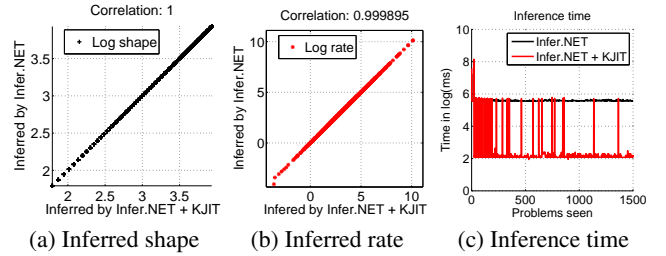

Figure 7: Shape (a) and rate (b) parameters of the inferred posteriors in the compound gamma problem. (c) KJIT is able to infer equally good posterior parameters compared to Infer.NET, while requiring a runtime several orders of magnitude lower.

**Experiment 4: Compound Gamma Factor** We next simulate the compound gamma factor, a heavy-tailed prior distribution on the precision of a Gaussian random variable. A variable  $\tau$  is said to follow the compound gamma distribution if  $\tau \sim \text{Gamma}(\tau; s_2, r_2)$  (shape-rate parameterization) and  $r_2 \sim \text{Gamma}(r_2; s_1, r_1)$  where  $(s_1, r_1, s_2)$  are parameters. The task we consider is to infer the posterior of the precision  $\tau$  of a normally distributed variable  $x \sim \mathcal{N}(x; 0, \tau)$  given realizations  $\{x_i\}_{i=1}^n$ . We consider the setting  $(s_1, r_1, s_2) = (1, 1, 1)$  which was used in Heess et al. (2013). Infer.NET’s implementation requires two gamma factors to specify the compound gamma. Here, we collapse them into one factor and let the operator learn to

Figure 8: Uncertainty estimate of KJIT for outgoing messages on the four UCI datasets.

directly send an outgoing message  $m_{f \rightarrow \tau}$  given  $m_{\tau \rightarrow f}$ , using Infer.NET as the oracle. The default implementation of Infer.NET relies on a quadrature method. As in Eslami et al. (2014), we sequentially presented a number of problems to our algorithm, where at the beginning of each problem, a random number of observations  $n$  from 10 to 100, and the parameter  $\tau$ , were drawn from the model.

Fig. 7a and Fig. 7b summarize the inferred posterior parameters obtained from running only Infer.NET and Infer.NET + KJIT, i.e., KJIT with Infer.NET as the oracle. Fig. 7c shows the inference time of both methods. The plots collectively show that KJIT can deliver posteriors in good agreement with those obtained from Infer.NET, at a much lower cost. Note that in this task only one message is passed to the factor in each problem. Fig. 7c also indicates that KJIT requires fewer oracle consultations as more problems are seen.

**Experiment 5: Classification Benchmarks** In the final experiment, we demonstrate that our method for learning the message operator is able to detect changes in the distribution of incoming messages via its uncertainty estimate, and to subsequently update its prediction through additional oracle queries. The different distributions of incoming messages are achieved by presenting a sequence of different classification problems to our learner. We used four binary classification datasets from the UCI repository (Lichman, 2013): banknote authentication, blood transfusion, fertility and ionosphere, in the same binary logistic regression setting as before. The operator was required to learn just-in-time to send outgoing messages  $m_{f \rightarrow z_i}$  and  $m_{f \rightarrow p_i}$  on the four problems presented in sequence. The training observations consisted of 200 data points subsampled from each dataset by stratified sampling. For the fertility dataset, which contains only 100 data points, we subsampled half the points. The remaining data were used as test sets. The uncertainty threshold was set to -9, and the minibatch size was 500. All other parameters were the same as in the earlier JIT learning experiment.

Classification errors on the test sets and inference times are shown in Fig. 9a and Fig. 9b, respectively. The results demonstrate that KJIT improves the inference time on all the problems without sacrificing inference accuracy. The predictive variance of each outgoing message is shown in

Figure 9: Classification performance and inference times on the four UCI datasets.

Fig. 8. An essential feature to notice is the rapid increase of the uncertainty after the first EP iteration of each problem. As shown in Fig. 1, the distributions of incoming messages of the four problems are diverse. The sharp rise followed by a steady decrease of the uncertainty is a good indicator that the operator is able to promptly detect a change in input message distribution, and robustly adapt to this new distribution by querying the oracle.

## 5 CONCLUSIONS AND FUTURE WORK

We have proposed a method for learning the mapping between incoming and outgoing messages to a factor in expectation propagation, which can be used in place of computationally demanding Monte Carlo estimates of these updates. Our operator has two main advantages: it can reliably evaluate the uncertainty of its prediction, so that it only consults a more expensive oracle when it is uncertain, and it can efficiently update its mapping online, so that it learns from these additional consultations. Once trained, the learned mapping performs as well as the oracle mapping, but at a far lower computational cost. This is in large part due to a novel two-stage random feature representation of the input messages. One topic of current research is hyperparameter selection: at present, these are learned on an initial mini-batch of data, however a better option would be to adapt them online as more data are seen.

## ACKNOWLEDGEMENT

We thank the anonymous reviewers for their constructive comments. WJ, AG, BL, and ZS thank the Gatsby Charitable Foundation for the financial support.

## Abstract

We give algorithms for Bayesian learning of decomposable graphical models from complete data. We build on a recently proposed dynamic programming algorithm that finds optimal graphs of  $n$  nodes in  $O(4^n)$  time and  $O(3^n)$  space (Kangas et al., NIPS 2014), and show how it can be turned into accurate averaging algorithms. Specifically, we show that certain marginals of the posterior distribution, like the posterior probability of an edge, can be computed in  $O(n^3 3^n)$  time, provided that the prior over the graphs is of an appropriate form. To overcome some limitations of the exact approach, we also give sampling schemes that—using essentially no extra space—can draw up to  $3^n$  independent graphs from the posterior in  $O(n 4^n)$  time. Through importance sampling, this enables accurate Bayesian inference with a broader class of priors. Using benchmark datasets, we demonstrate the method’s performance and the advantage of averaging over optimization when learning from little data.

## 1 INTRODUCTION

A *decomposable graphical model* represents conditional independence relations between a set of variables by an undirected graph that is *decomposable*, or equivalently, *triangulated* or *chordal*. Due to their various nice properties—in particular, convenient parameterization, straightforward parameter learning from complete data, and computationally efficient inference—decomposable models have played a central role in both methodological and applied works (Lauritzen and Spiegelhalter 1988, Dawid and Lauritzen 1993, Abel and Thomas 2011).

It is common that the modeller hesitates to fix any specific graph, and would rather like to learn the graph from data. Learning the graph has, however, proved to be computationally very challenging (Srebro 2003, Corander et al. 2013).

The Bayesian approach, in particular, requires us to turn a prior into a posterior over all possible decomposable graphs. Or more practically, the interest is in drawing a representative (random) sample from the posterior or summarizing the posterior by some of its marginals. Solving these tasks by exhaustive enumeration of all graphs is feasible only up to about eight nodes. To manage with larger graphs, several Markov chain Monte Carlo (MCMC) methods have been proposed (Madigan and York 1995, Giudici and Green 1999, Tarantola 2004, Corander et al. 2006, Green and Thomas 2013). While these methods may work well in many cases, they offer essentially no guarantees concerning the accuracy of the produced estimates.

In this paper, we present exact averaging and sampling algorithms that admit Bayesian learning of decomposable graphs up to about 20 nodes. We build on the recent dynamic programming (DP) algorithm of Kangas et al. (2014). Their algorithm finds a decomposable graph that *maximizes* a given decomposable scoring function, for example, the posterior probability. For graphs with  $n$  nodes the algorithm takes  $O(4^n)$  time and  $O(3^n)$  space. Generally, it is straightforward to turn a DP algorithm, designed for an optimization problem, into a “corresponding” averaging or sampling algorithm (and vice versa). At first glance, our result may thus look nothing but a rephrasing of the result of Kangas et al.

However, this view turns out to be only partial. Indeed, replacing maximization by averaging opens new algorithmic opportunities, which allow us to give an asymptotically faster,  $O(n^3 3^n)$ -time algorithm (Sect. 3). On the other hand, the averaging viewpoint also brings new difficulties: First, it turns out that the particular DP treatment applies to Bayesian model averaging only when the prior over the graphs is of a specific form; for example, the form cannot express the uniform prior over all decomposable graphs, whereas it can express the prior that is proportional to the number of so-called rooted junction trees of the graph. Second, it appears that exact computations are feasible only for marginal posterior probabilities of small subgraphs, like of an individual edge, but not of large subgraphs, not to mention more

complicated graph features. We overcome these difficulties by designing schemes that, using the computed DP tables, can efficiently generate large numbers of random samples from the posterior or its computationally convenient proxy (Sect. 4). We then feed the samples to usual Monte Carlo estimators of the quantities of interest (Sect. 5).

We demonstrate the performance of the methods using benchmark datasets (Sect. 6). First, we investigate whether averaging over graphs yields significantly better prediction results as compared to using a single maximum-a-posteriori graph. Second, we study the accuracy of the sampling based estimators for edge posterior probabilities.

Finally, we discuss straightforward ways to further enhance the presented methods, and also mention some major open questions (Sect. 7).

## 2 PRELIMINARIES

We review some fundamentals of decomposable models. For a more thorough treatment, see Lauritzen (1996).

### 2.1 DECOMPOSABILITY AND LEARNING

Consider an undirected graph  $G$  on a set of nodes  $V = \{1, \dots, n\}$ . We call a subset of nodes *complete* if it induces a complete subgraph. Further, we call a complete set a *clique* if it is *maximal*, that is, not a subset of any other complete set. We denote the set of cliques of  $G$  simply by  $\mathcal{C}$ , assuming there is no ambiguity about the referred graph.

We call  $G$  *decomposable* if it has the *running intersection property*, that is, there is an ordering of its cliques,  $C_1, \dots, C_k$ , such that for each  $i = 2, \dots, k$  we have that  $S_i = (C_1 \cup \dots \cup C_{i-1}) \cap C_i \subset C_j$  for some  $j < i$ . The sets  $S_i$  are called the *separators* and they form a multiset, which we denote by  $\mathcal{S}$ . We note that  $\mathcal{S}$  is uniquely specified by  $G$  and does not depend on the ordering of the cliques.

Suppose  $G$  is decomposable and with each node  $v \in V$  associate a random variable  $x_v$ . The graph  $G$  together with a joint distribution  $p$  over the variables form a *decomposable graphical model* if  $p$  factorizes as

$$p(x_V) = \frac{\prod_{C \in \mathcal{C}} p(x_C)}{\prod_{S \in \mathcal{S}} p(x_S)},$$

where we write  $x_S$  for the tuple  $(x_v : v \in S)$ . The factorization plays a central role in probabilistic inference in a given decomposable model, and in learning a model for a fixed graph from *data*, that is, multiple records over the variables.

The factorization is central also when learning the graph. In the Bayesian approach to learning we turn a *prior*  $\rho$  over the graphs into a *posterior*  $\pi$  by multiplying the prior by the (marginal) *likelihood*  $\ell$ , and dividing by the *normalizing constant* of the function  $\rho\ell$ , given as  $Z_{\rho\ell} = \sum_G \rho(G)\ell(G)$ .

The likelihood  $\ell(G)$  is the probability (density) of the data, given  $G$ . It is obtained by integrating out the parameters that specify the distribution  $p$  above. Under commonly adopted parameter priors (Dawid and Lauritzen 1993), the likelihood function factorizes into a product of local marginal likelihoods, one term per clique and separator. Thus the likelihood function is an example of a decomposable function:

**Definition 1** (decomposable function). Let  $V$  be a finite set and let  $\varphi$  be a function from the decomposable graphs on  $V$  to real numbers. We say that  $\varphi$  is *decomposable* over  $V$  if

$$\varphi(G) = \frac{\prod_{C \in \mathcal{C}} \varphi_c(C)}{\prod_{S \in \mathcal{S}} \varphi_s(S)}$$

for some functions  $\varphi_c$  and  $\varphi_s$ , we call the *local components*.

Clearly the product of two decomposable functions is also decomposable. It can also be shown that any constant function is decomposable. In particular, if the prior is a decomposable function, so is the posterior.

We illustrate the notion of decomposable functions by two further examples. Here and henceforth we use the Iverson bracket  $[Q]$  to denote 1 when  $Q$  is true, and 0 otherwise.

**Example 1** (uniform prior). Let  $w$  be a number. Let  $\rho$  be the decomposable function over  $V$  defined by

$$\rho_c(X) = [ |X| \leq w ] \quad \text{and} \quad \rho_s(X) = 1 \quad \text{for } X \subseteq V.$$

We observe that  $\rho(G) = 1$  if  $G$  contains only cliques of size at most  $w$ , and 0 otherwise. Thus the normalized function  $\rho/Z_\rho$  is the uniform distribution over the decomposable graphs on  $V$  whose cliques are of size at most  $w$ .

**Example 2** (absence of an edge). Let  $e \subseteq V$ ,  $|e| = 2$ . Let  $\varphi^e$  be the decomposable function over  $V$  defined by

$$\varphi_c^e(X) = [e \not\subseteq X] \quad \text{and} \quad \varphi_s^e(X) = 1 \quad \text{for } X \subseteq V.$$

We observe that  $\varphi^e(G) = 1$  if the edge  $e$  is absent in  $G$ , and 0 otherwise. Thus  $\varphi^e$  is the indicator function of the set of decomposable graphs that do not contain the edge  $e$ .

Note also that the indicator function for the *presence* of an edge is not decomposable.

### 2.2 COMPUTATIONAL TASKS

We will consider two classes of computational problems: (1) computing the *marginal* of a given function  $\varphi$  of decomposable graphs, defined as  $Z_\varphi = \sum_G \varphi(G)$ ; and (2) generating random samples of decomposable graphs from a distribution that is proportional to a given function. The first class includes the important task of computing posterior expectations of graph features, in particular, marginal posterior probabilities of edges (cf. Corollary 2 in Sect. 3). In the second class the distribution of interest is usually the posterior distribution. The input in these problems is always specified by decomposable functions, like a prior and a likelihood function. Thus we may assume an efficient access to these functions through their local components.

### 2.3 ROOTED JUNCTION TREES

It is convenient to represent a decomposable graph as a *junction tree*. Consider an undirected graph  $G$  and a tree  $\mathcal{J}$  that has the cliques of  $G$  as its vertices. We call  $\mathcal{J}$  a junction tree of  $G$  if it satisfies the *junction property*, that is, for any cliques  $C, C'$  the intersection  $C \cap C'$  is contained within every clique on the unique path between  $C$  and  $C'$  in  $\mathcal{J}$ . A graph has a junction tree if and only if it is decomposable. Importantly, the representation is in general not unique, as a graph may have multiple junction trees; we denote by  $\tau(G)$  the number of junction trees of  $G$ . In contrast, for each junction tree  $\mathcal{J}$  the represented graph,  $G(\mathcal{J})$ , is unique.

For our purposes it will be convenient to work with rooted junction trees. Specifically, we make use of the following recursive characterization of junction trees, adopted from the work of Kangas et al. (2014):

**Definition 2** (recursive partition tree, RPT). A *recursive partition tree* over a finite ground set  $V$  is a triplet  $(C, \{R_1, \dots, R_k\}, \{\mathcal{T}_1, \dots, \mathcal{T}_k\})$  such that

1.  $C$  is a non-empty subset of  $V$ , called the *root*;
2.  $\{R_1, \dots, R_k\}$  is a partition of  $V \setminus C$ ;
3. each  $\mathcal{T}_i$  is an RPT over  $C \cup R_i$  rooted at  $C_i$  such that  $C \cap C_i$  is a proper subset of both  $C$  and  $C_i$ .

Note that the implicit base case of the definition is when  $C = V$  and there are thus no subtrees.

An RPT  $\mathcal{T}$  rooted at  $C$  can be viewed as a directed tree, where  $C_1, \dots, C_k$  are the children and  $\mathcal{T}_1, \dots, \mathcal{T}_k$  the subtrees of  $C$ . Such a tree is a junction tree and, conversely, any junction tree can be represented as an RPT, which is unique up to the choice of the root (Kangas et al. 2014). Denoting by  $\kappa(G)$  the number of cliques of a decomposable graph  $G$ , we have that  $G$  has exactly  $\tau(G)\kappa(G)$  distinct RPTs.

### 2.4 DYNAMIC PROGRAMMING

Kangas et al. considered the problem of maximizing a given decomposable function, and gave a DP algorithm that stems from the recursive definition of RPTs. We next adapt the DP algorithm to the problem of summing up the values of a given function, that is, to compute the marginal. Due to the many-to-one relationship of RPTs and decomposable graphs, each value gets multiplied by the corresponding number of RPTs. Put otherwise, for any function  $\varphi$  we have

$$\sum_{\mathcal{T}} \varphi(G(\mathcal{T})) = \sum_G \varphi(G)\tau(G)\kappa(G), \quad (1)$$

where  $\mathcal{T}$  runs through all RPTs over  $V$  and  $G$  runs through all decomposable graphs on  $V$ . Since our DP treatment relies on the decomposability of the function  $\varphi$ , the computed sum will not be the marginal of the decomposable  $\varphi$ , but of the function  $\varphi\tau\kappa$ , that we shall call RPT-decomposable:

**Definition 3** (RPT-decomposable function). Let  $V$  be a finite set and let  $\varphi'$  be a function from the decomposable graphs on  $V$  to real numbers. We say that  $\varphi'$  is *RPT-decomposable* over  $V$  if  $\varphi'(G) = \varphi(G)\tau(G)\kappa(G)$  for some decomposable function  $\varphi$  over  $V$ .

**Example 3** (RPT-uniform prior). Let  $\rho$  be as defined in Example 1. Then  $\rho\tau\kappa$  is a RPT-decomposable function that is proportional to the uniform distribution on all RPTs over  $V$  whose cliques are of size at most  $w$ .

We are ready to present the DP algorithm for computing the sum (1) for a given a decomposable function  $\varphi$ . To this end, we denote by  $\text{RPT}(S, R)$  the set of all RPTs over  $S \cup R$  rooted at a proper superset of  $S$ , and let

$$f(S, R) = \sum_{\mathcal{T} \in \text{RPT}(S, R)} \varphi(G(\mathcal{T})).$$

In particular,  $f(\emptyset, V)$  equals the desired sum (1). Following Kangas et al. we obtain the following recurrence system:

$$f(S, R) = \sum_{S \subset C \subseteq S \cup R} \varphi_c(C) g(C, R \setminus C), \quad (2)$$

$$g(C, U) = \sum_{\min U \in R \subseteq U} h(C, R) g(C, U \setminus R), \quad (3)$$

$$h(C, R) = \sum_{S \subset C} f(S, R) / \varphi_s(S), \quad (4)$$

with the base case  $g(C, \emptyset) = 1$ . Each recurrence is defined for all disjoint pairs of subsets of  $V$  such that  $C$  and  $R$  are non-empty. A straightforward evaluation of  $f$ ,  $g$ , and  $h$  by using these recurrences takes  $O(4^n)$  time and  $O(3^n)$  space. These bounds and the correctness of the recurrences can be verified essentially by taking the proof of Kangas et al. and replacing maximization with summation.

The intuition here is that  $f$  considers all possible choices for the root clique  $C$  and factors in the  $\varphi_c(C)$ . For each  $C$  it then invokes  $g$ , which considers partitions  $\{R_1, \dots, R_k\}$  of the remaining nodes  $U$  by calling itself recursively. For each part  $R$  it also calls  $h$ , which considers possible separators  $S$  between  $C$  and the subtree in  $R$  and factors in the reciprocal of the marginals  $\varphi_s(S)$ . Finally,  $h$  calls  $f$  again to consider possible root cliques of the subtree. In (3), the least element of  $U$ , denoted  $\min U$ , is always placed in the next part  $R$  so as not to consider different permutations of the same partition. The base case corresponds to the case where all nodes have been assigned to some  $R_i$  and there are none left to partition.

### 3 EXACT AVERAGING

In this section we show:

**Theorem 1.** *The marginal of a given RPT-decomposable function over a set of  $n$  nodes can be computed in  $O(n^3 3^n)$  time and  $O(n 3^n)$  space.*

In effect, we show that the recurrence system (2–4) can be solved in the claimed time. Asymptotically, this is significantly faster than the  $O(4^n)$  time obtained by a straightforward evaluation. We achieve the improvement by computing the exponential-size summations for each of the functions  $f$ ,  $g$ , and  $h$  simultaneously for several pairs of arguments. Our algorithms for  $f$  and  $h$  apply as well to the maximization variant of the recurrence. In contrast, our algorithm for  $g$  relies crucially on subtraction (i.e., the existence of additive inverses), and thus does not apply to maximization.

Before we proceed to the proof (in Sections 3.1–3.5), let us note the following implication:

**Corollary 2.** *Suppose the probability distribution over decomposable graphs on a set of  $n$  nodes is proportional to a given RPT-decomposable function. Then the probability that the graph contains  $k$  specified edges can be computed in  $O(2^k n^3 3^n)$  time and  $O(n 3^n)$  space.*

*Proof.* Let  $e_1, \dots, e_k$  be distinct edges on the node set  $V = \{1, \dots, n\}$ . Let  $A_j$  denote the event that the graph does *not* contain the edge  $e_j$ . By the inclusion–exclusion principle, the probability that the graph contains the  $k$  edges is

$$\Pr[\bar{A}_1 \cap \dots \cap \bar{A}_k] = \sum_{J \subseteq \{1, \dots, k\}} (-1)^{|J|} \Pr\left[\bigcap_{j \in J} A_j\right].$$

Now, let  $\varphi'$  be the given RPT-decomposable function. It remains to observe that

$$\Pr\left[\bigcap_{j \in J} A_j\right] = \frac{\sum_G \varphi'(G) \prod_{j \in J} \varphi^{e_j}(G)}{\sum_G \varphi'(G)},$$

where each  $\varphi^{e_j}$  is the decomposable function that indicates whether  $e_j$  is absent in the graph, as defined in Example 2. Thus each of the  $2^k$  probabilities is obtained as a ratio of two marginals of RPT-decomposable functions.  $\square$

### 3.1 ZETA TRANSFORM AND SUBSET CONVOLUTION

Our algorithms employ the so-called *fast zeta transform*, FZT (Yates 1937, Kennes and Smets 1990, Björklund et al. 2012). The *zeta transform* of a function  $\alpha$  from the subsets of a ground set  $\{1, \dots, n\}$  to real numbers is the set function defined by  $\hat{\alpha}(Y) = \sum_{X \subseteq Y} \alpha(X)$  for each subset  $Y$  of the ground set. FZT computes the zeta transform of a given function in  $O(n 2^n)$  time, as follows: Let  $\alpha_0 = \alpha$  and for  $i = 1, \dots, n$  let

$$\alpha_i(Y) = \alpha_{i-1}(Y) + [i \in Y] \cdot \alpha_{i-1}(Y \setminus \{i\}).$$

It follows that  $\alpha_n = \hat{\alpha}$ . Note that there are two different ways to organize the computations: either compute the  $n$  steps one after another, which requires only  $O(2^n)$  space; or

compute all the  $n$  functions for each set  $Y$  one after another in increasing order by the size  $|Y|$ , which requires  $O(n 2^n)$  space. We will need the latter “level-wise” implementation.

Another tool we use is known as the *fast subset convolution*, FSC (Björklund et al. 2007). The *subset convolution* of two functions  $\alpha$  and  $\beta$  from the subsets of a ground set  $\{1, \dots, n\}$  to real numbers is the set function defined by  $(\alpha * \beta)(Y) = \sum_{X \subseteq Y} \alpha(X) \beta(Y \setminus X)$  for each subset  $Y$  of the ground set. FSC computes the subset convolution in  $O(n^2 2^n)$  time and  $O(n 2^n)$  space. We refer to Björklund et al. (2007) for details.

### 3.2 COMPUTING $h$

Consider first the recurrence for  $h$ . For a moment, fix a set  $R \subseteq V$  and define the functions  $h_R$  and  $f_R$  by

$$h_R(C) = h(C, R) \quad \text{and} \quad f_R(S) = f(S, R) / \varphi_s(S),$$

where  $C$  and  $S$  are subsets of  $V \setminus R$ . By the recurrence (4) we have that  $h_R(C) = \sum_{S \subseteq C} f_R(S) = \hat{f}_R(C) - f_R(C)$ . Using FZT we can compute  $h_R$  in  $O(k 2^k)$  time for each  $R$ , where  $k = n - |R|$ . Note that we use the level-wise implementation and evaluate the  $k$  steps of the transform for one  $C$  in turn. Thus computing  $h$  takes  $O(n 3^n)$  time in total. (While we here used subtraction, it is not difficult to see how FZT can be modified to avoid that, and that the result thus applies to the maximization variant as well.)

### 3.3 COMPUTING $f$

Consider then the recurrence for  $f$ . It might be tempting to try the above trick also in this case, that is, to fix either  $R$  or  $S$ , and then employ a suitable fast zeta transform variant. However, that approach fails because now the involved three sets  $S$ ,  $R$ , and  $C$  have more intricate dependencies. Instead, we define the function  $g'$  by

$$g'(C, R \setminus C) = \varphi_c(C) g(C, R \setminus C),$$

for  $C \subseteq R \subseteq V$ . The idea is to extend FZT to pairs of disjoint sets and transform  $g'$  into  $f$  by computing the sum (2) in  $n$  steps: Let  $g'_0 = g'$  and for  $i = 1, \dots, n$  let

$$g'_i(S, R) = g'_{i-1}(S, R) + [i \in R] \cdot g'_{i-1}(S \cup \{i\}, R \setminus \{i\}).$$

It can be shown by simple induction that  $g'_n(S, R) = f(S, R) + g'(S, R \setminus S)$  (see the supplement). Thus, given  $g'$ , we can compute  $f$  in  $O(n 3^n)$  time. Note that we use the level-wise approach to compute the values  $f(S, R)$  in *decreasing* order of  $|S|$  and in *increasing* order of  $|R|$ .

### 3.4 COMPUTING $g$

Finally consider the recurrence for  $g$ . Now we fix a  $C \subseteq V$  for a moment and, for convenience, write  $g_C(U)$  for  $g(C, U)$

and  $h_C(R)$  for  $h(C, R)$ . We will show that the values

$$g_C(U) = \sum_{\min U \in R \subseteq U} h_C(R) g_C(U \setminus R)$$

can be computed for all  $U \subseteq V$  of size  $|U| = u$  in  $O(n^2 2^n)$  time, assuming the values  $h_C(R)$  and  $g_C(U')$  are available for all  $R, U' \subseteq V$  of sizes  $|R| \leq u$  and  $|U'| < u$ . This then implies that computing  $g$  takes  $O(n^3 3^n)$  time in total (by summing over  $u$  and  $C$ ).

To compute the values  $g_C(U)$ , we break the computations further into  $n$  separate subtasks. For each  $s \in V$ , define the function  $g^s$  by

$$g^s(U) = \sum_{s \in R \subseteq U} h(R) g(U \setminus R),$$

where  $U \subseteq V$  such that  $|U| = u$  and  $\min U = s$ . Note that each such  $U$  is of the form  $\{s\} \cup X$  with  $X \subseteq V \setminus \{1, \dots, s\}$ . We observe that for each  $s$  the task can be solved using FSC in  $O(n^2 2^{n-s})$  time, implying a time requirement of  $O(n^2 2^n)$  in total. It remains to observe that  $g(U)$  is obtained as  $g^{\min U}(U)$ .

### 3.5 SPACE REQUIREMENT

The level-wise computations of  $h$  and  $f$  assume that the intermediate values of the transforms are stored in memory. This incurs a space requirement of  $(n 3^n)$  in total.

The computation of  $g$ , instead, uses FSC in a black-box fashion and computes a bunch of values  $g(C, U)$  for a fixed  $C$  and several sets  $U$  of a fixed size  $u$ , assuming only that the values  $h(C, R)$  and  $g(C, U')$  are available for all  $R$  and  $U'$  such that  $|R| \leq u$  and  $|U'| < u$ . Because the same space can be reused for different  $C$ , the “extra” space requirement is only that of FSC,  $O(n 2^n)$ .

## 4 SAMPLING

We now turn to the task of sampling decomposable graphs from the posterior. Specifically, we extend the DP algorithm of Sect. 2 with a natural backtracking procedure that draws an RPT by choosing its cliques, partitions, and separators according to their conditional marginal probabilities, and returns the corresponding graph. Since each graph  $G$  has  $\tau(G)\kappa(G)$  distinct RPTs, the resulting graph sample follows the RPT-decomposable distribution  $\pi \propto \varphi \tau \kappa$ , where  $\varphi$  is the decomposable function that the DP algorithm was applied to. By employing importance sampling (Sect. 5) that weights each graph sample  $G$  by  $(\tau(G)\kappa(G))^{-1}$ , we are able to target the distribution proportional to  $\varphi$  instead.

For the remainder of this section we focus on sampling from  $\pi \propto \varphi \tau \kappa$ . Given the DP tables for  $f$ ,  $g$ , and  $h$  (for  $\varphi$ ), the backtracking procedure to sample from  $\pi$  works as follows.

### Algorithm: Sampling a decomposable graph

Begin by visiting  $f(\emptyset, V)$  and recursively visit  $f$ ,  $g$  and  $h$  as follows: In  $f(S, R)$ , choose the root clique  $C$  of the subtree over  $S \cup R$  randomly according to its marginal distribution  $\Pr(C) \propto \varphi_c(C) g(C, R \setminus C)$  and proceed to corresponding  $g(C, R \setminus C)$ . In  $g(C, U)$ , choose the first part  $R$  of the partition according to its marginal distribution  $\Pr(R) \propto h(C, R) g(C, U \setminus R)$  and recursively proceed to  $h(C, R)$  and  $g(C, U \setminus R)$ . In  $h(C, R)$ , choose a separator  $S$  according to its marginal probability  $\Pr(S) \propto f(S, R) / \varphi_s(S)$  and proceed to  $f(S, R)$ . Continue the recursion until all branches terminate at a visit to  $g(C, \emptyset)$ . Then, from the resulting recursion tree, obtain the cliques  $C$  and return the corresponding graph.

The efficiency of this backtracking procedure depends on how much time is spent on choosing random sets  $C$ ,  $R$ , and  $S$  during the visits. Consider the general problem of drawing a sample from a discrete distribution over  $s$  elements. A naive method is to pick a number  $r$  from the continuous uniform distribution on  $[0, 1)$ , then iterate the elements in a predefined order and select the first item for which the cumulative probability exceeds  $r$ . The method uses  $O(s)$  time and  $O(1)$  space. It can be shown that, if the sets  $C$ ,  $R$ , and  $S$  are sampled using this naive method, sampling a single graph requires  $O(2^n)$  time. (In fact, this result is proved as a special case in the next subsection.) Next we introduce a more general sampling scheme that allows us to spend less time in sampling by using more space.

### 4.1 TRADING TIME FOR SPACE

We can avoid spending exponential time per sample by first preprocessing the probabilities so that the sets can thereafter be chosen much faster. First, it should be noted that it is not possible to just precompute the cumulative probabilities and use, for example, binary search to find the item that corresponds to  $r$ , without increasing the asymptotic space requirement. On the other hand, if we allow additional space usage, then it is better to use the *alias method* (Vose 1991), which requires  $O(s)$  additional space and  $O(s)$  preprocessing time but allows us to draw samples in  $O(1)$  time per sample. Moreover, it turns out we obtain a tunable tradeoff between sampling time and extra space. Specifically, we propose the following algorithm:

#### Subroutine: Parameterized sampling

Let  $b \in \{0, \dots, n\}$  be a tradeoff parameter that is chosen beforehand. As preprocessing, divide the  $s$  elements into bins of size  $2^b$  (at most, the last bin can be smaller), and for each bin, compute and store the sum of the probabilities of its elements. This requires space that is linear in the number of bins.

Now a new sample can be drawn in two phases: first a bin is selected according to its precomputed total proba-

bility and then a term is selected from the bin according to its relative probability in the bin. We apply the alias method to the first phase, and the naive sampling to the second phase. Thus, the first phase requires  $O(1)$  time per sample. The additional space requirement is linear in the number of bins. The second phase uses  $O(2^b)$  time and no additional space. The total space requirement is thus  $O(s/2^b)$  and time requirement is  $O(s)$  for preprocessing and  $O(2^b)$  per sample.

By selecting a fixed  $b$  and applying the above algorithm to each (nonterminating)  $f(S, R)$ ,  $g(C, U)$ , and  $h(C, R)$  we get the following theorem:

**Theorem 3.** *For any  $b \in \{0, \dots, n\}$  we can draw  $T$  independent graphs from  $\pi$  in  $O(4^n + T \cdot 2^b(1 + n - b))$  time and  $O(4^n/2^b + 3^n)$  space.*

In order to prove the theorem, we first bound the number of visits to  $f$ ,  $g$ , and  $h$  by the following lemma:

**Lemma 4.** *The sampling procedure makes at most  $n$  nonterminating visits to functions  $f$ ,  $g$ , and  $h$  each.*

The proof of Lemma 4 is given in the supplement.

Now, by using Lemma 4 and the fact that on each visit to  $f$ ,  $g$  or  $h$ , the time required to choose the set  $C$ ,  $R$  or  $S$  correspondingly is at most  $O(2^b)$ , we get a bound  $O(2^b n)$  for the time consumption per sample. However, in order to get the bound down to  $O(2^b(1+n-b))$  as in Theorem 3, we need to bound the amount of work done on each visit more carefully. To this end, observe that each nonterminating visit to  $f(S, R)$ ,  $g(C, U)$ , and  $h(C, R)$  involves drawing a random set from a discrete distribution over  $2^{|R|} - 1 < 2^{|S|+|R|}$ ,  $2^{|U|}/2 < 2^{|C|+|U|}$ , and  $2^{|C|} - 1 < 2^{|C|+|R|}$  sets respectively. The following lemma bounds  $|S| + |R|$ ,  $|C| + |U|$ , and  $|C| + |R|$  on different steps of the backtracking.

**Lemma 5.** *For  $f$ ,  $g$ , and  $h$  let  $(S_1, R_1), \dots, (S_{d_f}, R_{d_f})$ ,  $(C_1, U_1), \dots, (C_{d_g}, U_{d_g})$ , and  $(C_1, R_1), \dots, (C_{d_h}, R_{d_h})$  be all the set pairs visited during backtracking. Then there exist orderings of those set pairs such that,*

$$|S_i| + |R_i| \leq n - i + 1 \quad \text{for all } i = 1, \dots, d_f,$$

$$|C_i| + |U_i| \leq n - i + 1 \quad \text{for all } i = 1, \dots, d_g,$$

$$|C_i| + |R_i| \leq n - i + 1 \quad \text{for all } i = 1, \dots, d_h.$$

The proof of Lemma 5 is given in the supplement.

Now we are ready to prove the theorem presented above.

*Proof of Theorem 3.* Consider the space and time needed for  $f$  (respectively:  $g, h$ ).

**Space:** For each  $R$  (respectively:  $U, C$ ) of size  $k$  there are  $2^{n-k}$  ways to choose  $S$  (respectively:  $C, R$ ). The space needed by the alias method for each such set pair is less

than  $\max\{2^k/2^b, 1\}$ . Thus the total space requirement for all set pairs of all sizes is

$$\sum_k \binom{n}{k} 2^{n-k} \max\{2^{k-b}, 1\} \leq \sum_k \binom{n}{k} (2^{n-b} + 2^{n-k}) = \frac{4^n}{2^b} + 3^n.$$

**Time:** The preprocessing requires enumeration over all terms of the sums in the recurrences for all entries of  $f$ ,  $g$ , and  $h$ . Like computing  $f$ ,  $g$ , and  $h$ , this consumes  $O(4^n)$  time. It remains to analyze the time needed to draw a single graph sample. Let  $(S_1, R_1), \dots, (S_d, R_d)$  (respectively:  $(R_1, U_1), \dots, (R_d, U_d)$ ,  $(C_1, R_1), \dots, (C_d, R_d)$ ) be the  $d$  visited set pairs for  $f$  (respectively:  $g, h$ ). In each visit the algorithm first chooses a bin in constant time and then chooses one of its elements in time linear in its size but at most  $2^b$ . Therefore, the backtracking requires at most time

$$\sum_{i=1}^d \min\{2^b, 2^{k_i}\},$$

where  $k_i = |R_i|$  (respectively:  $k_i = |U_i|$ ,  $k_i = |C_i|$ ). By Lemma 5, there exists an ordering of the set pairs such that  $k_i \leq n - i + 1$ . By Lemma 4,  $d \leq n$ . We get

$$\begin{aligned} \sum_{j=1}^n \min\{2^b, 2^j\} &\leq \sum_{j=b+1}^n 2^b + \sum_{j=1}^b 2^j \\ &\leq (n-b)2^b + 2^{b+1} \\ &= (2+n-b)2^b. \end{aligned}$$

The claim thus follows.  $\square$

Theorem 3 has, for example, the following corollaries. Setting  $b = 0$  allows us to draw each sample in linear time but using  $O(4^n)$  extra space, while setting  $b = n$  effectively yields the naive method. From an asymptotical viewpoint, it makes sense to set  $b \leq n \log_2(4/3) \simeq 0.42n$ , since for larger  $b$  the  $3^n$  term dominates the space requirement. Since the DP phase requires  $O(4^n)$  time, we can in a sense draw  $O(4^n/2^{n \log_2(4/3)}) = O(2^n/n)$  samples for “free.”

## 4.2 ADAPTIVE SAMPLING

Usually most of the probability mass is concentrated on a small set of graphs. Thus, when sampling graphs, some of the indexing set pairs for  $f$ ,  $g$ , and  $h$  are visited rarely if at all. The additional space that is used by the alias method for such set pairs may outweigh the gain in speed. As an alternative, we propose the following approach that periodically draws and caches multiple samples at once on those indices that are visited more often.

### Subroutine: Adaptive sampling

On the first visit to any  $f(S, R)$ ,  $g(C, U)$ , or  $h(C, R)$ , draw and consume one set from the corresponding discrete distribution using the naive method. On any subsequent visit: If there are no cached samples left from

the previous visits, then use the alias method to draw twice as many sets as the last time on the same index, consume one and cache the rest. Otherwise, consume one set from the cache.

The following lemma characterizes the space consumption of the graph sampler that uses the above adaptive sampling subroutine.

**Lemma 6.** *After  $T$  sampled graphs, adaptive sampling consumes at most  $O(nT)$  extra space.*

*Proof.* A cache of size  $s$  is constructed when the corresponding set pair is visited for the  $(s + 1)$ th time. By Lemma 4 the total number of visits to all set pairs is at most  $nT$ . The claim then trivially follows.  $\square$

Furthermore, we get the following special case bounds for space and time consumption:

**Theorem 7.** *We can draw  $3^n$  independent samples from  $\pi$  in  $O(n4^n)$  time and  $O(n3^n)$  space.*

*Proof.* The space complexity follows from Lemma 6.

Consider then the time used on visits to  $f$ .

Without rebuilding the caches, the time per sample is  $O(n)$ , or  $O(n3^n)$  in total. In order to analyze the time needed for cache rebuilds, consider an arbitrary disjoint set pair  $(S, R)$  and let  $k = |R|$ .

Let  $t$  be the number of visits to the set pair in question. Then its cache is rebuilt  $\lfloor \log_2(t) + 1 \rfloor$  times. As rebuilding the cache the  $i$ th time requires  $O(2^k + 2^i)$  time (the first term comes from constructing the distribution and initializing the alias method, the second term comes from drawing the sets), in total this requires time

$$\sum_{i=1}^{\lfloor \log_2(t)+1 \rfloor} O(2^k + 2^i) = O((\log(t) + 1)2^k) + O(t).$$

To get the total time used to rebuild caches, we must sum these for all set pairs  $(S, R)$ . Since each backtracking visits at most  $n$  set pairs (Lemma 4), the sum over the last term  $O(t)$  results in  $O(n3^n)$ . It remains to analyze the first term.

For  $k = 1, \dots, n$ , let  $L_k$  consist of all the set pairs  $(S, R)$  such that  $|R| = k$ . For a fixed  $k$ , there are  $|L_k| = \binom{n}{k} 2^{n-k}$  such pairs, and each may be visited at most once per sample, that is, at most  $3^n$  times in total. Thus, the sum of the first term over all pairs in  $L_k$  amounts to  $O(|L_k|(\log(3^n) + 1)2^k) = O\left(n \binom{n}{k} 2^n\right)$ . Summing over  $k$  yields the claimed running time bound.

The time used on visits to  $g$  and  $h$  can be bounded analogously (selecting  $k = |U|$  and  $k = |C|$ , respectively).  $\square$

## 5 MONTE CARLO ESTIMATION

We have observed in Sections 2 and 3 that the posterior probabilities of some graph properties can be computed exactly in  $O(4^n)$  time, and asymptotically even faster in  $O(n^3 3^n)$  time. However, we had to assume (i) that the properties can be expressed by decomposable functions (e.g., in terms of forbidden cliques), and (ii) that the prior, and hence the posterior, is RPT-decomposable, ruling out the natural uniform prior.

In this section, we employ Monte Carlo methods to relax these restrictive assumptions and still obtain good approximations. Throughout the section, we consider an arbitrary function  $\psi$  from decomposable graphs to  $\{0, 1\}$ . Our interest is in estimating the quantity

$$Z_{\pi\psi} = \sum_G \pi(G)\psi(G),$$

where  $\pi$  is the posterior distribution.

### 5.1 RPT-DECOMPOSABLE PRIOR

Consider first relaxing only the first assumption (i). Since we keep the assumption that the prior is RPT-decomposable, we can draw  $T$  independent graphs  $G_1, \dots, G_T$  from the posterior  $\pi$ , using the methods described in Sect. 4. The estimate

$$\hat{Z}_{\pi\psi} = \frac{1}{T} \sum_{i=1}^T \psi(G_i)$$

is unbiased and, by the law of large numbers, it concentrates around  $Z_{\pi\psi}$  as  $T$  grows.

### 5.2 DECOMPOSABLE PRIOR

Consider then relaxing also the second assumption (ii). For convenience, assume however that the prior is decomposable, for example, the uniform distribution over all decomposable graphs on the node set  $V$ . Now, we can draw  $T$  independent graphs  $G_1, \dots, G_T$  from a distribution proportional to  $\pi\tau\kappa$ , using the methods described in Sect. 4. In this case, we need to correct the deviance of the sampling distribution from the posterior. We do this by using the self-normalized importance sampling estimate

$$\tilde{Z}_{\pi\psi} = \frac{\sum_{i=1}^T w_i \psi(G_i)}{\sum_{i=1}^T w_i}, \quad w_i = \frac{1}{\tau(G_i)\kappa(G_i)}.$$

This estimate concentrates around  $Z_{\pi\psi}$  as  $T$  grows.

To make this method practical, we need an efficient way to count the number of junction trees  $\tau(G_i)$  and the number of cliques  $\kappa(G_i)$  of a given decomposable graph  $G_i$ . The latter problem is easy, as the cliques are readily available in the RPT (or junction tree) representation. For counting junction

Table 1: Benchmark datasets on  $n$  variables and  $m$  records.

| Dataset     | $n$ | $m$   |
|-------------|-----|-------|
| Asia        | 8   | 10000 |
| Bridges     | 12  | 108   |
| Flare       | 13  | 1066  |
| House-votes | 17  | 435   |

Table 2: The running time of our algorithm on the benchmark datasets. We measure in seconds the time spent on the dynamic programming phase (DP) as well as sampling of  $10^5$ ,  $10^6$ , and  $10^7$  graphs. These include the time spent finding the number of junction trees per sample.

| Dataset     | DP    | $10^5$ | $10^6$ | $10^7$ |
|-------------|-------|--------|--------|--------|
| Asia        | 0.018 | 0.32   | 3.2    | 33     |
| Bridges     | 5.6   | 0.66   | 5.5    | 54     |
| Flare       | 24    | 1.5    | 8.8    | 77     |
| House-votes | 7497  | 16     | 40     | 167    |

trees, a method described by Thomas and Green (2009) has, to our knowledge, the best worst case guarantees, running in time  $O(n^2)$ . It also starts by finding a single junction tree of the graph, which in our case is already given.

## 6 EXPERIMENTS

We report experimental results on the proposed sampling and estimation methods, using benchmark datasets (Table 1). *Asia* is sampled from a network defined by Lauritzen and Spiegelhalter (1988) and others are from the UCI repository (Bache and Lichman 2013). For all datasets we use the Dirichlet–multinomial model with the equivalent sample size parameter 1 (Dawid and Lauritzen 1993, Heckerman et al. 1995). Our C++ implementation<sup>1</sup> uses the straightforward  $O(4^n)$  time dynamic programming (Sect. 2) and the adaptive variant of the sampling phase (Sect. 4). The running times are detailed in Table 2.

### 6.1 PREDICTION

We first study how well averaging over graphs using our sampling method performs on a prediction task, as compared to using a single maximum-a-posteriori graph. Specifically, we split each dataset into a fixed test set and a training set. From the training data we then learn both a maximum-a-posteriori graph and the full posterior given a uniform prior over decomposable graphs and measure how the probability of the test data given the training data behaves under these models as the size of the training set varies.

The maximum-a-posteriori graph is obtained using the

<sup>1</sup>Our implementation is available at [www.cs.helsinki.fi/u/jwkangas/junctor](http://www.cs.helsinki.fi/u/jwkangas/junctor).

method of Kangas et al. (2014). The full posterior model is approximated by sampling  $2^n$  graphs, where  $n$  is the number of variables in the dataset, and then measuring the average probability of the test data over the sampled graphs (weighting each graph by the number of its RPTs).

Intuitively, the full posterior should in general yield better results, as the maximum-a-posteriori graph has a tendency to overfit the training data, especially for a small training set. Our results (Fig. 1) conform to this expectation. We observe that the probability of the test data under the full posterior model tends to be significantly higher for small training sets and the gap diminishes as the size of the training set grows.

### 6.2 EDGE POSTERIOR PROBABILITIES

In the second set of experiments we apply the Monte Carlo methods described in Sect. 5 to estimating the posterior probabilities of individual edges under the uniform prior over decomposable models.

For each dataset, we use the method from Sect. 5.2 to estimate the posterior probability of each edge. We compute the *estimation error*, i.e., the difference between an edge’s estimated probability and our best available estimate for the probability. Ideally, we would like the best available estimate to be the true posterior probability of the edge. For *Asia* we are able to obtain the true probability by enumerating all decomposable graphs up to 8 nodes. As this task comes infeasible for larger  $n$ , for other datasets we instead compare to the best estimate given by our method after drawing one million samples. Such “self-comparison” is still useful for studying the rate of convergence.

To quantify convergence, we measure how the maximum estimation error over edges develops as we draw more samples (Fig. 2). We also study the distribution of the error in a more refined way by counting the number of edges whose error exceeds  $10^{-k}$  for  $k \in \{1, \dots, 4\}$  (Fig. 3). We observe that the rate of convergence remains steady for each dataset. In all cases we reach a maximum error of about 0.01 or less after  $10^5$  samples and a lot sooner for smaller datasets.

## 7 CONCLUDING REMARKS

We have presented algorithms for Bayesian learning of moderate-size decomposable graphical models. Unlike the recent related algorithm that finds a single optimal model (Kangas et al. 2014), our algorithm enables more principled treatment of the posterior uncertainty. Unlike the brute-force approach, our algorithm scales well beyond 8 variables, up to about 20 variables. Unlike the popular MCMC methods, our algorithm enjoys accuracy guarantees (see also below). We believe our algorithms can be valuable for solving actual data-analysis instances, for testing the performance of other (approximate) methods, and as a building block for developing new methods that scale to larger instances.

Figure 1: The (log unnormalized) probability of the test data given the training data (y-axis) as an average under sampled graphs and under the maximum-a-posteriori model for various sizes of the training set (x-axis).

Figure 2: The maximum error of the estimate over all edges (y-axis) as the number of samples (x-axis) grows.

Figure 3: The number of edges (y-axis) with an estimation error less than  $10^{-k}$  as the number of samples (x-axis) grows. The curves represents  $k = 1, \dots, 4$  from top to down.

While this work has touched several aspects of accurate Bayesian learning of decomposable graphs, it also leaves many questions for future work. Some are rather straightforward extension and implementation issues: From a practical point of view, the most important one is to make the algorithms accommodate a user-specified upper bound on the clique sizes, and thereby expedite computations and reduce memory requirements. Another issue is to tune the recursive sampling schemes so as to fully exploit the (typical) low entropy of the distributions. Conceptually, the biggest shortcoming in our current importance sampling implementation is the lack of controllable approximation guarantees. However, we believe this gap can be closed in an efficient and practical way by using the so-called optimal Monte

Carlo algorithms (Cheng 2001, Dagum et al. 2000), as the sampled graphs tend to have relatively few junction trees.

The main open research questions are: Can the asymptotically faster algorithm be implemented to run fast also in practice? Are there significantly faster and, particularly, more space-efficient algorithms for Bayesian learning of decomposable graphs, with good accuracy guarantees?

## Abstract

We are concerned with obtaining novel concentration inequalities for the *missing mass*, i.e. the total probability mass of the outcomes not observed in the sample. We not only derive - for the first time - distribution-free Bernstein-like deviation bounds with *sublinear* exponents in deviation size for missing mass, but also improve the results of McAllester and Ortiz (2003) and Berend and Kontorovich (2013, 2012) for small deviations which is the most interesting case in learning theory. It is known that the majority of standard inequalities cannot be directly used to analyze heterogeneous sums i.e. sums whose terms have large difference in magnitude. Our generic and intuitive approach shows that the heterogeneity issue introduced in McAllester and Ortiz (2003) is resolvable at least in the case of missing mass via regulating the terms using our novel thresholding technique.

## 1 INTRODUCTION

Missing mass is the total probability associated to the outcomes that have not been seen in the sample which is one of the important quantities in machine learning and statistics. It connects density estimates obtained from a given sample to the population for discrete distributions: the less the missing mass, the more useful the information that can be extracted from the dataset. Roughly speaking, the more the missing mass is the less we can discover about the true unknown underlying distribution which would imply the less we can statistically generalize to the whole population. In other words, missing mass measures how representative a given dataset is assuming that it has been sampled according to the true distribution.

Often, one is interested in understanding the behaviour of the missing mass as a random variable. One of the

important approaches in such studies involves bounding the fluctuations of the random variable around a certain quantity namely its mean. Concentration inequalities are powerful tools for performing analysis of this type. Let  $X$  be any non-negative real-valued random variable with finite mean. The goal is to establish for any  $\epsilon > 0$ , probability bounds of the form

$$\begin{aligned}\mathbb{P}(X - \mathbb{E}[X] \leq -\epsilon) &\leq \exp(-\eta_l(\epsilon)), \\ \mathbb{P}(X - \mathbb{E}[X] \geq \epsilon) &\leq \exp(-\eta_u(\epsilon)),\end{aligned}\quad (1)$$

where  $\eta_l(\epsilon)$  and  $\eta_u(\epsilon)$  are some non-decreasing functions of  $\epsilon$  and where it is desirable to find the largest such functions for variable  $X$  and for the ‘target’ interval of  $\epsilon$ . These bounds are commonly called lower and upper deviations bounds respectively. In most practical scenarios, we are in a non-asymptotic setting where we have access to a sample  $X_1, \dots, X_n$  and we would like to derive concentration inequalities that explicitly describe dependence on sample size  $n$ . Namely, we would like to obtain bounds of the form

$$\begin{aligned}\mathbb{P}(X - \mathbb{E}[X] \leq -\epsilon) &\leq \exp(-\eta_l(\epsilon, n)), \\ \mathbb{P}(X - \mathbb{E}[X] \geq \epsilon) &\leq \exp(-\eta_u(\epsilon, n)),\end{aligned}\quad (2)$$

where  $\eta_l(\epsilon, n)$  and  $\eta_u(\epsilon, n)$  are both non-decreasing functions of  $\epsilon$  and  $n$ . Many of such bounds are distribution-free i.e. they hold irrespective of the underlying distribution.

McAllester and Schapire (2000) established concentration inequalities for the missing mass for the first time. A follow-up work by McAllester and Ortiz (2003) pointed out inadequacy of standard inequalities, developed a thermodynamical viewpoint for addressing this issue and sharpened these bounds. Berend and Kontorovich (2013) further refined the bounds via arguments similar to Kearns-Saul inequality (Kearns and Saul (1998)) and logarithmic Sobolev inequality (Boucheron et al. (2013)). These previous works, however, not only involve overly specific approaches to concentration and handling heterogeneity issue but also do not yield sharp bounds for small deviations which is the most interesting case in learning theory.

In this paper, we shall derive distribution-free concentration inequalities for missing mass in a novel way. The

primary objective of our approach is to introduce a notion of *heterogeneity control* which allows us to *regulate* the magnitude of bins in histogram of the discrete distribution being analyzed. This mechanism in turn enables us to control the behaviour of central quantities such as the variance or martingale differences of the random variable in question. These are the main quantities that appear in standard concentration inequalities such as Bernstein, Bennett and McDiarmid just to name a few. Consequently, instead of discovering a new method for bounding fluctuations of each random variable of interest, we will be able to directly apply standard inequalities to obtain probabilistic bounds on many discrete random variables including missing mass.

The rest of the paper is structured as follows. Section 2 contains the background information and introduces the notations. Section 3 outlines motivations and the main contributions. In Section 4, we explain negative dependence, information monotonicity and develop a few fundamental tools whereas Section 5 presents the proofs of our upper and lower deviation bounds based on these tools. Finally, Section 6 concludes the paper and compares our bounds with existing results for small deviations.

## 2 PRELIMINARIES

In this section, we will provide definitions, notations and other background material.

Consider  $P : \mathcal{I} \rightarrow [0, 1]$  to be a fixed but unknown discrete distribution on some finite or countable non-empty set  $\mathcal{I}$  with  $|\mathcal{I}| = N$ . Let  $\{w_i : i \in \mathcal{I}\}$  be the probability (or frequency) of drawing the  $i$ -th outcome. Moreover, suppose that we observe an i.i.d. sample  $\{X_j\}_{j=1}^n$  from this distribution with  $n$  being the sample size. Now, missing mass is defined as the total probability mass corresponding to the outcomes that are not present in our sample. Namely, missing mass is a random variable that can be expressed as:

$$Y := \sum_{i \in \mathcal{I}} w_i Y_i, \quad (3)$$

where we define each  $\{Y_i : i \in \mathcal{I}\}$  to be a Bernoulli variable that takes on 0 if the  $i$ -th outcome exists in the sample and 1 otherwise. Namely, we have

$$Y_i = \mathbb{1}_{[(X_1 \neq i) \wedge (X_2 \neq i) \wedge \dots \wedge (X_n \neq i)]}. \quad (4)$$

We assume that for all  $i \in \mathcal{I}$ ,  $w_i > 0$  and  $\sum_{i \in \mathcal{I}} w_i = 1$ . Denote  $P(Y_i = 1) = q_i$  and  $P(Y_i = 0) = 1 - q_i$  and let us suppose that  $Y_i$ s are independent: as we will see later in this section, such an assumption will not impose a burden on our proof structure and flow. Hence, we will have that  $q_i = \mathbb{E}[Y_i] = (1 - w_i)^n \leq e^{-nw_i}$  where  $q_i \in (0, 1)$ . Namely, defining  $f : (1, n) \rightarrow (e^{-n}, \frac{1}{e}) \subset (0, 1)$  where  $f(\theta) = e^{-\theta}$  with  $\theta \in D_f$  and taking  $w_i > \frac{\theta}{n}$  amounts to  $q_i(w_i) \leq f(\theta)$ . This provides a basis for our ‘thresholding’ technique that we will employ in our proof.

Choosing the representation (3) for missing mass, one has

$$\mathbb{E}[Y]_{\mathcal{I}} = \sum_{i \in \mathcal{I}} w_i q_i = \sum_{i \in \mathcal{I}} w_i (1 - w_i)^n, \quad (5)$$

$$V[Y]_{\mathcal{I}} = \sum_{i \in \mathcal{I}} w_i^2 \text{VAR}[Y_i], \quad (6)$$

$$\underline{\sigma}_{\mathcal{I}}^2 := \sum_{i \in \mathcal{I}} w_i \text{VAR}[Y_i], \quad (7)$$

where we have introduced the weighted variance notation  $\underline{\sigma}_{\mathcal{I}}^2$  and where each quantity is attached to a set over which it is defined. Note that  $\text{VAR}[Y_i]$  is the individual variance corresponding to  $Y_i$  which is defined as

$$\text{VAR}[Y_i] = q_i(1 - q_i) = (1 - w_i)^n(1 - (1 - w_i)^n). \quad (8)$$

One can define the above quantities not just over the set  $\mathcal{I}$  but on some (proper) subset of it that may depend on or be described by some variable(s) of interest. For instance, in our proofs the variable  $\theta$  may be responsible for choosing  $\mathcal{I}_{\theta} \subseteq \mathcal{I}$  over which the above quantities will be evaluated. For lower deviation and upper deviation, we find it convenient to refer to the associated set by  $\mathcal{L}$  and  $\mathcal{U}$  respectively. Likewise, we will use subscripts  $l$  and  $u$  to refer to objects that characterize lower deviation and upper deviation respectively. Also, we use the notation  $Y^{ij} = Y_i, \dots, Y_j$  to refer to sequence of variables whose index starts at  $i$ -th variable and ends at  $j$ -th variable. Finally, other notation or definitions may be introduced within the body of the proof when required.

We will encounter Lambert  $W$ -function - also known as product logarithm function - in this paper which describes the inverse relation of  $f(x) = xe^x$  and which cannot be expressed in terms of elementary functions. This function is double-valued when  $x \in \mathbb{R}$ . However, it becomes invertible in restricted domain. The lower branch of it is denoted by  $W_{-1}(\cdot)$ , which is the only branch that will prove beneficial in this paper. The reader is advised to refer to Corless et al. (1996) for a detailed treatment.

Throughout the paper, we shall use the convention that capital letters refer to random variables whereas lower case letters correspond to realizations thereof.

We will utilize Bernstein’s inequality in our derivation. Suitable representations of this result are outlined below without the proof.

**Theorem.** [Bernstein] *Let  $Z_1, \dots, Z_N$  be independent zero-mean random variables such that one has  $|Z_i| \leq \alpha$  almost surely for all  $i$ . Then, using Bernstein’s inequality (Bernstein (1924)) one obtains for all  $\epsilon > 0$ :*

$$\mathbb{P}\left(\sum_{i=1}^N Z_i > \epsilon\right) \leq \exp\left(-\frac{\epsilon^2}{2(V + \frac{1}{3}\alpha\epsilon)}\right), \quad (9)$$

where  $V = \sum_{i=1}^N \mathbb{E}[Z_i^2]$ .

Now, consider the sample mean  $\bar{Z} = n^{-1} \sum_{i=1}^n Z_i$  and let  $\bar{\sigma}^2$  be the sample variance, namely  $\bar{\sigma}^2 := n^{-1} \sum_{i=1}^n \text{VAR}[Z_i] = n^{-1} \sum_{i=1}^n \mathbb{E}[Z_i^2]$ . So, using (9) with  $n \cdot \epsilon$  in the role of  $\epsilon$ , we get

$$\mathbb{P}(\bar{Z} > \epsilon) \leq \exp\left(-\frac{n\epsilon^2}{2(\bar{\sigma}^2 + \frac{1}{3}\alpha\epsilon)}\right). \quad (10)$$

If  $Z_1, \dots, Z_n$  are, moreover, not just independent but also identically distributed, then  $\bar{\sigma}^2$  is equal to  $\sigma^2$  i.e. the variance of each  $Z_i$ . The latter presentation makes explicit: (1) the exponential decay with  $n$ ; (2) the fact that for  $\bar{\sigma}^2 \leq \epsilon$  we get a tail probability with exponent of order  $n\epsilon$  rather than  $n\epsilon^2$  (Lugosi (2003); Boucheron et al. (2013)) which has the potential to yield stronger bounds for small  $\epsilon$ .

### 3 MOTIVATIONS AND MAIN RESULTS

In this section, we motivate this work by pointing out the heterogeneity challenge and how we approach it. Our bounds also improve the functional form of the exponent, which is of independent significance. In the final part of this section, we summarize our main results.

#### 3.1 The Challenge and the Remedy

McAllester and Ortiz (2003) point out that for highly heterogeneous sums of the form (3), the standard form of Bernstein's inequality (9) does not lead to concentration inequalities of form (10): at least for the upper deviation of the missing mass, (9) does not imply any non-trivial bounds of the form (2). The reason is basically the fact that the  $w_i$  can vary wildly: some can be of order  $O(1/n)$ , other may be constants independent of  $n$ . For similar reasons, other standard inequalities such as Bennett, Angluin-Valiant and Hoeffding cannot be used to get bounds on the missing mass of the form (2) either (McAllester and Ortiz (2003)).

Having pointed out the deficiency of these standard inequalities, McAllester and Ortiz (2003) succeed in giving bounds of the form (2) on the missing mass, for a function  $\eta(\epsilon, n) \propto n\epsilon^2$ , both with a direct argument and using the Kearns-Saul inequality (Kearns and Saul (1998)). Recently, the constants appearing in the bounds were refined by Berend and Kontorovich (2013). The bounds proven by McAllester and Ortiz (2003) and Berend and Kontorovich (2013) are qualitatively similar to Hoeffding bounds for i.i.d. random variables: they do *not* improve the functional form from  $n\epsilon^2$  to  $n\epsilon$  for small variances.

This leaves open the question whether it is also possible to derive bounds which are more reminiscent of the Bernstein bound for i.i.d. random variables (10) which does exploit variance. In this paper, we show that the answer is a qualified yes: we give bounds that depend on weighted variance  $\underline{\sigma}^2$  defined in (7) rather than sample variance  $\bar{\sigma}^2$  as in (10) which is tight exactly in the

important case when  $\underline{\sigma}^2$  is small, and in which the denominator in (10) is specified by a factor depending on  $\epsilon$ ; in the special case of the missing mass, this factor turns out to be logarithmic in  $\epsilon$  and a free parameter  $\gamma$  as it will become clear later.

We derive - using Bernstein's inequality - novel bounds on missing mass that take into account explicit variance information with more accurate scaling and demonstrate their superiority for small deviations.

#### 3.2 Main Results

Consider the following functions

$$\gamma_\epsilon = -2W_{-1}\left(-\frac{\epsilon}{2\sqrt{e}}\right), \quad (11)$$

$$c(\epsilon) = \frac{3(\gamma_\epsilon - 1)}{5\gamma_\epsilon^2}. \quad (12)$$

Let  $Y$  denote the missing mass,  $n$  the sample size and  $\epsilon$  the deviation size.

**Theorem 1.** *For any  $0 < \epsilon < 1$  and any  $n \geq \lceil \gamma_\epsilon \rceil - 1$ , we obtain the following upper deviation bound*

$$\mathbb{P}(Y - \mathbb{E}[Y] \geq \epsilon) \leq e^{-c(\epsilon) \cdot n\epsilon}. \quad (13)$$

**Theorem 2.** *For any  $0 < \epsilon < 1$  and any  $n \geq \lceil \gamma_\epsilon \rceil - 1$ , we obtain the following lower deviation bound*

$$\mathbb{P}(Y - \mathbb{E}[Y] \leq -\epsilon) \leq e^{-c(\epsilon) \cdot n\epsilon}. \quad (14)$$

**Corollary 1.** *For any  $0 < \epsilon < 1$  and any  $n \geq \lceil \gamma_\epsilon \rceil - 1$ , using union bound we obtain the following deviation bound*

$$\mathbb{P}(|Y - \mathbb{E}[Y]| \geq \epsilon) \leq 2e^{-c(\epsilon) \cdot n\epsilon}. \quad (15)$$

The proof of the above theorems is provided in Section 5. However, let us develop a few tools in Section 4 which will be used later in our proofs.

### 4 NEGATIVE DEPENDENCE AND INFORMATION MONOTONICITY

Probabilistic analysis of most random variables and specifically the derivation of the majority of probabilistic bounds rely on independence assumption between variables which offers considerable simplification and convenience. Many random variables including the missing mass, however, consist of random components that are not independent.

Fortunately, even in cases where independence does not hold, one can still use some standard tools and methods provided variables are dependent in specific ways. The following notions of dependence are among the common ways that prove useful in these settings: negative association and negative regression.

#### 4.1 Negative Dependence and Chernoff's Exponential Moment Method

Our proof involves variables with a specific type of dependence known as negative association. One can infer concentration of sums of negatively associated random variables from the concentration of sums of their independent copies in certain situations. In exponential moment method, this property allows us to treat such variables as independent in the context of probability inequalities as we shall elaborate later in this section.

In the sequel, we present negative association and regression and supply tools that will be essential in proofs.

**Negative Association:** Any real-valued random variables  $X_1$  and  $X_2$  are negatively associated if

$$\mathbb{E}[X_1 X_2] \leq \mathbb{E}[X_1] \cdot \mathbb{E}[X_2]. \quad (16)$$

More generally, a set of random variables  $X_1, \dots, X_m$  are negatively associated if for any disjoint subsets  $A$  and  $B$  of the index set  $\{1, \dots, m\}$ , we have

$$\mathbb{E}[X_i X_j] \leq \mathbb{E}[X_i] \cdot \mathbb{E}[X_j] \quad \text{for } i \in A, j \in B. \quad (17)$$

**Stochastic Domination:** Assume that  $X$  and  $Y$  are real-valued random variables. Then,  $X$  is said to stochastically dominate  $Y$  if for all  $a$  in the range of  $X$  and  $Y$  we have

$$P(X \geq a) \geq P(Y \geq a). \quad (18)$$

We use the notation  $X \succeq Y$  to reflect (18) in short.

**Stochastic Monotonicity:** A random variable  $Y$  is stochastically non-decreasing in random variable  $X$  if

$$x_1 \leq x_2 \implies P(Y|X = x_1) \leq P(Y|X = x_2). \quad (19)$$

Similarly,  $Y$  is stochastically non-increasing in  $X$  if

$$x_1 \leq x_2 \implies P(Y|X = x_1) \geq P(Y|X = x_2). \quad (20)$$

The notations  $(Y|X = x_1) \preceq (Y|X = x_2)$  and  $(Y|X = x_1) \succeq (Y|X = x_2)$  represent the above definitions using the notion of stochastic domination. Also, we will use shorthands  $Y \uparrow X$  and  $Y \downarrow X$  to refer to the relations described by (19) and (20) respectively.

**Negative Regression:** Random variables  $X$  and  $Y$  have negative regression dependence relation if  $X \downarrow Y$ .

Dubhashi and Ranjan (1998) as well as Joag-Dev and Proschan (1983) summarize numerous notable properties of negative association and negative regression. Specifically, the former provides a proposition that indicates that Hoeffding-Chernoff bounds apply to sums of negatively associated random variables. Further, McAllester and Ortiz (2003) generalize these observations to essentially any concentration result derived based on the exponential moment

method by drawing a connection between deviation probability of a discrete random variable and Chernoff's entropy of a related distribution.

We provide a self-standing account by presenting the proof for some of these existing results as well as developing several generic tools that are applicable beyond missing mass problem.

**Lemma 1. [Binary Stochastic Monotonicity]** Let  $Y$  be a binary random variable (Bernoulli) and let  $X$  take on values in a totally ordered set  $\mathcal{X}$ . Then, one has

$$Y \downarrow X \implies X \downarrow Y. \quad (21)$$

*Proof.* For any  $x$ , we have

$$\begin{aligned} P(Y = 1 | X \leq x) &\geq \inf_{a \leq x} P(Y = 1 | X = a) \\ &\geq \sup_{a > x} P(Y = 1 | X = a) \\ &\geq P(Y = 1 | X > x). \end{aligned} \quad (22)$$

The above argument implies that random variables  $Y$  and  $\mathbf{1}_{X > x}$  are negatively associated and since the expression  $P(X > x | Y = 1) \leq P(X > x | Y = 0)$  holds for all  $x \in \mathcal{X}$ , it follows that  $X \downarrow Y$ .  $\square$

**Lemma 2. [Independent Binary Negative Regression]**

Let  $X_1, \dots, X_m$  be negatively associated random variables and  $Y_1, \dots, Y_m$  be binary random variables (Bernoulli) such that either  $Y_i \downarrow X_i$  or  $Y_i \uparrow X_i$  holds for all  $i \in \{1, \dots, m\}$ . Then  $Y_1, \dots, Y_m$  are negatively associated.

*Proof.* For any disjoint subsets  $A$  and  $B$  of  $\{1, \dots, m\}$ , taking  $i \in A$  and  $j \in B$  we have

$$\mathbb{E}[Y_i Y_j] = \mathbb{E}[\mathbb{E}[Y_i Y_j | X_1, \dots, X_m]] \quad (23)$$

$$= \mathbb{E}[\mathbb{E}[Y_i | X_i] \cdot \mathbb{E}[Y_j | X_j]] \quad (24)$$

$$\leq \mathbb{E}[\mathbb{E}[Y_i | X_i]] \cdot \mathbb{E}[\mathbb{E}[Y_j | X_j]] \quad (25)$$

$$= \mathbb{E}[Y_i] \cdot \mathbb{E}[Y_j]. \quad (26)$$

Here, (24) holds since each  $Y_i$  only depends on  $X_i$ . Inequality (25) follows because  $X_i$  and  $X_j$  are negatively associated and we have  $\mathbb{E}[Y_i | X_i] = P(Y_i | X_i)$ .  $\square$

**Lemma 3. [Chernoff]** For any real-valued random variable  $X$  with finite mean  $\mathbb{E}[X]$  and for any  $x > 0$ , we have:

$$DP(X, x) \leq \exp(-S(X, x)), \quad (27)$$

$$S(X, x) = \sup_{\lambda} \{\lambda x - \ln(Z(X, \lambda))\}, \quad (28)$$

$$Z(X, \lambda) = \mathbb{E}[e^{\lambda X}]. \quad (29)$$

The lemma follows from the observation that for  $\lambda \geq 0$ , we have the following

$$P(X \geq x) = P(e^{\lambda X} \geq e^{\lambda x}) \leq \inf_{\lambda} \frac{\mathbb{E}[e^{\lambda X}]}{e^{\lambda x}}. \quad (30)$$

This approach is known as *exponential moment method* (Chernoff (1952)) because of the inequality in (30).

**Lemma 4. [Negative Association]** In the exponential moment method, concentration of sums of negatively associated random variables can be deduced from the concentration of sums of their independent copies.

*Proof.* Let  $X_1, \dots, X_m$  be any set of negatively associated variables. Let  $X'_1, \dots, X'_m$  be independent shadow variables, i.e., independent variables such that each  $X'_i$  is distributed identically to  $X_i$ . Let  $X = \sum_i^m X_i$  and  $X' = \sum_i^m X'_i$ . For any set of negatively associated random variables, one has  $S(X, \epsilon) \geq S(X', \epsilon)$  since:

$$\begin{aligned} Z(X, \lambda) &= \mathbb{E}[e^{\lambda X}] = \mathbb{E}\left[\prod_i^m e^{\lambda X_i}\right] \\ &\leq \prod_i^m \mathbb{E}[e^{\lambda X_i}] = \mathbb{E}[e^{\lambda X'}] = Z(X', \lambda). \end{aligned} \quad (31)$$

The lemma is due to McAllester and Ortiz (2003) which follows from definition of entropy function  $S$  given by (28).  $\square$

This lemma is very helpful in the context of large deviation bounds: it implies that one can treat negatively associated variables as if they were independent (McAllester and Ortiz (2003); Dubhashi and Ranjan (1998)).

**Lemma 5. [Balls and Bins]** Let  $S$  be any sample comprising  $n$  items drawn i.i.d. from a fixed distribution on integers  $\mathcal{N} = \{1, \dots, N\}$  (bins). Define  $C_i$  to be the number of times that integer  $i$  occurs in  $S$ . The random variables  $C_1, \dots, C_N$  are negatively associated.

*Proof.* Let  $f$  and  $g$  be non-decreasing and non-increasing functions respectively. We have

$$(f(x) - f(y))(g(x) - g(y)) \leq 0. \quad (32)$$

Further, assume that  $X$  is a real-valued random variable and  $Y$  is an independent shadow variable corresponding to  $X$ . Exploiting (32), we obtain

$$\mathbb{E}[f(X)g(X)] \leq \mathbb{E}[f(X)] \cdot \mathbb{E}[g(X)], \quad (33)$$

which implies that  $f(X)$  and  $g(X)$  are negatively associated. Inequality (33) is an instance of Chebychev's fundamental *association inequality*.

Now, suppose without loss of generality that  $N = 2$ . Take  $X \in [0, n]$ , and consider the following functions

$$\begin{cases} f(X) = X, \\ g(X) = n - X, \end{cases} \quad (34)$$

where  $n = C_i + C_j$  is the total counts. Since  $f$  and  $g$  are non-decreasing and non-increasing functions of  $X$ , choosing  $X = f(C_i) = C_i$  we have for all  $i, j \in \mathcal{N}$  that

$$\mathbb{E}[C_i \cdot C_j] \leq \mathbb{E}[C_i] \cdot \mathbb{E}[C_j], \quad (35)$$

which concludes the proof for  $N = 2$ . Now, taking  $f(C_i) = C_i$  and  $g(C_i) = n - \sum_{j \neq i} C_j$  where  $n = \sum_{k=1}^N C_k$ , for  $N > 2$  the same argument implies that  $C_i$  and  $C_j$  are negatively associated for all  $i \in \mathcal{N}$  and  $j \in \mathcal{N} \setminus i$ . That is to say, any increase in  $C_i$  will cause a decrease in some or all of  $C_j$  variables with  $j \neq i$  and vice versa. It is easy to verify that the same is true for any disjoint subsets of the set  $\{C_1, \dots, C_N\}$ .  $\square$

**Lemma 6. [Monotonicity]** For any negatively associated random variables  $X_1, \dots, X_m$  and any non-decreasing functions  $f_1, \dots, f_m$ , we have that  $f_1(X_1), \dots, f_m(X_m)$  are negatively associated. The same holds if the functions  $f_1, \dots, f_m$  were non-increasing.

**Remark:** The proof is in the same spirit as that of association inequality (33) and motivated by composition rules for monotonic functions that one can repeatedly apply to (32).

**Lemma 7. [Union]** The union of independent sets of negatively associated random variables yields a set of negatively associated random variables.

Suppose that  $X$  and  $Y$  are independent vectors each of which comprising a negatively associated set. Then, the concatenated vector  $[X, Y]$  is negatively associated.

*Proof.* Let  $[X_1, X_2]$  and  $[Y_1, Y_2]$  be some arbitrary partitions of  $X$  and  $Y$  respectively and assume that  $f$  and  $g$  are non-decreasing functions. Then, one has

$$\begin{aligned} \mathbb{E}[f(X_1, Y_1) \cdot g(X_2, Y_2)] &= \\ \mathbb{E}[\mathbb{E}[f(X_1, Y_1) \cdot g(X_2, Y_2) \mid Y_1, Y_2]] &\leq \\ \mathbb{E}[\mathbb{E}[f(X_1, Y_1) \mid Y_1] \cdot \mathbb{E}[g(X_2, Y_2) \mid Y_2]] &\leq \\ \mathbb{E}[\mathbb{E}[f(X_1, Y_1) \mid Y_1]] \cdot \mathbb{E}[\mathbb{E}[g(X_2, Y_2) \mid Y_2]] &= \\ \mathbb{E}[f(X_1, Y_1)] \cdot \mathbb{E}[g(X_2, Y_2)]. \end{aligned} \quad (36)$$

The first inequality is due to independence of  $[X_1, X_2]$  from  $[Y_1, Y_2]$  which results in negative association being preserved under conditioning and the second inequality follows because  $[Y_1, Y_2]$  are negatively associated (Joag-Dev and Proschan (1983)). The same holds if  $f$  and  $g$  were non-increasing functions.  $\square$

**Lemma 8. [Splitting]** Splitting an arbitrary subset of bins of any fixed discrete distribution yields a set of negatively associated random bins.

*Proof.* Let  $w = (w_1, \dots, w_m)$  be a discrete distribution and  $\mathcal{W} = \{W_1, \dots, W_m\}$  be the associated set of random bins. Assume that  $w_i$  is split into  $k$  bins  $\mathcal{W}_i^S = \{W_{i1}, \dots, W_{ik}\}$  such that  $w_i = \sum_{j=1}^k W_{ij}$ . Then, by Lemma 5 members of split set  $\mathcal{W}_i^S$  are negatively associated. Clearly, the same holds for all  $1 \leq i \leq m$  as well as any other subset of set  $\mathcal{W}$ . Moreover, for all  $1 \leq i \leq m$  the sets  $\mathcal{W}_i^S$  and  $\mathcal{W} \setminus W_i$  are negatively associated by Lemma 5 and Lemma 7.  $\square$

**Lemma 9. [Absorption]** Absorbing any subset of bins of a discrete distribution yields negatively associated bins.

*Proof.* Let  $w = (w_1, \dots, w_N)$  be a discrete distribution and let  $\mathcal{W} = \{W_1, \dots, W_N\}$  be the associated set of random bins. Assume without loss of generality that  $\mathcal{W}^A = \{W_1^A, \dots, W_{N-1}^A\}$  is the absorption-induced set of random bins where  $w_N$  is absorbed to produce  $w^A = (w_1^A, \dots, w_{N-1}^A)$  and where  $w_i^A = w_i + \frac{w_N}{N-1}$  for  $i = 1, \dots, N-1$ . So,  $w_N$  is discarded and we have  $\sum_{i=1}^{N-1} W_i^A = 1 - w_N$ . The rest of the proof concerns applying Lemma 5 to the absorb set  $\mathcal{W}^A$ . The same holds if we absorb  $w_N$  to a subset of  $\mathcal{W} \setminus W_N$ .  $\square$

## 4.2 Negative Dependence and the Missing Mass

For missing mass, the variables  $W_i = \frac{C_i}{n}$  are negatively associated owing to Lemma 5 and linearity of expectation. Also, one has  $\forall i : Y_i \downarrow W_i$ . So, by Lemma 1 we infer that  $\forall i : W_i \downarrow Y_i$ . Now,  $Y_1, \dots, Y_N$  are negatively associated because they are a set of independent binary variables with negative regression dependence (Lemma 2). Thus, concentration variables  $Z_i = w_i Y_i - \mathbb{E}[w_i Y_i] := \zeta(Y_i)$  are negatively associated by Lemma 6 since we have

$$\zeta(Y_i) = \begin{cases} -w_i q_i & \text{if } Y_i = 0, \\ w_i(1 - q_i) & \text{if } Y_i = 1. \end{cases} \quad (37)$$

For all  $i$ ,  $\zeta$  is a non-decreasing function of  $Y_i$ . Likewise, concentration variables  $-Z_i$  are negatively associated.

## 4.3 Information Monotonicity and Partitioning

**Lemma 10. [Information Monotonicity]** Let  $p = (p_1, \dots, p_N)$  be a discrete distribution on  $X = (x_1, \dots, x_N)$  such that for  $1 \leq i \leq N$  we have  $P(X = x_i) = p_i$ . Suppose we partition  $X$  into  $m \leq N$  non-empty disjoint groups  $G_1, \dots, G_m$ , namely

$$\begin{aligned} X &= \cup G_i, \\ \forall i \neq j : G_i \cap G_j &= \emptyset. \end{aligned} \quad (38)$$

This is called *coarse binning* since it generates a new distribution with groups  $G_i$  whose dimensionality is less than that of the original distribution. Note that once the distribution is transformed, considering any outcome  $x_i$  from the original distribution we will only have access to its group membership information; for instance, we can observe that it belongs to  $G_j$  but we will not be able to recover  $p_i$ .

Let us denote the induced distribution over the partition  $G = (G_1, \dots, G_m)$  by  $p^G = (p_1^G, \dots, p_m^G)$ . Clearly, we have

$$p_i^G = P(G_i) = \sum_{j \in G_i} P(x_j). \quad (39)$$

Now, consider the  $f$ -divergence  $D_f(p^G || q^G)$  between induced probability distributions  $p^G$  and  $q^G$ . Information

monotonicity states that information is lost as we partition elements of  $p$  and  $q$  into groups to produce  $p^G$  and  $q^G$  respectively. Namely, for any  $f$ -divergence one has

$$D_f(p^G || q^G) \leq D_f(p || q), \quad (40)$$

which is due to Csiszár (Csiszár (1977, 2008); Amari (2009)). This inequality is tight if and only if for any outcome  $x_i$  and partition  $G_j$ , we have  $p(x_i | G_j) = q(x_i | G_j)$ .

**Lemma 11. [Partitioning]** In the exponential moment method, one can establish a deviation bound for any discrete random variable  $X$  by invoking Chernoff's method on the associated discrete partition random variable  $X^G$ .

Formally, assume  $X$  and  $X_\lambda$  are discrete random variables defined on the set  $\mathcal{X}$  endowed with probability distributions  $p$  and  $p_\lambda$  respectively. Further, suppose that  $X^G$  and  $X_\lambda^G$  are discrete variables on a partition set  $\mathcal{X}^G$  endowed with  $p^G$  and  $p_\lambda^G$  that are obtained from  $p$  and  $p_\lambda$  by partitioning using some partition  $G$ . Then, we have

$$\forall x > 0 : DP(X, x) \leq \exp(-S(X^G, x)). \quad (41)$$

*Proof.* Let  $\lambda(x)$  be the optimal  $\lambda$  in (28). Then, we have

$$\begin{aligned} S(X, x) &= x\lambda(x) - \ln(Z(X, \lambda(x))) \\ &= D_{KL}(p_{\lambda(x)} || p) \\ &\geq D_{KL}(p_{\lambda(x)}^G || p^G) \\ &= S(X^G, x), \end{aligned} \quad (42)$$

where we have introduced the  $\lambda$ -induced distribution

$$P_\lambda(X = x) = \frac{e^{\lambda x}}{Z(X, \lambda)} P(X = x). \quad (43)$$

The inequality step in (42) follows from (40) and the observation that  $D_{KL}$  is an instance of  $f$ -divergence where  $f(v) = v \ln(v)$  with  $v \geq 0$ .  $\square$

## 5 PROOF OF THE MAIN RESULTS

The central idea of the proof is to regulate the terms in the sum given by (3) via controlling the magnitude of bins of the distribution using operations that preserve negative association. This mechanism will help defeat the heterogeneity issue leading to the failure of standard probability inequalities described by McAllester and Ortiz (2003).

### 5.1 Proof of Theorem 1: Upper Deviation Bound

We consider the thresholds  $\tau = \frac{\theta}{n}$  and  $\tau' = \frac{2\theta}{n}$  and reduce the problem to one in which all bins that are larger than  $\tau$  are eliminated, where  $\theta \in \mathbb{R}$  will depend on the target deviation size  $\epsilon$ .

The reduction is performed by *splitting* the bins that are larger than  $\tau$  and then *absorbing* the bins that are smaller

than  $\tau$ . This is followed by choosing a threshold that yields the sharpest bound for the choice of  $\epsilon$ . It turns out that the optimal threshold will too be a function of  $\epsilon$ .

Let  $\mathcal{I}_\tau \subseteq \mathcal{I}$  denote the subset of bins that are at most as large as  $\tau$ ,  $\mathcal{I}_\theta$  the subset of bins whose magnitude is between  $\tau$  and  $\tau'$ ,  $\mathcal{I}_{\tau'}$  the subset of bins larger than  $\tau'$  and  $\mathcal{I}'_\theta$  and  $\mathcal{I}'_{\tau'}$ , the set of bins that we obtain after splitting members of  $\mathcal{I}_\theta$  and  $\mathcal{I}_{\tau'}$ , respectively.

Now, for each  $i \in \mathcal{I} \setminus \mathcal{I}_\tau = \{\mathcal{I}_\theta \cup \mathcal{I}_{\tau'}\}$  and for some  $k \in \mathbb{N}$  that depends on  $i$  (but we suppress that notation below), we will have that  $k \cdot \tau \leq w_i < (k+1) \cdot \tau$ . For all such  $i$ , we define extra independent Bernoulli random variables  $Y_{ij}$  with  $j \in \mathcal{J}_i := \{1, \dots, k\}$  and their associated bins  $w_{ij}$ . For  $j \in \{1, \dots, k-1\}$ ,  $w_{ij} = \tau$  and  $w_{ik} = w_i - (k-1) \cdot \tau$ . In this way, all bins that are larger than  $\tau$  are split up into  $k$  bins, each of which is in-between  $\tau$  and  $\tau'$ ; more precisely, the first  $k-1$  are exactly  $\tau$  and the last one may be larger. Therefore, we consider the split random variable  $Y' = \sum_{i \in \mathcal{I}_\tau} w_i Y_i + \sum_{i \in \{\mathcal{I}'_{\tau'} \cup \mathcal{I}'_\theta\}} \sum_{j \in \mathcal{J}_i} w_{ij} Y_{ij}$  and the set  $\mathcal{U}' = \{i \mid w_i < \tau'\} = \{\mathcal{I}_\tau \cup \mathcal{I}'_\theta \cup \mathcal{I}'_{\tau'}\}$ . Furthermore, we introduce the random variable  $Y'' = \sum_{i \in \mathcal{U}''} w_i Y_i$  on the absorption-induced set  $\mathcal{U}'' = \{i \mid \tau \leq w_i < \tau'\}$ . The set  $\mathcal{U}''$  is generated from  $\mathcal{U}'$  as follows: we take the largest element  $j \in \mathcal{U}'$  with  $w_j < \tau$ , update  $w_l$  using  $w_l \leftarrow w_l + \frac{w_j}{|\mathcal{U}'|-1}$  for  $\{l \in \mathcal{U}' : l \neq j, w_l < \tau\}$  and discard  $w_j$ . Repeating this procedure gives a set of bins whose sizes are in-between  $\tau$  and  $\tau'$  plus a single bin of size smaller than  $\tau$ ; absorbing the latter into one of the members of the former with size  $\tau$  yields  $\mathcal{U}''$ .

Now, by choosing  $\theta$  such that  $f(\theta) = e^{-\theta} = \frac{\epsilon}{\gamma}$  and  $\theta = f^{-1}(\frac{\epsilon}{\gamma}) = \ln(\frac{\gamma}{\epsilon})$  for any  $0 < \epsilon < 1$  and  $e\epsilon < \gamma < e^n \epsilon$  as generic domain for  $\gamma$ , we derive the upper deviation bound for missing mass as follows

$$\mathbb{P}(Y - \mathbb{E}[Y] \geq \epsilon) \leq \quad (44)$$

$$\mathbb{P}(Y' - \mathbb{E}[Y'] \geq \epsilon) = \quad (45)$$

$$\mathbb{P}(Y' - \mathbb{E}[Y'] + (\mathbb{E}[Y'] - \mathbb{E}[Y]) \geq \epsilon) \leq \quad (46)$$

$$\mathbb{P}(Y' - \mathbb{E}[Y'] + f(\theta) \geq \epsilon) = \quad (47)$$

$$\mathbb{P}\left(Y' - \mathbb{E}[Y'] \geq \left(\frac{\gamma-1}{\gamma}\right)\epsilon\right) = \quad (48)$$

$$\exp\left(-\frac{\left(\frac{\gamma-1}{\gamma}\right)^2 \epsilon^2}{2(V_{\mathcal{U}''} + \frac{\alpha_n}{3} \cdot \left(\frac{\gamma-1}{\gamma}\right) \cdot \epsilon)}\right) \leq \quad (49)$$

$$\exp\left(-\frac{\left(\frac{\gamma-1}{\gamma}\right)^2 \epsilon^2}{2\left(\frac{\theta}{n} \cdot \epsilon + \frac{2\theta}{3n} \cdot \left(\frac{\gamma-1}{\gamma}\right) \cdot \epsilon\right)}\right) \leq \quad (50)$$

$$\inf_{\gamma} \left\{ \exp\left(-\frac{3n\epsilon(\gamma-1)^2}{10\gamma^2 \ln(\frac{\gamma}{\epsilon})}\right) \right\} = \quad (51)$$

$$e^{-c(\epsilon) \cdot n\epsilon}. \quad (52)$$

Clearly, we will have that  $\tau^* = \frac{\theta^*}{n}$  where  $\theta^* = \ln(\frac{\gamma\epsilon}{\epsilon})$ .

Inequality (45) follows because the splitting procedure cannot decrease deviation probability of missing mass.

Formally, assume without loss of generality that  $\mathcal{I} \setminus \mathcal{I}_\tau$  has only one element corresponding to  $Y_1$ ,  $\mathcal{J}_1 = \{1, 2\}$  and  $k_1 = 1$  i.e.  $w_1$  is split into two parts. Then, deviation probability of  $Y$  can be thought of as the total probability mass associated to independent Bernoulli variables  $Y_1, \dots, Y_N$  whose weighted sum is bounded below by some tail  $t > 0$ . Hence, we have

$$\begin{aligned} \mathbb{P}(Y \geq t) &= \sum_{Y^{1N}; \hat{Y} \geq t} P(Y_1, \dots, Y_N) \\ &= \sum_{Y^{1N}; \hat{Y} \geq t} R(Y_1) \cdot \prod_{i=2}^N R(Y_i) \\ &\quad + \sum_{Y^{1N}; \hat{Y} < t; Y \geq t} R(Y_1) \cdot \prod_{i=2}^N R(Y_i) \\ &= \sum_{Y^{1N}; \hat{Y} \geq t} R(Y_1) \cdot \prod_{i=2}^N R(Y_i) \\ &\quad + \sum_{Y^{1N}; \hat{Y} < t; Y \geq t, Y_1=1} R(Y_1) \cdot \prod_{i=2}^N R(Y_i) \\ &= \sum_{Y^{2N}; \hat{Y} \geq t} \prod_{i=2}^N R(Y_i) \\ &\quad + \sum_{Y^{2N}; \hat{Y} < t; Y \geq t} q_1 \cdot \prod_{i=2}^N R(Y_i), \end{aligned} \quad (53)$$

where  $\hat{Y} = \sum_{i \geq 2} w_i Y_i$  and  $R(Y_i) = q_i$  if  $Y_i = 1$  and  $R(Y_i) = 1 - q_i$  otherwise. Likewise, one can express the upper deviation probability of  $Y'$  as follows

$$\begin{aligned} \mathbb{P}(Y' \geq t) &= \sum_{Y_{1N}; \hat{Y} \geq t} R(Y_1) \cdot \prod_{i=2}^N R(Y_i) \\ &\quad + \sum_{Y_{11}, Y_{12}, Y^{2N}; \hat{Y} < t; Y' \geq t} \left(R(Y_{11}) \cdot R(Y_{12})\right) \prod_{i=2}^N R(Y_i) \\ &= \sum_{Y_{2N}; \hat{Y} \geq t} \prod_{i=2}^N R(Y_i) \\ &\quad + \sum_{Y_{11}, Y_{12}, Y^{2N}; \hat{Y} < t; Y' \geq t} \left(R(Y_{11}) \cdot R(Y_{12})\right) \prod_{i=2}^N R(Y_i) \\ &\geq \sum_{Y^{2N}; \hat{Y} \geq t} \prod_{i=2}^N R(Y_i) \\ &\quad + \sum_{Y^{2N}; \hat{Y} < t; Y' \geq t} (q_{11} \cdot q_{12}) \prod_{i=2}^N R(Y_i), \end{aligned} \quad (54)$$

where  $R(Y_{ij}) = q_{ij}$  if  $Y_{ij} = 1$  and  $R(Y_{ij}) = 1 - q_{ij}$  otherwise. Thus, combining (53) and (54) we have

$$\begin{aligned} \mathbb{P}(Y' \geq t) - \mathbb{P}(Y \geq t) &\geq \\ &\sum_{Y^{2N}; \hat{Y} < t; Y' \geq t; Y \geq t} (q_{11} \cdot q_{12} - q_1) \prod_{i=2}^N R(Y_i) = \\ &\sum_{Y^{2N}; \hat{Y} < t; Y' \geq t} (q_{11} \cdot q_{12} - q_1) \prod_{i=2}^N R(Y_i). \end{aligned} \quad (55)$$

To complete the proof for (45), we require the expression for the difference between deviation probabilities in (55) to be non-negative for all  $t > 0$  which holds if  $q_1 \leq q_{11} \cdot q_{12}$ . For the missing mass, this condition holds. Without loss of generality, assume that  $w_i$  is split into two terms; namely, we have  $w_i = w_{ij} + w_{ij'}$ . Then, we can check the above condition as follows

$$\begin{aligned} q_i &= (1 - w_i)^n \leq (1 - w_{ij})^n \cdot (1 - w_{ij'})^n \\ &= \left(1 - \underbrace{(w_{ij} + w_{ij'})}_{w_i} + \underbrace{w_{ij} \cdot w_{ij'}}_{\geq 0}\right)^n. \end{aligned} \quad (56)$$

One can verify using induction that (56) holds also for cases where the split operation produces more than two terms. Now, choosing tail size  $t = \epsilon + \mathbb{E}Y$  implies (45).

Inequality (47) follows because the gap between the expectations will be negligible. Denoting  $\mathbb{E}[Y'_i] = q'_i$ , we have

$$q'_i = \begin{cases} q_i & \text{if } i \in \mathcal{I}_\tau, \\ q_{ij} & \text{if } i \in \{\mathcal{I}'_\tau, \cup \mathcal{I}'_\theta\}, \\ 0 & \text{otherwise.} \end{cases} \quad (57)$$

Namely, we can write

$$\begin{aligned} g_u(\theta) &= \mathbb{E}[Y'] - \mathbb{E}[Y] = \sum_{i \in \mathcal{I}} w_i (q'_i - q_i) \\ &= \sum_{i \in \mathcal{I}_\tau} w_i q_i + \sum_{i \in \{\mathcal{I}'_\tau, \cup \mathcal{I}'_\theta\}} \sum_{j \in \mathcal{J}_i} w_{ij} q_{ij} - \sum_{i \in \mathcal{I}} w_i q_i \\ &= \sum_{i \in \{\mathcal{I}'_\tau, \cup \mathcal{I}'_\theta\}} \sum_{j \in \mathcal{J}_i} w_{ij} q_{ij} - \sum_{i \in \{\mathcal{I}_\tau, \cup \mathcal{I}_\theta\}} w_i q_i \\ &\leq \sum_{i \in \{\mathcal{I}'_\tau, \cup \mathcal{I}'_\theta\}} \sum_{j \in \mathcal{J}_i} w_{ij} q_{ij} \\ &\leq \sum_{i \in \{\mathcal{I}'_\tau, \cup \mathcal{I}'_\theta\}} \sum_{j \in \mathcal{J}_i} w_{ij} f(\theta) \leq f(\theta). \end{aligned} \quad (58)$$

The expression in (49) is Bernstein's inequality applied to the random variable  $Z_u = \sum_{i \in \mathcal{U}''} Z_i$  relying upon Lemma 11. Here, the concentration variables are  $Z_i = w_i Y_i - \mathbb{E}[w_i Y_i]$  with  $i \in \mathcal{U}''$  and we set  $\alpha_u = \tau'$ .

Let  $V_{\mathcal{U}''}$  be variance proxy term  $V$  in Bernstein's inequality as defined in (9) attached to  $\mathcal{U}''$ . The functions  $f, g : (0, 1) \times \mathbb{N} \rightarrow (0, 1)$  with  $f(x, n) = x(1-x)^n(1-(1-x)^n)$

and  $g(x, n) = x^2(1-x)^n(1-(1-x)^n)$  are non-increasing with respect to  $x$  on  $(\frac{1}{n+1}, 1)$  and  $(\frac{2}{n+2}, 1)$  respectively. We obtain for  $1 < \theta < n$ , an upperbound on  $V_{\mathcal{U}''}$  as follows:

$$\begin{aligned} V_{\mathcal{U}''} &= \sum_{i: w_i \in \mathcal{U}''} w_i^2 (1 - w_i)^n \left(1 - (1 - w_i)^n\right) \\ &\leq \tau \cdot \sum_{i: w_i \in \mathcal{U}''} w_i (1 - w_i)^n \left(1 - (1 - w_i)^n\right) \\ &= \tau \cdot \sigma_{\mathcal{U}''}^2 \\ &\leq \tau \cdot \sum_{i: \tau \leq w_i < \tau'; \sum_i w_i = 1} w_i (1 - w_i)^n \\ &\leq \underbrace{|\mathcal{I}(\theta, n)|}_{\leq \frac{n}{\theta}} \cdot \left(\frac{\theta}{n}\right)^2 \cdot \left(1 - \frac{\theta}{n}\right)^n \\ &\leq \frac{\theta}{n} \cdot e^{-\theta} < \frac{\theta}{n} \cdot \epsilon. \end{aligned} \quad (59)$$

In order to see why (52) holds, consider  $c(\gamma, \epsilon) = \frac{\epsilon(\gamma-1)^2}{\gamma^2 \ln(\frac{\gamma}{\epsilon})}$  and let us examine the derivatives as follows

$$\frac{\partial c(\gamma, \epsilon)}{\partial \gamma} = -\frac{\epsilon^2(\gamma-1)(\gamma-1-2\ln(\frac{\gamma}{\epsilon}))}{\gamma^3 \ln^2(\frac{\gamma}{\epsilon})}, \quad (60)$$

$$\begin{aligned} \frac{\partial^2 c(\gamma, \epsilon)}{\partial \gamma^2} &= \frac{\epsilon^2}{\gamma^4 \ln^3(\frac{\gamma}{\epsilon})} \left[ (6-4\gamma) \ln^2\left(\frac{\gamma}{\epsilon}\right) + \right. \\ &\quad \left. (\gamma^2 - 6\gamma + 5) \ln\left(\frac{\gamma}{\epsilon}\right) + 2(\gamma-1)^2 \right]. \end{aligned} \quad (61)$$

Solving for the first derivative using (60), we obtain

$$\gamma_\epsilon = -2W_{-1}\left(-\frac{\epsilon}{2\sqrt{e}}\right). \quad (62)$$

Inspecting the second derivative given by (61), we can see that the function  $c(\gamma, \epsilon)$  is concave with respect to  $\gamma$  for any  $\gamma > 2$ . Recall, moreover, that there are interrelated restrictions on  $\gamma, \epsilon$  and  $n$  in derivation of (51) and (52) which are collectively expressed as

$$\max\{e \cdot \epsilon, 1, 2, \gamma(1)\} < \gamma < e^n, \quad n \geq \lceil \gamma_\epsilon \rceil - 1. \quad (63)$$

## 5.2 Proof of Theorem 2: Lower Deviation Bound

The proof for lower deviation bound proceeds in the same spirit as section 5.1. The idea is again to reduce the problem to one in which all bins that are larger than the threshold  $\tau$  are eliminated.

We split large bins and then absorb small bins to enable us shrink the variance while controlling the magnitude of terms (and consequently the key quantities  $\alpha$  and  $V$ ) before applying Bernstein's inequality.

By choosing  $\theta$  such that  $f(\theta) = e^{-\theta}$  so that  $\theta = \ln(\frac{\gamma}{\epsilon})$ , for any  $0 < \epsilon < 1$  with  $e\epsilon < \gamma < e^n \epsilon$  being generic domain

for  $\gamma$  we obtain a lower deviation bound as follows

$$\mathbb{P}(Y - \mathbb{E}[Y] \leq -\epsilon) \leq \quad (64)$$

$$\mathbb{P}(Y' - \mathbb{E}[Y] \leq -\epsilon) = \quad (65)$$

$$\mathbb{P}(Y' - \mathbb{E}[Y'] + (\mathbb{E}[Y'] - \mathbb{E}[Y]) \leq -\epsilon) \leq \quad (66)$$

$$\mathbb{P}(Y' - \mathbb{E}[Y'] - f(\theta) \leq -\epsilon) = \quad (67)$$

$$\mathbb{P}\left(Y' - \mathbb{E}[Y'] \leq -\left(\frac{\gamma-1}{\gamma}\right)\epsilon\right) \leq \quad (68)$$

$$\leq \exp\left(-\frac{\left(\frac{\gamma-1}{\gamma}\right)^2 \epsilon^2}{2(V_{\mathcal{L}''} + \frac{\alpha_l}{3} \cdot \left(\frac{\gamma-1}{\gamma}\right) \cdot \epsilon)}\right) \leq \quad (69)$$

$$\leq \exp\left(-\frac{\left(\frac{\gamma-1}{\gamma}\right)^2 \epsilon^2}{2\left(\frac{\theta}{n} \cdot \epsilon + \frac{2\theta}{3n} \cdot \left(\frac{\gamma-1}{\gamma}\right) \cdot \epsilon\right)}\right) \leq \quad (70)$$

$$\inf_{\gamma} \left\{ \exp\left(-\frac{3n\epsilon(\gamma-1)^2}{10\gamma^2 \ln\left(\frac{\gamma}{\epsilon}\right)}\right) \right\} = \quad (71)$$

$$e^{-c(\epsilon) \cdot n\epsilon}, \quad (72)$$

where  $c(\epsilon)$  and  $\tau^*$  are as before and domain restrictions are determined similar to (63).

The variables  $Y'$  and  $Y''$ , and the sets  $\mathcal{L}'$  and  $\mathcal{L}''$  are defined in the same fashion as Section 5.1.

The first inequality is proved in the same way as (45). Now, we set  $\mathbb{E}[Y'_i] = q'_i$  such that

$$q'_i = \begin{cases} q_i & \text{if } w_i < \tau', \\ 0 & \text{otherwise.} \end{cases} \quad (73)$$

Inequality (67) follows because the compensation gap will remain small since we have

$$\begin{aligned} g_l(\theta) &= \mathbb{E}[Y'] - \mathbb{E}[Y] = \sum_{i \in \mathcal{I}} w_i (q'_i - q_i) \\ &= \sum_{i: w_i < \tau'} w_i q_i - \sum_{i \in \mathcal{I}} w_i q_i = - \sum_{i: w_i \geq \tau'} w_i q_i \\ &\geq - \sum_{i: w_i \geq \tau'} w_i f(\theta) \geq -f(\theta). \end{aligned} \quad (74)$$

The expression given by (69) is Bernstein's inequality applied to random variable  $Z_l = \sum_{i \in \mathcal{L}''} Z_i$  where we have defined  $Z_i = w_i(\mu - w_i Y_i) - \mathbb{E}[w_i(\mu - w_i Y_i)]$  with  $\mu$  being the upper bound on the value of the  $w_i Y_i$  terms.

Further, we choose  $\alpha_l = \tau'$ . Observe that  $Z_l = -Z_u$  and  $\mu = \alpha_l$ . Finally, an upperbound on  $V_{\mathcal{L}''}$  can be determined with arguments identical to that of  $V_{\mathcal{L}'}$ .

The rest of the proof proceeds in an analogous manner to the proof of upper deviation bound.

## 6 CONCLUSIONS

We proposed a new technique for establishing concentration inequalities and applied it to the missing mass using

Bernstein's inequality. Along the way, we introduced a collection of concepts and tools in the intersection of probability theory and information theory that have the potential to be advantageous in more general settings.

Recall that Bernstein's inequality hinges on establishing an upperbound on  $Z(X, \lambda)$  given by (29) in a particular way. Clearly, this choice is not unique and one can choose any other upperbound (e.g. c.f. Lugosi (2003)) and apply the same technique to derive potentially tight bounds achievable within the framework of exponential moment method.

Our bounds sharpen the leading results for missing mass in the case of small deviations. These inequalities hold subject to the mild condition that the sample size is large enough, namely  $n \geq \lceil \gamma \epsilon \rceil - 1$ .

We select the best known bounds in Berend and Kontorovich (2013) for the comparison. Our lower deviation and upper deviation bounds improve state-of-the-art for any  $0 < \epsilon < 0.021$  and any  $0 < \epsilon < 0.045$  respectively.

Plugging in the definitions, we can see that the compensation gap can be expressed as a function of  $\epsilon$  and show that the following holds

$$|g(\epsilon)| \leq \sqrt{\epsilon} \cdot \exp\left(W_{-1}\left(\frac{-\epsilon}{2\sqrt{\epsilon}}\right)\right), \quad (75)$$

where we have dropped the subscript of gap  $g$ . Note that the gap is negligible for small  $\epsilon$  compared to large values of  $\epsilon$  for both (52) and (72). This observation supports the fact that we obtained sharper bounds for small deviations.

Mathematical analysis of missing mass via concentration inequalities has various important applications including density estimation, generalization bounds and handling missing data just to name a few. Needless to say that any refinement in bounds or tools developed for the former may directly contribute to advancement in those applications.

## Abstract

We consider the problem of learning perturbation-based probabilistic models by computing and differentiating expected losses. This is a challenging computational problem that has traditionally been tackled using Monte Carlo-based methods. In this work, we show how a generalization of parametric min-cuts can be used to address the same problem, achieving higher accuracy and faster performance than a sampling-based baseline. Utilizing our proposed *Skeleton Method*, we show that we can learn the perturbation model so as to directly minimize expected losses. Experimental results show that this approach offers promise as a new way of training structured prediction models under complex loss functions.

## 1 INTRODUCTION

Many problems in machine learning can be formulated as structured-output prediction, such as pixel labelling problems in computer vision and protein side-chain prediction in bio-informatics. A key challenge in the solution of these problems is to build structured prediction models that capture key correlations within the outputs and to learn these models from data. There are a range of approaches to this problem, including training a deterministic predictor to minimize (regularized) empirical risk (e.g., structural SVMs (Taskar et al., 2003; Tsochantaridis et al., 2005)), PAC Bayesian-based approaches where the goal is to train a randomized predictor to minimize a regularized empirical risk (Keshet et al., 2011), and probabilistic modelling paired with Bayesian decision theory (Schmidt et al., 2010).

Perturbation models (Papandreou & Yuille, 2011; Tarlow et al., 2012; Hazan & Jaakkola, 2012) are an approach that have been a focus of interest in recent years, and are closely

related to both PAC-Bayesian approaches and probabilistic modelling. The idea is to build a probabilistic model over structured outputs by drawing a random energy function and then returning the argmin of the random energy function as a sample from the model. These models can then be trained under maximum likelihood-like objectives (Papandreou & Yuille, 2011; Tarlow et al., 2012; Hazan & Jaakkola, 2012) or to minimize expected loss (Keshet et al., 2011; Hazan et al., 2013). Typically the distribution over energy functions is restricted so that the optimization step is tractable (e.g., it is a min-cut problem). When this is the case, perturbation models have the desirable property that exact samples can be drawn efficiently with a single call to an efficient optimization procedure.

Our aim in this work is to revisit the problem of training perturbation models to minimize expected losses. Previous works (Keshet et al., 2011; Hazan et al., 2013) have used Monte Carlo-based methods to estimate the needed gradients. A concern with these approaches is that the gradient estimates can have high variance, as is the case with the well-known REINFORCE algorithm (Williams, 1992). Instead, our approach here is to explore combinatorial methods that take advantage of the structure of the optimization problem in order to more efficiently make use of optimizer runs. As a first foray into this approach, we restrict attention to the case where the perturbation model takes the form of a uniform distribution over model parameters followed by a call to a min-cut/maxflow routine.

Our method is based on a generalization of the parametric min-cut algorithm (Gallo et al., 1989) which in the 1-dimensional case is able to efficiently compute all parameter values (breakpoints) where the minimum energy (MAP) solution changes. To demonstrate the efficacy of our method, we compare estimated expected losses and their gradients computed by our method with those obtained from a sampling-based scheme. Experimental results show that we get more accurate solutions with fewer calls to the optimization procedure and less overall wall time.

As a full application, we also show that our method is use-

ful towards training structured prediction models to minimize expected losses. The method is indifferent to the loss function used, so there is potential to use the same method for loss functions that are typically difficult to work with. Experimentally, we compare our method to learning using Perturb-and-MAP (a.k.a. P&M) (Papandreou & Yuille, 2011) to learn a probabilistic model, then making loss-aware predictions using Bayesian Decision theory. We also show that the Skeleton method can be used in place of sampling within the training procedure from (Papandreou & Yuille, 2011) to give gradients with lower variance.

## 2 BACKGROUND: PERTURBATIONS, EXPECTED LOSSES

We will focus on the case where perturbation models are used to define a conditional probability model  $P(y|x; \theta)$ , where  $x$  is an input (e.g., an image),  $y \in \{0, 1\}^n$  is a structured output (e.g., a foreground-background image segmentation), and  $\theta \in \mathbb{R}^m$  is a real-valued vector of parameter values. We additionally assume access to a feature vector  $\phi(x, y) \in \mathbb{R}^m$  which contains unary and pairwise potentials. Perturbation models begin by defining an energy function  $E(y|x; \theta) = \langle \theta, \phi(x, y) \rangle$ . The second component to a perturbation model is the noise distribution  $P(\gamma)$  which is a distribution over noise vectors  $\gamma \in \mathbb{R}^m$ . The probabilistic model  $P(y|x; \theta)$  can then be defined as follows:

$$\gamma \sim P(\gamma) \quad (1)$$

$$y = \operatorname{argmin}_{y'} E(y'|x; \theta + \gamma). \quad (2)$$

It will be useful to define *minimizer*  $f(\theta) = \operatorname{argmin}_y E(y|x; \theta)$ , *dual function*  $g(\theta) = \min_y E(y|x; \theta)$ , and *inverse set*  $f^{-1}(y) = \{\theta : f(\theta) = y\}$ . Under this definition, the probability of a configuration  $y$  can be expressed as  $P(y|x; \theta) = \int \mathbf{1}_{\{\theta + \gamma \in f^{-1}(y)\}} P(\gamma) d\gamma$ . We are interested in expected losses under perturbation models. The expected loss (or *risk*) is a function of a given  $y^*$  (in our case, the ground truth configuration) and parameters  $\theta$ . It is defined as

$$\begin{aligned} R(y^*, \theta) &= \sum_{y \in \{0, 1\}^n} P(y|x; \theta) L(y^*, y) \quad (3) \\ &= \sum_{y \in \{0, 1\}^n} \int \mathbf{1}_{\{\theta + \gamma \in f^{-1}(y)\}} P(\gamma) L(y^*, y) d\gamma, \quad (4) \end{aligned}$$

where  $L(y^*, y)$  assigns a loss value for predicting  $y$  when the ground truth is  $y^*$ . The ultimate goal we are working towards is to learn parameters  $\theta$  so as to minimize  $R(y^*, \theta)$ . First, we focus on the prerequisite tasks of computing and differentiating  $R(y^*, \theta)$ . We will use deterministic update rules to calculate gradients with the Skeleton method to learn the model.

## 3 ALGORITHM: SKELETON METHOD

We begin by making some assumptions. First, let  $P(\gamma)$  be a uniform distribution such that  $\theta + \gamma$  is distributed uniformly over a  $m$ -dimensional hyperrectangular region  $S_\theta = \prod_{i=1}^m [\theta_i, \theta_i + w_i]$ , where  $\gamma_i \in [0, w_i]$  and  $w_i \in \mathbb{R}^{>0}$ . Also assume that the minimizer  $f(\theta)$  is unique for all  $\theta$  except for a set with measure zero, so  $f(\theta)$  can be treated as having a unique value. Finally, assume that for all  $\theta \in S$ ,  $E(y|x; \theta)$  is submodular and can be optimized efficiently.

In the following, it will be convenient for us to redefine the inverse set  $f^{-1}(y)$  so that only regions in  $S$  are included. That is,  $f^{-1}(y) = \{\theta : f(\theta) = y \wedge \theta \in S\}$ . Then from above, we have that  $R(y^*, \theta) = \sum_{y \in \{0, 1\}^n} \int \mathbf{1}_{\{\theta + \gamma \in f^{-1}(y)\}} P(\gamma) L(y^*, y) d\gamma$ . Noting that  $L(y^*, y)$  is not a function of  $\gamma$  and that  $\int \mathbf{1}_{\{\theta + \gamma \in f^{-1}(y)\}} P(\gamma) d\gamma = \text{Volume}(f^{-1}(y)) / \text{Volume}(S)$ , we can rewrite  $R(\cdot)$  as  $\sum_{y \in Y_S} L(y^*, y) \text{Volume}(f^{-1}(y)) / \text{Volume}(S)$ , where  $Y_S = \{y : \exists \theta, \theta \in S \wedge f(\theta) = y\}$  is the set of configurations that are minimizers for some  $\theta \in S$ .

In this paper, we introduce a novel method to find the minimizers  $y \in Y_S$  and their inverse sets by iteratively updating a graph structure that we call a *skeleton*. Note that for a fixed  $y$ ,  $E(y|x; \theta)$  is a linear function of  $\theta$ , which implies that the dual function  $g(\theta) = \min_y E(y|x; \theta)$  is a piecewise concave function, where pieces are hyperplanes corresponding to minimizers  $y$ . Let  $h_y$  be the corresponding hyperplane for some fixed minimizer  $y$ . Intuitively, the skeleton  $G_Y = (V_Y, E_Y)$  is a graphical representation of the dual  $g(\theta)$  over  $S$ . The skeleton will be constructed on the given parameter space  $S$  by finding new minimizers, or hyperplanes, at each iteration until there are no more minimizers. At each iteration, the growing skeleton represents an upper bound on the dual  $g$ , which we call the *subset dual*.

**Definition 1 (Subset dual  $g_Y$ )** For some given minimizer set  $Y \subseteq Y_S$ , let  $g_Y(\theta) = \min_{y \in Y} E(y|x; \theta)$  be the subset dual, which is a piecewise concave function.

For some given subset dual  $g_Y(\cdot)$ , each hyperplane  $h_y$  has a corresponding graph which we refer as a *facet*  $G_y$ . A facet  $G_y = (V_y, E_y)$  is defined as the smallest convex hull made by the intersections of  $h_y$  and other hyperplanes, where  $V_y, E_y$  are boundary vertices and edges of the convex hull. Let  $\theta_v$  be the parameter value and  $z_v = g_Y(\theta_v)$  be the subset dual value corresponding to the vertex  $v$ . Note that a facet can be cut because of the boundaries the given parameter space makes. A skeleton is defined using the union of these facets as follows.

**Definition 2 (Skeleton of  $g_Y$  over  $S$ )** For some given subset dual  $g_Y$ , the skeleton of  $g_Y$  on  $S$  can be represented by the following structure  $G_Y = (V_Y, E_Y)$ . Let  $(u, v)$  be

an edge between  $u$  and  $v$ , where  $u, v \in V_Y$ .

- $V_Y = \bigcup_{y \in Y} \{v : \text{Boundary vertices of } G_y, \text{ where } \theta_v \in S, z_v = g_Y(\theta_v)\}$
- $E_Y = \bigcup_{y \in Y} \{(u, v) : \text{Boundary edges of } G_y, \text{ where } u, v \in V_Y\} \cup \{(u, v) : u \in V_Y, \theta_u \in \Pi_{i=0}^m \{w_i^-, w_i^+\}, v = (\theta_u, -\infty)\}$

For example, Figure 1 is a skeleton over some parameter space  $S \in \mathbb{R}^2$  given a subset dual  $g_Y$ , where  $Y = \{y_1, \dots, y_5\}$ . There are five facets on the skeleton, where four are cut by the boundaries of  $S$ .

From the given definitions, it is clear that an inverse set  $f_Y^{-1}(y) = \{\theta : y = \operatorname{argmin}_{y' \in Y} f_\theta(y') \wedge \theta \in S\}$  of  $y$  defined on a subset dual  $g_Y$  directly corresponds to the projection of the facet  $G_y$ . Thus, in order to calculate the volume of  $\theta_Y(y)$ , we can use the projected vertices of  $G_y$  on  $S$ . One of the main points of our method is that we are able to track every facet with every iteration, so that we can calculate the approximate expected loss every time we update the skeleton.

We now describe our *Skeleton method* and how it works. Figure 1 describes a visual example on how a skeleton is constructed and updated by a single iteration of our algorithm. Algorithm 1 is the pseudo code of the algorithm.

### 3.1 INITIALIZATION

The initial skeleton  $G_Y = (V_Y, E_Y)$  is given by the following.

- $Y = \phi$
- $V_Y = \{(\theta_{v_n}, z_{v_n}) : \theta_{v_n} = \Pi_{i=0}^m \{w_i^-, w_i^+\}, z_{v_n} = \infty\}$
- $E_Y = \{(u, v) : u \in V_Y, v = (\theta_u, -\infty)\}$

### 3.2 FINDING A NEW FACET

In order to find a new facet, the algorithm first picks some vertex  $u = (\theta_u, z_u) \in V_Y$ . Using graph cut, a new solution  $y_u = f(\theta_u)$  can be found. The first step is to determine whether the new solution improves the current dual in any region. This can be checked by  $h_{y_u}(\theta_u) < z_u$ . If this is the case, we say that a *cut* is made, and  $y_u$  is added to  $Y$ .

Next, we must find new intersection points where  $h_{y_u}$  intersects other hyperplanes defining the subset dual. The key property of the new intersection points is that they will either appear at existing vertices  $v \in V_Y$ , or they appear on an edge  $(p_h, p_t) \in E_Y$  that ‘‘crosses’’ the new hyperplane; that is  $h_{y_{p_h}}(\theta_{p_h}) < z_{p_h}$  and  $h_{y_{p_t}}(\theta_{p_t}) > z_{p_t}$ . The set of vertices where  $h_{y_v}(\theta_v) < z_v$ , form a connected component

---

### Algorithm 1 Skeleton Method

**Input:** Oracle  $f$ , Loss function  $L(y^*, y)$   
 $(Y, G_Y) \leftarrow \text{InitSkeleton}()$   
**for all**  $u = (\theta_u, z_u) \in V_i$  **do**  
     $y_u = f(\theta_u)$   
    **if**  $h_{y_u}(\theta_u) < z_u$  **then**  
        Add  $y_u$  to  $Y$   
         $(I, H) \leftarrow \text{FindIntersection}(G_Y, h_{y_u})$   
        Add  $f_{y_u} = (y_u, I)$  to  $F_Y$   
         $V_Y = (V_Y \cup I) - H$   
        **for all** Intersection vertices  $p \in I$  **do**  
            **if**  $p$  is a new vertex **then**  
                Add  $p$  to all  $G_y \in \{\text{Facets sharing } (p_t, p_h), \text{ where } p_h \text{ is above and } p_t \text{ is below } h_{y_u}\}$   
                Append new edge  $(p_t, p)$  to  $E_Y$   
            **end if**  
        **end for**  
        Remove vertices  $r \in H$  above  $h_{y_u}$  from all facets  
        Remove  $E_- = \{(u, v) : u \text{ or } v \in H\}$  from  $E_Y$   
        Append  $E_+ = \{\text{Boundary edges of } G_{y_u}\}$  to  $E_Y$   
         $R = \sum_{y \in Y} \text{Volume}_{f^{-1}(y)} L(y^*, y)$   
    **end if**  
**end for**

---

$H \subset G_Y$ , and the crossing edges are the boundary edges of this connected component. Thus, the intersection points can be found by exploring a search tree outwards from  $u$ . When a vertex  $v$  is encountered such that  $h_{y_v}(\theta_v) < z_v$ , the intersection point between  $v$  and its parent is computed by finding some point  $p$  where  $h_{y_p}(\theta_p) = z_p$ , and the search tree is not searched further down that path. Upon termination, vertices of the connected component  $H$  are removed from  $V_Y$ , and the new intersection points, notated as  $I$ , are added. A step of this procedure is illustrated in Figure 1(b), where there is a cut after selecting vertex  $u_i$ , colored in red.

### 3.3 UPDATING THE SKELETON $G_Y$

When a cut is done in the skeleton, it should be updated with the new upper bound made by  $h_{y_u}$ . The nontrivial case is when some intersection point  $p \in I$  is a new point made on some edge  $(p_h, p_t) \in E_Y$ , which is  $(u_1, v_1)$  for  $p_1$  in Figure 1b. The new vertex  $p$  is added to all facets which share the edge  $(p_h, p_t)$ . Also, a new edge  $(p_t, p)$  should be added to the skeleton. Boundary edges made from the convex hull of the new polytope  $G_{y_u}$  are also added to  $E_Y$ . Finally, the skeleton update is done when all vertices  $r \in H$  are deleted from every facet and all edges including  $r$  are removed from  $E_Y$ .

### 3.4 CALCULATING EXPECTED LOSS $R$

At this point, the skeleton is fully updated. To compute expected loss  $R(y^*, \theta)$ , we use an off-the-shelf subroutine

for computing the volume of each inverse set  $f_Y^{-1}(y)$  for  $y \in Y$ . The volumes are multiplied by the loss value for each  $y$ , and the products are summed to get the full expected loss. For normalization, the value is divided by the volume of  $S$ .

### 3.5 EXAMPLE : TWO PARAMETERS

Figure 1 describes a single iteration of the Skeleton Method on a perturbation model having two parameters,  $\theta_1, \theta_2$ . Note that the leftside represents the subset dual  $g_Y$  and that the right image is the projection of facets on the given parameter space  $S$ . The iteration starts from a skeleton which has already done five iterations by the algorithm ( $Y = \{y_1 \dots y_5\}$ ). There are five facets on the parameter space so that the expected loss is  $R(y^*, \theta) = \sum_{n=1}^5 \text{Volume}(f_Y^{-1}(y_n))L(y^*, y_n) / \text{Volume}(S)$ . Suppose we take some unused vertex  $u_1$ . In this case, we can see that the hyperplane  $h_{y_6}$  makes a cut in the skeleton ( $Y' = Y \cup \{y_6\}$ ). By updating the skeleton, a new facet  $f_6$  is found. Since there is a unique loss value for each facet, we can calculate the expected loss as  $R(y^*, \theta) = \sum_{n=1}^6 \text{Volume}(f_{Y'}^{-1}(y_n))L(y^*, y_n) / \text{Volume}(S)$ .

## 4 LEARNING

### 4.1 COMPUTING GRADIENTS: SLICING

Our main focus is not only computing expected losses; the ultimate aim is to learn parameters that yield a perturbation model that achieves low expected loss. In order to update the perturbation model to minimize the expected loss, we calculate the gradients by applying a simple finite-differencing-based technique named **slicing**.

Before going through details, we add more assumptions from the previous section. To be more flexible, let the parameter space where  $\theta + \gamma$  is sampled from notated as  $S_\theta = \theta + S = \theta + \Pi_i^m \gamma$ , where  $\gamma_i \in [0, w_i]$ . The expected loss of the region which  $S$  creates on parameter  $\theta$  will be notated as  $R_S(y^*, \theta)$ . The approximation we use is

$$\frac{\partial R(y^*, \theta)}{\partial \theta_i} \approx \frac{R_S(y^*, \theta + \delta e_i) - R_S(y^*, \theta)}{\delta}, \quad (5)$$

where  $\delta$  is a small value and  $e_i \in \mathbb{R}^m$  is a unit vector with 1 in the  $i$ th coordinate and 0 elsewhere. Intuitively, this is identical to the difference between expected losses of regions shifted to the + direction of  $\theta_i$  by a small distance of  $\delta$ . Therefore, we can use a Monte Carlo-based method or the Skeleton method on these two regions and compute the differences to find the gradients.

When shifting a region by  $\delta$ , we see that the contribution to the gradient comes just from the  $\delta$ -width end-regions illustrated in Figure 3 (b). We call these end regions *slices*. Motivated by this, instead of computing expected losses of

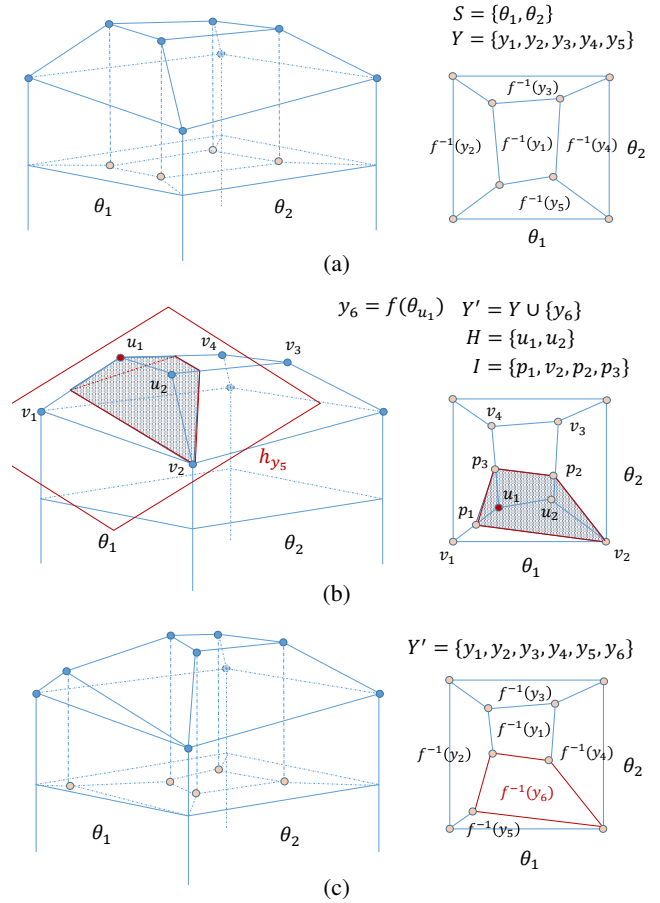

Figure 1: Visual Example of the Skeleton Method with Two Parameters.

the shifted and unshifted full regions, we compute expected losses only on the slices. Intuitively, we expect the slices to have fewer minimizers defining the Skeleton structure than the full regions that include them, and we expect that focusing only on the regions of difference will lead to faster and more accurate gradient estimates.

Let  $s^i = \Pi_j^m \gamma_j$  be the size of the thin slice where  $\gamma_j = [0, w_j]$  except the  $i$ th range  $\gamma_i \in [0, \delta]$ . From this setting,  $R_{s^i}(y^*, \theta)$  stands for the expected loss of the sliced region of size  $s^i$ . Using this we can apply gradient descent updates.

$$\frac{\partial R(y^*, \theta)}{\partial \theta_i} \approx R_{s^i}(y^*, \theta + w_i) - R_{s^i}(y^*, \theta) \quad (6)$$

$$\theta_i(t+1) = \theta_i(t) - \alpha_i \frac{\partial R(y^*, \theta)}{\partial \theta_i} \quad (7)$$

Each parameter  $\theta_i$  in iteration  $t+1$  is updated with the gradient value with a constant step size of  $\alpha_i$ , which is proportional to the feature size of  $\theta_i$ . One thing to be cautious about when selecting a learning rate is, that if the

Figure 2: Comparisons between the Monte Carlo Estimator and the Skeleton Method. Using both methods we computed expected Hamming losses to identical settings and compared by runtime. Images of size [90x120] taken from (Rother et al., 2004) are used.

Figure 3: Visual Discription of Slices. The Slicing method computes the differences in gray regions in (b) to estimate the gradient with respect to parameter  $\theta_i$ .

learning rate is too large, then the parameters may make the model jump to an **unlearnable** state (plateau in the objective), which is a state where  $S_\theta$  holds only one inverse set.

## 4.2 TRAINING

In order to learn the parameters for our perturbation model, we exploit the Slicing method so that the model is trained directly from minimizing expected loss. One main advantage for our method is that we can use an arbitrary loss function very easily in this process. Suppose we have a training set with a size of  $N$  and have  $m$  parameters. For each iteration, we make  $2m$  slices from the model. Parameters are updated by using the mean value of gradients from all training images like the following equation.

$$\theta_i(t+1) = \theta_i(t) + \alpha_i \frac{1}{N} \sum_n \frac{\partial R(y_n^*, \theta)}{\partial \theta_i} \quad (8)$$

Note that it is not necessary to evaluate the expected loss objective at every step of the optimization.

## 4.3 EXPLOITING THE SKELETON METHOD

Previous approaches focus on how to use sampling methods to learn their models, which although many have well understood theoretical convergence properties as the sample size goes to infinity, suffer from problems with high variance in practice. In fact, the Skeleton method can be used in place of sampling more generally; for example, the P&M model in (Papandreou & Yuille, 2011) is trained using a moment-matching objective described in Eq. 9-11.

$$\theta_i(t+1) = \theta_i(t) - \alpha_i \Delta \theta_i \quad (9)$$

$$\Delta \theta_i = E_{S_\theta}[\phi_i(y)] - E[\phi_i(y^*)] \quad (10)$$

$$E_{S_\theta}[\phi_i(y)] = \frac{1}{M} \sum_j^M \phi_i(y_j) \quad (11)$$

To compute the expectations  $E_{S_\theta}[\phi_i(y)]$ , where  $\phi_i(y)$  is a feature function, the standard approach is to use sampling. However, we can replace the sampling-based approach with a skeleton-based approach. Specifically, we replace the term to be  $E_{S_\theta}[\phi_i(y)] = \sum_{y \in \{0,1\}^n} P(y|x, \theta) L_H(y^*, y_j)$  and then use the method described above to compute the quantities needed in Eq. 9-11. This gives an alternative method for optimizing the original P&M objective; we call this approach Skeleton Perturb-and-MAP (Skeleton P&M).

## 5 EXPERIMENTS AND DISCUSSION

### 5.1 DATA AND SETUP

In this section, we apply the Skeleton Method to a foreground-background image segmentation task, comparing against Monte Carlo baselines which estimate expected losses by drawing samples from the prior and reporting the average incurred loss. All images used in experiments are

originally from the Berkeley image segmentation set by (Rother et al., 2004). The energy function used is of the following form:

$$\begin{aligned}
 E(y | x; \theta) &= \langle \theta, \phi(x, y) \rangle \\
 &= E(x) + \theta_1 \sum_i^n x_i \\
 &\quad + \theta_2 \sum_{(y_i, y_j) \in E_v} (y_i \neq y_j) + \theta_3 \sum_{(y_i, y_j) \in E_h} (y_i \neq y_j)
 \end{aligned}
 \tag{12}$$

where  $E_v, E_h$  are each sets of neighboring vertical and horizontal pairs of pixels respectively.  $x_i$  is the  $i$ th pixel’s label of the noised input, which is made by switching values of ground truth labels with a uniform probability of 5%.

Expected losses were computed over a parameter space  $S_\theta = \theta + \gamma \subseteq \mathbb{R}^m$  defined from a uniform distribution  $\gamma \sim P(\gamma)$  where  $\gamma \in [0, 1]^3$ . Intuitively,  $S_\theta$  is a cube shaped region positioned by  $\theta$  on the parameter space where parameters are sampled from. Expected loss over region  $S_\theta$  will be notated as  $R_S(y^*, \theta)$ .

In default, the loss function for the following experiments will be defined as the Hamming distance,  $L_H(y^*, y) = \sum_{i=1}^n (y_i \neq y_i^*)$ . Note that this formulation supports arbitrary loss functions other than the Hamming distance.

## 5.2 CALCULATING EXPECTED LOSSES

To evaluate the methods, it would be ideal to have a ground truth value of expected losses for a given parameter setting. Unfortunately this is hard to calculate accurately, because the Skeleton method does not always run to termination within practical time, and there is necessarily some variance in the estimates returned by the sampling estimate. Thus, we report the estimates from each method along with 95% confidence intervals derived from the sampling method. For the sampling method, in each trial, parameters were independently sampled 100k times, and this was repeated 10 times.

Figure 2 shows plots of expected losses calculated by the two methods versus runtime. The average sampling estimate (across all trials) appear as red dashed lines in Figure 2(a) -2(c). Also shown are the cumulative averages for three representative trials of the sampling (green to blue curves), and the Skeleton method (magenta). The main take-away is that the expected loss values of both methods converge to similar values, but particularly with few samples, there is high variance in sampling. While the Monte Carlo estimator has significant variance even after 1000 seconds, the Skeleton Method has essentially converged to its final, accurate estimate after approximately 10 seconds. This suggests that we can even stop running the method in the middle of the algorithm to estimate the expected loss with high accuracy. The reason such behavior appears is

Figure 4: Gradients of Expected Hamming Loss for  $\theta_1$ . (a) Sampling and Skeleton method on two full regions (b) Skeleton method on full regions and Slicing method.

related to the high concentration of vertices in the later iterations of the algorithm. Many calculations made in later iterations induce inverse sets which have very small volumes, implying the low contribution to the expected loss.

## 5.3 CALCULATING GRADIENTS

We now turn attention to evaluating the Skeleton method and Monte Carlo method for computing gradients of expected losses. For the Skeleton method, we evaluate our recommended Slicing method, and also a variant that computes expected losses over full regions that are shifted by  $\delta$ , which would be the more standard finite-difference approach. We use the thickness  $\delta = 0.001$  and parameter  $\theta_1$ , which is for the unary term, for the experiments. A comparison of the Monte Carlo approach (red) and the full-region Skeleton method (magenta) appear in Figure 4 (a). The red curve shows the cumulative average Monte Carlo estimate averaged across 10 repetitions. Even with this averaging, we see a great deal of variance in the estimates. The Skeleton method, by contrast, quickly converges to a value near where the Monte Carlo estimator appears to be converging to.

We then zoom in (note the y-axis scales) and consider the recommended Slicing variant of the Skeleton method and compare it to the full-region version shown in Figure 4 (a). The result appears in Figure 4 (b). Here we see that the Slicing variant is faster and much more stable than the full-region variant. As mentioned above, we believe the reason for the disparity is that number of unique inverse sets in the Slicing variant is smaller, and there is no variance that arises from the two runs computing slightly different estimates of the expected loss in the middle region that is contained by both the original and shifted full region.

## 5.4 MODEL LEARNING

Learning was done on an image set including 30 images each having approximately 2500 pixels. The data set was randomly split into  $N = 24$  training images and  $N' = 6$  test

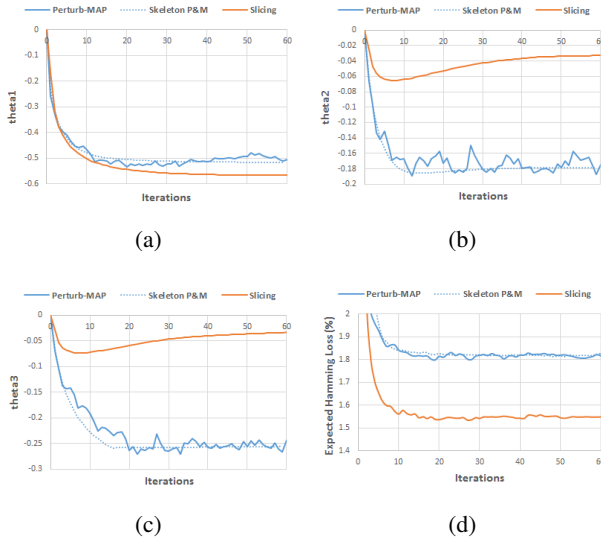

Figure 5: Parameter Learning with P&M and the Slicing Method. (a)-(c): Parameter updates (d): Expected Hamming Loss updates

images.

#### 5.4.1 Learning

We performed learning with the Slicing method, where gradients are computed with slices having a thickness of  $\delta = 0.001$ . The starting parameter is  $\theta = (0, 0, 0)$ , with a uniform perturbation  $\gamma \in \Pi_i^3[0, 1]$  defining a cube-shaped region on the parameter space. Gradients are computed for each parameter, which makes 6 slices to use. All slices can be computed independently, where in most cases 1-3 seconds are enough to get significant accuracy. By every iteration, the region will shift to a certain direction, and the process is repeated. The orange plots of Figure 5 show how the Slicing method learns the model for 60 iterations.

As a baseline for our method, we trained the P&M model with the same settings. Note that the Slicing method and P&M model have different behaviors, which are due to the difference in objectives; our Slicing method directly tries to minimize expected Hamming loss while the P&M model uses a moment-matching rule to estimate the posterior. The behavior of the learning P&M model is illustrated as the solid blue line of Figure 5, with the Skeleton P&M model being the dotted blue line. Take note that the Skeleton P&M strongly resembles the original P&M trace, but its trajectory is smoother, presumably due to lower variance in the gradient estimates.

At test time, instead of computing expected losses accurately, there may be a desire to sacrifice accuracy over runtime in estimating the value. One easy example is to use a finite number of samples such as 20 and compute the average of losses. Another approach is to sample a single output

Table 1: Expected Hamming Losses. Expected losses are computed with three ways 1) Average loss of 20 samples 2) Skeleton method 3) Single sampled loss from center. The performance for each model is described in each row, where values were computed separately on the training set and test set.

| METHOD            | SAMPLED            | EXPECTED     | CENTER       |
|-------------------|--------------------|--------------|--------------|
| P&M (Train)       | 1.694±.0011        | 1.812        | <b>.2369</b> |
| Skel. P&M (Train) | 1.764±.0017        | 1.816        | <b>.2369</b> |
| Slicing (Train)   | <b>1.480±.0012</b> | <b>1.535</b> | .2932        |
| P&M (Test)        | 2.186±.0011        | 2.257        | <b>1.172</b> |
| Skel. P&M (Test)  | 2.197±.0016        | 2.268        | 1.178        |
| Slicing (Test)    | <b>2.048±.0043</b> | <b>2.134</b> | 1.391        |

from a moderate position such as the center of the parameter space. Table 1 shows the expected losses computed from the mentioned methods. Each column represents the method we choose to compute expected loss. Each row represents the selected model trained for 60 iterations. Both from Figure 5(d) and Table 1, it is clear that our method is superior to the P&M model in optimizing the expected Hamming loss.

#### 5.4.2 Other Loss Functions

With our method, it is possible to minimize an arbitrary loss function’s expected value. In the following experiments we try to minimize the following loss function.

- **Boundary-only Pixel Loss**  $L_P$ : Hamming loss on only pixels which have at least one neighbor with a different label in the ground truth

$$L_P(y^*, y) = \sum_{y_i^* \neq y_j^*} (y_i \neq y_j)$$

The solid lines of Figure 6 shows the expected losses changing by the Slicing method in 60 iterations. The dashed lines are loss values from a baseline where we use the learned Skeleton P&M parameters to make loss-directed predictions using an approximation of Bayesian decision theory, similar to that used by (Premachandran et al., 2014). approximation Bayesian Decision Theory prediction framework. Specifically, we sample  $M = 100$  segmentations  $Y = \{y^{(1)}, \dots, y^{(M)}\}$  from the learned model, then we make predictions by restricting possible predictions to be one of the  $M$  sampled segmentations, and we approximate expected losses by taking averages over the  $M$  segmentations; specifically, we predict as  $\arg \min_{y' \in Y} \sum_{y \in Y} \Delta(y', y)$ . Figure 6 shows the expected boundary-only pixel loss being learned from the Slicing method as solid lines and the approximate Minimum Bayes Risk (MBR) prediction loss as dashed lines. This experiment shows that our method gives better results than the classical approach in minimizing expected losses.

Figure 6: Learning Other Expected Losses. Orange and blue lines represent the values computed from the test set and training set respectively. Dashed lines are Approximate MBR prediction loss values, while the solid lines are learned from the Slicing method.

## 5.5 EXPECTED SEGMENTATIONS

To visualize how different parameters, or regions, effect the expected loss, we can use a probabilistic image constructed from every solution captured by our algorithm. This image or *expected segmentation* is made by weighting each configuration by the volume of its inverse set and summing up to a gray scale image. Note that this implies that the values of Table 1 are identical to the  $l_1$  distance between the ground truth image and the expected segmentation. Examples are shown in Figure 7. The example images were selected from the test set. From the figure, you can see that expected segmentations made from our perturbation model have higher quality, smoother segmentations than those from the P&M models.

## 6 CONCLUSION

Our results show that the Skeleton method is a promising alternative to Monte Carlo methods. The Skeleton method converges in a nice deterministic behavior, which shows higher accuracy than using samples. Another benefit of the Skeleton method is that it is applicable for any loss function. We have shown it applied to a boundary-only pixel loss; in future work it would be interesting to apply it to even more complicated loss functions. The Skeleton method also appears to be a general drop-in replacement for sampling-based computation of expectations in perturbation models. We showed this by adapting the method to the moment-matching objective that the original P&M paper proposed, showing that the Skeleton method leads to similar-but-smoother learning trajectories.

The idea of iteratively building piecewise linear approxi-

mations arises in many cases, such as when computing the value function in POMDPs (Porta et al., 2006; Isom et al., 2008; Brechtel et al., 2013). While the high level ideas are similar to these and other methods, the details are quite different; for example, in the above works, no volume computations are required, whereas they are core to our method.

The primary challenge going forward is to broaden the applicability of the method, extending to higher dimensions and enlarging the space of supported perturbation distributions. It is likely in these cases that exactness of the method will need to be abandoned due to the fact that the number of solutions will likely grow, and the computations of necessary volumes will become computationally hard. Despite this, we believe the algorithm presented here will be useful going forward. There are two possibilities we are interested in exploring: first, using a hybrid of the Skeleton and sampling methods where some dimensions are sampled and some are integrated analytically using the Skeleton method (producing a Rao-Blackwellized sampler); second, we believe there to be opportunities for computing and differentiating upper bounds based on the Skeleton structure, which could lead to interesting new learning methods.

## Abstract

Bayesian predictive inference analyzes a dataset to make predictions about new observations. When a model does not match the data, predictive accuracy suffers. We develop population empirical Bayes (POP-EB), a hierarchical framework that explicitly models the empirical population distribution as part of Bayesian analysis. We introduce a new concept, the latent dataset, as a hierarchical variable and set the empirical population as its prior. This leads to a new predictive density that mitigates model mismatch. We efficiently apply this method to complex models by proposing a stochastic variational inference algorithm, called bumping variational inference (BUMP-VI). We demonstrate improved predictive accuracy over classical Bayesian inference in three models: a linear regression model of health data, a Bayesian mixture model of natural images, and a latent Dirichlet allocation topic model of scientific documents.

## 1 INTRODUCTION

Bayesian modeling is a powerful framework for analyzing structured data. It covers many important methods in probabilistic machine learning, such as regression, mixture models, hidden Markov models, and probabilistic topic models (Bishop, 2006; Murphy, 2012). Bayesian models provide an intuitive language to express assumptions about data, as well as general-purpose algorithms (such as variational methods) to reason under those assumptions.

Bayesian models describe data  $\mathbf{X}$  as a structured probability density with latent variables  $\theta$ ,  $p(\mathbf{X}, \theta) = p(\mathbf{X} | \theta)p(\theta)$ . The first term is the likelihood, the second is the prior. We use this joint density to both analyze data and form predictions. We analyze data through the posterior density of the latent variables,  $p(\theta | \mathbf{X})$ . This conditional density derives from the joint. We form predictions by combining the

likelihood and posterior density as

$$p(\mathbf{x}_{\text{new}} | \mathbf{X}) = \int p(\mathbf{x}_{\text{new}} | \theta)p(\theta | \mathbf{X}) d\theta. \quad (1)$$

This is the Bayesian predictive density, the conditional density of a new observation given the dataset.

Frequentist statistics take a different perspective. Here we analyze a set of observations  $\mathbf{X}$  to draw conclusions about the mechanism  $F$  that gave rise to them.  $F(\mathbf{X})$  is an unknown distribution; it is called the *population*. Nonparametric frequentist methods, like the bootstrap (Efron and Tibshirani, 1994), work directly with  $F$  while still respecting its unknown nature. This leads to powerful tools that work well across many statistical settings. One goal is to use a given dataset to learn about  $F$  and predict new observations; this is predictive inference (Young and Smith, 2005).

**Main idea.** We combine the flexibility of Bayesian modeling with the robustness of nonparametric frequentist statistics. The issue is that Bayesian theory, under frequentist scrutiny, assumes the model is correct (Bernardo and Smith, 2000). But this is rarely true; the model is almost always mismatched, which can lead to brittle data analysis and poor predictions. Our goal is to use the unknown population  $F$  to improve a Bayesian model's predictive performance.

We call our framework population empirical Bayes (POP-EB). It describes a simple procedure. The input is a model  $p(\mathbf{X}, \theta)$  and a dataset  $\mathbf{X}$  of  $N$  observations. For example, a mixture of Gaussians and a dataset of natural images.

1. Draw  $B$  bootstrap samples of the dataset,  $\{\mathbf{X}^{(1)}, \dots, \mathbf{X}^{(B)}\}$ . Each sample is a dataset of size  $N$ , drawn with replacement from the original dataset (Efron and Tibshirani, 1994).
2. Compute the posterior for each bootstrapped dataset,  $p(\theta | \mathbf{X}^{(b)})$ . Evaluate the average predictive accuracy of the original dataset with Equation (1).
3. Pick the bootstrapped dataset  $\mathbf{X}^{(b^*)}$  that best predicts the original dataset. Use the corresponding predictive density  $p(\mathbf{x}_{\text{new}} | \mathbf{X}^{(b^*)})$  to form future predictions.

POP-EB applies to any Bayesian model and can improve its predictive performance. Above we describe its simplest form. Alternatives, which we discuss below, include one that weights the bootstrapped datasets and another that embeds the population into a stochastic variational inference algorithm (Hoffman et al., 2013).

In this paper, we develop, motivate, and study POP-EB. We show that it yields a predictive density that incorporates the unknown population distribution  $F$  in a type of empirical Bayes model (Robbins, 1955, 1964). Compared to traditional Bayesian inference, it better predicts held-out data for models such as regression (Table 1), mixtures of Gaussians (Figure 5), and probabilistic topic models (Figure 7).

**Related work.** There are several running themes in this paper. The first is Bayesian/frequentist compromise and empirical Bayes. A rich literature relates Bayesian and frequentist ideas. Bayarri and Berger (2004) and Aitkin (2010) give thorough reviews. One thread of ideas around combining these two schools of thought is empirical Bayes (EB) (Robbins, 1955; Morris, 1983; Carlin and Louis, 2000). Loosely, EB uses frequentist statistics to estimate prior specifications in Bayesian models. EB enjoys good statistical properties (Efron, 2010); it can explain challenging concepts, such as the James-Stein paradox (Berger, 1985).

The second theme is predictive inference. One approach to Bayesian inference is to study the Bayesian predictive density. The goal is to design models such that the predictive density is high for new observations (Geisser, 1993). Machine learning also strives to develop models that deliver high predictive accuracy (Bishop, 2006). Our method explicitly optimizes the Bayesian predictive density.

A final theme is model misspecification. To paraphrase Box and Draper (1987), the challenge of Bayesian statistics is that while many models are useful, all of them are wrong. Robust statistics offer some remedies (Berger, 1994), such as using likelihoods and priors that are “insensitive to small deviations from the assumptions” (Huber and Ronchetti, 2009). Our work uses empirical Bayes to induce a model that is robust to misspecification.

## 2 POPULATION EMPIRICAL BAYES

Population empirical Bayes (POP-EB) incorporates the model-independent population  $F$  into Bayesian analysis. We first develop the structure of our framework and then discuss the motivation behind it in Section 2.3.

### 2.1 EMPIRICAL BAYES

Let  $\mathbf{X} = \{\mathbf{x}_n\}_1^N$  be a dataset with  $N$  observations. The dataset is a sample from an unknown population distribution  $F$ . The population is the “true” distribution of the data; it is independent of any model (Shao, 2003).

**Figure 1:** Graphical model for Bayesian predictive inference. The likelihood relates the dataset  $\mathbf{X} = \{\mathbf{x}_n\}_1^N$ , along with the new observation  $\mathbf{x}_{\text{new}}$ , to the latent variables  $\theta$ . Conditioning on the observations and marginalizing over  $\theta$  gives the Bayesian predictive density of Equation (1).

A Bayesian model has two parts. The first is the likelihood,  $p(\mathbf{x}_n | \theta)$ . It relates an observation  $\mathbf{x}_n$  to a set of latent random variables  $\theta$ . If the observations are independent and identically distributed, the likelihood of the dataset becomes  $p(\mathbf{X} | \theta) = \prod_{n=1}^N p(\mathbf{x}_n | \theta)$ .

The second is the prior density,  $p(\theta)$ . This induces the joint density  $p(\mathbf{X}, \theta) = p(\mathbf{X} | \theta) p(\theta)$ . In predictive inference, we additionally consider a new observation  $\mathbf{x}_{\text{new}}$ . It shares the same likelihood of the data,  $p(\mathbf{x}_{\text{new}} | \theta)$ . This expands the joint density to  $p(\mathbf{x}_{\text{new}}, \mathbf{X}, \theta)$ , shown in Figure 1.

A predictive density describes  $\mathbf{x}_{\text{new}}$  given the observed dataset  $\mathbf{X}$ . A simple recipe supplies such a density: condition on the observations and marginalize over the latent variables. This gives the Bayesian predictive density in Equation (1). It depends on the Bayesian posterior density,

$$p(\theta | \mathbf{X}) = \frac{p(\mathbf{X} | \theta) p(\theta)}{\int p(\mathbf{X} | \theta') p(\theta') d\theta'}, \quad (2)$$

which describes how the latent variables  $\theta$  vary conditioned on a given dataset  $\mathbf{X}$ .

The main idea behind Empirical Bayes (EB) is to build estimates from the population into Bayesian inference (Robbins, 1955; Morris, 1983). EB uses the observed data to estimate parts of a Bayesian model. There are many variants of EB. Robbins (1955) proposed the following approach.

First, augment the model such that each observation  $\mathbf{x}_n$  gets its own set of latent variables  $\theta_n$ . This is sometimes called the “compound sampling model” (Berger, 1985). It has connections to robust inference (Berger and Berliner, 1986) through an intuitive justification.<sup>1</sup> Then, assume the latent variables are exchangeable and distributed according to an unknown prior density  $g$ . Figure 2 shows the EB framework.

<sup>1</sup>When pondering outliers in Bayesian inference, de Finetti explains: “We know that each observation is taken using an instrument with [some] error, but each time chosen at random from a collection of instruments of different precisions” (de Finetti, 1961)

**Figure 2:** Graphical model for empirical Bayes (EB) predictive inference. We augment the Bayesian model and estimate the prior  $g$  from the dataset.

“Nonparametric EB” estimates the prior  $g$  using nonparametric statistics of the data (Robbins, 1955, 1964). The name emphasizes its model-independent approach. “Parametric EB” assumes a parametric family for  $g$  and estimates its parameters from the data (Morris, 1983). The result is a hierarchical Bayesian model whose top-level parameters are determined by the observations. The name emphasizes its model-based approach.

Both variants of EB introduce population information from the dataset  $\mathbf{X}$ . But neither directly builds the population  $F$  into the analysis. How can we adapt EB to directly model the population distribution of data?

## 2.2 POPULATION EMPIRICAL BAYES

We take a two-step approach. We first introduce an additional latent variable into EB and then use it to define a conditional density on  $\theta$ .

The new variable  $\mathbf{Z}$  is a latent dataset. This is a hypothetical dataset that we do not observe. It has the same size and dimension as the observed dataset  $\mathbf{X}$ , but with unknown observations. It lives one level above the  $\theta$  variables.

Given the latent dataset, we then define a conditional density on  $\theta$ . We choose a density that depends on the latent dataset,  $p(\theta | \mathbf{Z})$ . Figure 3 shows the framework.

This is a valid EB model; we simply propose a conditional density on  $\theta$  via a new latent variable  $\mathbf{Z}$ . However, it is incomplete. We must also choose a prior on  $\mathbf{Z}$  and then define the form of  $p(\theta | \mathbf{Z})$ .

We set the prior on the latent dataset  $\mathbf{Z}$  to be the population  $F$ . The unknown, model-independent distribution of data acts as the prior on the latent dataset  $\mathbf{Z}$ .

We match the conditional density on  $\theta$  to the Bayesian posterior density of the original Bayesian model. Instead of conditioning on the observed dataset  $\mathbf{X}$ , we condition on the latent dataset  $\mathbf{Z}$ . This is how we interface the frequentist population distribution with the Bayesian model.

This fully describes the POP-EB framework. (We motivate these choices in Section 2.3.)

**Figure 3:** Graphical model for the population empirical Bayes (POP-EB) framework. We introduce  $\mathbf{Z}$ , the latent dataset, and assign the population distribution  $F$  as its prior.

**Definition.** POP-EB defines the joint density

$$p(\mathbf{x}_{\text{new}}, \theta_{\text{new}}, \mathbf{X}, \theta, \mathbf{Z}) = p(\mathbf{x}_{\text{new}} | \theta_{\text{new}}) p(\theta_{\text{new}} | \mathbf{Z}) \times \prod_{n=1}^N p(\mathbf{x}_n | \theta_n) p(\theta_n | \mathbf{Z}) \times F(\mathbf{Z}). \quad (3)$$

To obtain a predictive density from the joint density, we follow the same recipe as before: condition on the observations  $\mathbf{X}$  and marginalize over the latent variables.

Marginalizing over  $\theta$  is straightforward. In addition, we marginalize over the latent dataset  $\mathbf{Z}$ , which gives the predictive density

$$p(\mathbf{x}_{\text{new}} | \mathbf{X}) = \int p(\mathbf{x}_{\text{new}} | \mathbf{Z}) p(\mathbf{Z} | \mathbf{X}) d\mathbf{Z}. \quad (4)$$

This is the POP-EB predictive density. It integrates the Bayesian predictive density over the latent dataset  $\mathbf{Z}$  using the conditional density

$$p(\mathbf{Z} | \mathbf{X}) = \frac{p(\mathbf{X} | \mathbf{Z}) F(\mathbf{Z})}{\int p(\mathbf{X} | \mathbf{Z}') F(\mathbf{Z}') d\mathbf{Z}'}. \quad (5)$$

This is a key conditional density in POP-EB. It describes how the latent dataset varies given the observed dataset. The original Bayesian model prescribes the form of  $p(\mathbf{X} | \mathbf{Z})$  and the population  $F(\mathbf{Z})$  factors in as the prior.

Thus, POP-EB directly incorporates the population  $F$  as a prior on the latent dataset. But the population is, by definition, unknown. We address this next.

**Plug-in principle.** The empirical population  $\hat{F}$  is the distribution that puts weight  $1/N$  on each observation in the observed dataset  $\{\mathbf{x}_n\}_1^N$ . The plug-in estimator of a function of  $F$  is simply the same function evaluated with  $\hat{F}$  instead. In the absence of any other information about the population, the plug-in principle is asymptotically efficient (Efron and Tibshirani, 1994).

The plug-in principle provides a nonparametric estimate of  $F$ . It enjoys a tight connection to the bootstrap and related techniques. We discuss computation in greater detail in Section 3. But now, we owe the reader an explanation.

## 2.3 MOTIVATION

Here is the story so far. The population  $F$  is the model-independent mechanism that generates  $\mathbf{X}$ . Bayesian analysis employs a model  $p(\mathbf{X}, \theta)$ . The model is helpful; it gives strength to the statistical analysis (Young and Smith, 2005). However, Bayesian theory assumes the model is correct.<sup>2</sup> This is not always true; the model is often misspecified.

We focus on predictive inference. Our goal is to help a Bayesian model provide the best predictive accuracy, in spite of model misspecification. So, we seek a way to incorporate the model-independent population  $F$  into our model-based Bayesian analysis.

This is why we set  $F$  as the prior on the latent dataset  $\mathbf{Z}$ . In principle, there is no obstacle in using any other prior density. The prior on  $\mathbf{Z}$  captures knowledge about the data generating mechanism that might otherwise be difficult to express in the model. In our case, this knowledge is precisely the population distribution  $F$ .

Consistency motivates our design of the conditional density on  $\theta$ . Any density that depends on  $\mathbf{Z}$  would be valid. We choose the Bayesian posterior density to mimic the original Bayesian model. Consider the Bayesian predictive density from Equation (1). It integrates the likelihood over the posterior density of the latent variables. The POP-EB predictive density of Equation (4) mirrors this form by integrating the Bayesian predictive density over the posterior density of the latent dataset.

## 3 COMPUTATION

We describe two empirical approximations to the POP-EB predictive density, develop some insight through simulation, and study a linear regression model with real data. More results follow in the empirical study of Section 5.

### 3.1 BOOTSTRAP

The plug-in principle replaces the population  $F$  with its empirical counterpart  $\hat{F}$ . However, direct computation with  $\hat{F}$  is also challenging. The POP-EB predictive density requires evaluating  $p(\mathbf{Z} | \mathbf{X})$ . This involves considering all possible datasets in the support of  $\hat{F}$ , an intractable task.

The bootstrap is a computational technique for approximating functions of  $\hat{F}$ . Define the bootstrapped dataset as  $\mathbf{Z}^{(b)} = \{\mathbf{x}_n^{(b)}\}_1^N$  where each  $\mathbf{x}_n^{(b)}$  is uniformly sampled from  $\hat{F}$  with replacement. The bootstrapped dataset  $\mathbf{Z}^{(b)}$  contains as many observations as  $\mathbf{X}$ ; some observations appear multiple times, others not at all.

All bootstrapped datasets are equally likely. So we can approximate calculations of  $\hat{F}$  with a uniform distribution.

<sup>2</sup>Bernardo and Smith (2000) identify this as the  $\mathcal{M}$ -closed view.

Call this distribution  $\hat{G}$ ; it is a discrete uniform distribution over the  $B$  bootstrapped datasets  $\{\mathbf{Z}^{(b)}\}_1^B$ . This reduces the space of possible datasets to  $\mathcal{O}(B)$ .

### 3.2 MAP APPROXIMATION

A simple way to approximate the POP-EB predictive density is maximum a posteriori (MAP) estimation. In our setup, we find the most likely latent dataset  $\mathbf{Z}^*$  from  $p(\mathbf{Z} | \mathbf{X})$  and plug it into the Bayesian predictive density.

The POP-EB MAP predictive density is simply

$$p_{\text{MAP}}(\mathbf{x}_{\text{new}} | \mathbf{X}) = p(\mathbf{x}_{\text{new}} | \mathbf{Z}^*),$$

where the most likely dataset is

$$\begin{aligned} \mathbf{Z}^* &= \arg \max_{\mathbf{Z}} p(\mathbf{Z} | \mathbf{X}) \\ &= \arg \max_{\mathbf{Z}} p(\mathbf{X} | \mathbf{Z}) \hat{F}(\mathbf{Z}). \end{aligned}$$

MAP estimation evades the intractable denominator in Equation (5), as the maximization only depends on  $\mathbf{Z}$ . However, the maximization is still intractable, so we replace  $\hat{F}$  with  $\hat{G}$  to get

$$\mathbf{Z}^{(b^*)} \approx \arg \max_{\mathbf{Z}^{(b)} \in \hat{G}} p(\mathbf{X} | \mathbf{Z}^{(b)}).$$

This turns out to be a special case of the bumping technique (Tibshirani and Knight, 1999). Bumping is a bootstrap-based method to fit arbitrary models to a dataset; it finds the fit that minimizes some metric over bootstrapped datasets. Our metric is the average predictive density evaluated on the original dataset. Evaluating the metric on the original dataset guards against overfitting; it includes both held-in and held-out samples.

Enumeration spells the procedure out:

1. Draw  $B$  bootstrapped datasets. This gives a set of datasets  $\{\mathbf{Z}^{(b)}\}_1^B \sim \hat{G}$ .<sup>3</sup>
2. For each bootstrap index  $b = 1, \dots, B$ :  
Compute and evaluate the Bayesian predictive density on the original dataset

$$p(\mathbf{X} | \mathbf{Z}^{(b)}) = \prod_{n=1}^N p(\mathbf{x}_n | \mathbf{Z}^{(b)}).$$

3. Return the bootstrap index  $b^*$  that maximizes the Bayesian predictive density above.

We approximate the POP-EB MAP predictive density as

$$p_{\text{MAP}}(\mathbf{x}_{\text{new}} | \mathbf{X}) \approx \int p(\mathbf{x}_{\text{new}} | \theta_{\text{new}}) p(\theta_{\text{new}} | \mathbf{Z}^{(b^*)}) d\theta_{\text{new}}. \quad (6)$$

<sup>3</sup>Tibshirani and Knight (1999) recommend including the observed dataset. We follow their advice.

It has the same form as the Bayesian predictive density, but integrates over the Bayesian posterior conditioned on the bootstrapped dataset  $\mathbf{Z}^{(b^*)}$ .

### 3.3 FULL BAYESIAN APPROXIMATION

We also consider directly evaluating the POP-EB predictive density of Equation (4). In general, the posterior  $p(\mathbf{Z} | \mathbf{X})$  is intractable. Luckily, replacing  $\hat{F}$  with  $\hat{G}$  reduces the integral to a finite sum over  $B$ . We call this a full Bayes (FB) approximation, as it is an exact evaluation of the POP-EB predictive density under the  $\hat{G}$  approximation of the empirical population. (The supplement contains a derivation.)

The POP-EB FB predictive density is a weighted sum,

$$p_{\text{FB}}(\mathbf{x}_{\text{new}} | \mathbf{X}) = \sum_{b=1}^B w_b p(\mathbf{x}_{\text{new}} | \mathbf{Z}^{(b)}),$$

where the weights are

$$w_b = \frac{p(\mathbf{X} | \mathbf{Z}^{(b)}) \hat{G}(\mathbf{Z}^{(b)})}{\sum_b p(\mathbf{X} | \mathbf{Z}^{(b)}) \hat{G}(\mathbf{Z}^{(b)})} = \frac{p(\mathbf{X} | \mathbf{Z}^{(b)})}{\sum_b p(\mathbf{X} | \mathbf{Z}^{(b)})},$$

and the  $\mathbf{Z}^{(b)}$  are drawn from  $\hat{G}$ . The probabilities  $\hat{G}(\mathbf{Z}^{(b)})$  are all equal to  $1/B$ , and so they disappear. As with the MAP case, the intractable denominator from Equation (5) also drops out of the calculation.

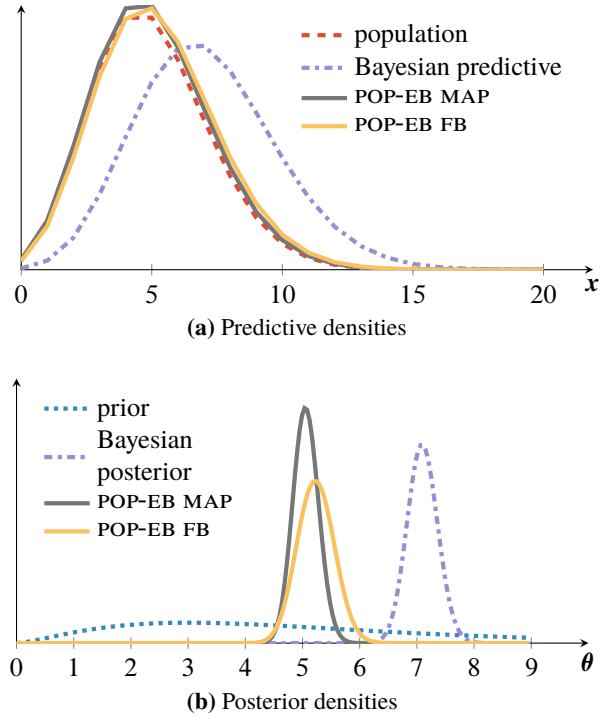

### 3.4 SIMULATION STUDY

To investigate these POP-EB quantities, we construct a toy example of model mismatch. The example is intentionally simple; it provides insight into why and how POP-EB mitigates model misspecification.

Consider that we typically observe data from a Poisson distribution with rate  $\theta = 5$ . (For instance, a router receives packets over a network; the wait-times are the measurements.) We model the data using a Poisson likelihood  $p(\mathbf{x} | \theta) = \text{Poisson}(\theta)$ , and center a Gamma prior at  $\theta = 5$  as  $p(\theta) = \text{Gam}(\alpha = 2.5, \beta = 0.5)$ .

Imagine that five percent of the time, the network fails. During these failures, the wait-times come from a different Poisson with rate  $\theta = 50$ . The population describes a mixture of two Poisson distributions. But the single Poisson model likelihood does not. A good predictive density should accurately describe the population.

Figure 4a shows the predictive densities. The Bayesian predictive density exhibits poor predictive accuracy; it describes neither of the two Poisson distributions in the population. In contrast, both POP-EB predictive densities match the dominant Poisson distribution. POP-EB uses the empirical population to focus on the observations in the dataset that give it greater predictive power.

**Figure 4:** Gamma-Poisson simulation. The population in subpanel (a) has an small extra bump at 50 (not shown).

Figure 4b shows the underlying posterior densities on the latent variable  $\theta$  that describes the wait-time. For POP-EB MAP this is the posterior density  $p(\theta | \mathbf{Z}^{(b^*)})$ ; a single Gamma distribution that, when put through the Bayesian predictive density, gives the highest accuracy. For the POP-EB FB case, the posterior is a weighted sum of Gamma distributions. Both POP-EB posterior densities sit closer to the dominant rate of  $\theta = 5$ . This explains the behavior of the POP-EB predictive densities in Figure 4a.

The POP-EB MAP predictive density is easy to compute; it is a negative binomial distribution, like the Bayesian predictive density. In contrast, the POP-EB FB predictive density must be numerically calculated using all bootstrap samples; it has no simple analytic form.

We generate these plots using  $B = 100$  bootstrapped datasets. The exact shape of the POP-EB densities depend on the bootstrapped datasets, but they are reproducibly closer to  $\theta = 5$ . The results are also insensitive to different prior configurations, such as a sharp prior centered at  $\theta = 5$ . EB is also of little use here; it estimates a nearly flat prior on  $\theta$  from the data. (See supplementary note and code.)

### 3.5 BAYESIAN LINEAR REGRESSION

We now apply the POP-EB framework to a real-world dataset. Consider a Bayesian linear regression model. The likelihood is a Gaussian distribution and the latent random variables are the regression coefficients  $\beta$  and the variance  $\sigma^2$ . Using

**Table 1:** Bayesian linear regression predictive accuracy results on random held-out splits of the bodyfat dataset.

|            | Split #1    |               |               | Split #2    |               |               |

conjugate priors (Gaussian for the coefficients and inverse Gamma for the variance) gives a Bayesian predictive density that follows a t-distribution (Murphy, 2012). We posit an uninformative prior.

We study the predictive performance of both POP-EB predictive densities on the bodyfat dataset (StatLib, 1995). Accurate measurements of body fat are costly. The dataset contains the body fat percentages of  $N = 252$  men along with 14 other features that are cheaper to measure. We want to predict body fat percentage using these 14 features.

We randomly extract datasets of 200 measurements and hold the remaining 52 to evaluate predictive accuracy. Table 1 reports the average logarithm of the predictive densities (logp), along with mean squared error (MSE) and mean absolute error (MAE). In all cases, the POP-EB predictive densities reach higher predictive accuracy on held-out data. The POP-EB FB density performs similarly to the POP-EB MAP density, but exhibits slightly better MSE and MAE values. Since the dataset is small, we split it six times. These results are reproducible across a variety of splits. We use  $B = 25$  bootstrap samples. (See supplementary code.)

The POP-EB FB density is a better approximation to the POP-EB predictive density than its MAP counterpart. The results in Table 1 corroborate this. However, POP-EB FB density lack an analytic form. In contrast, the POP-EB MAP predictive density offers an attractive improvement in predictive accuracy while maintaining the form of the Bayesian predictive density. We now turn to approximating it for complex Bayesian models.

## 4 POPULATION EMPIRICAL VARIATIONAL INFERENCE

Modern Bayesian statistics and machine learning has moved well past simple conjugate models like Bayesian linear re-

gression. In complex models, such as Bayesian mixture models (Bishop, 2006) or probabilistic topic models (Blei et al., 2003), the posterior and predictive densities are intractable to compute. Monte Carlo sampling and variational techniques are two popular frameworks for approximation.

In this section, we develop an efficient variational approximation to the POP-EB MAP predictive density.

### 4.1 VARIATIONAL INFERENCE

Variational inference is an optimization-based approach to approximate posterior computation in a Bayesian model  $p(\mathbf{X}, \theta)$  (Jordan et al., 1999; Wainwright and Jordan, 2008). The idea is to posit a simple parameterized density family over the latent variables,  $q(\theta; \lambda)$ . We then seek the member of the family that is closest in Kullback-Leibler (KL) divergence to the true posterior density  $p(\theta | \mathbf{X})$ . Minimizing  $\text{KL}(q || p)$  is equivalent to maximizing a lower bound on the marginal density of the data. This gives a variational objective function, called the evidence lower bound (ELBO)

$$\mathcal{L}(\mathbf{X}, \lambda) = \mathbb{E}_q [\log p(\mathbf{X}, \theta)] - \mathbb{E}_q [\log q(\theta; \lambda)].$$

Variational inference maximizes this objective function with respect to the set of parameters  $\lambda$ .

In mean-field variational inference, we assume the variational density fully factorizes. This divides the variational parameters into  $M$  parts,  $\lambda = \{\lambda_m\}_1^M$ . We then maximize the ELBO using coordinate ascent (Jordan et al., 1999). This means iteratively maximizing one variational parameter at a time, holding all others fixed. The separation of latent variables leads to independent updates for each variational parameter. This coordinate ascent scheme guarantees convergence to a local maximum of the ELBO (Bishop, 2006).

### 4.2 APPROXIMATING THE POP-EB MAP PREDICTIVE DENSITY

Our aim is to employ variational inference to approximate the POP-EB MAP predictive density. It shares the same form as the Bayesian predictive density, but integrates over the Bayesian posterior density evaluated on a particular bootstrapped dataset. To that end, consider the ELBO evaluated on a bootstrapped dataset,  $\mathcal{L}(\mathbf{Z}^{(b)}, \lambda)$ .

The variational objective becomes a joint optimization of the variational parameters and the bootstrap index

$$\lambda_{\dagger}^{(b^*)} = \arg \max_{\lambda} \mathcal{L}(\mathbf{Z}^{(b^*)}, \lambda)$$

$$b^* = \arg \max_b \prod_{n=1}^N \int p(x_n | \theta_n) q(\theta_n; \lambda_{\dagger}^{(b)}) d\theta_n.$$

The two optimization problems are coupled: the first seeks the best approximation to the Bayesian posterior density while the second seeks the latent dataset index that gives the highest predictive accuracy. The variational density  $q(\theta; \lambda_{\dagger}^{(b^*)})$  is the closest KL approximation to the Bayesian posterior density inside the POP-EB MAP predictive density of Equation (6).

The naïve way to solve the joint optimization above is to adapt our earlier technique from Section 3.2. Bootstrap the dataset  $B$  times, maximize the ELBO for each dataset, and choose the one that gives the best predictive performance. This is a costly procedure. It requires multiple maximizations of the ELBO, which we wish to avoid.

### 4.3 BUMPING VARIATIONAL INFERENCE

We propose a stochastic optimization algorithm that maximizes the ELBO once. We weave bumping into each iteration of the optimization. We call this method bumping variational inference (BUMP-VI) (Algorithm 1). At a high level, the algorithm works as follows.

Consider a single iteration. We bootstrap the dataset  $B$  times. For each bootstrapped dataset, we compute a gradient  $\mathbf{g}_{\lambda}^{(b)}$  in the parameters  $\lambda$ . These gradients are noisy estimates of the “true” gradient, had we taken the naïve approach above and determined which bootstrapped dataset  $\mathbf{Z}^{(b^*)}$  led to the best predictive performance. The cost of computing  $B$  gradients is small in many Bayesian models. (The supplement describes an efficient implementation.)

Then, we employ the bumping procedure from Section 3.2. This means taking a step in the parameters for each bootstrapped dataset and evaluating the Bayesian predictive density on the original dataset. This evaluation is the main added cost of BUMP-VI over classical variational methods. We pick the index  $b^{(*)}$  that gives the highest predictive performance and take a step in the direction it indexes.

BUMP-VI is a stochastic optimization method; the step-size sequence matters for establishing convergence guarantees (Robbins and Monro, 1951). We use a constant step-size as it isolates the performance of the algorithm from any sequence-related effects and provides quantifiable error bounds (Nemirovski et al., 2009). Code is available at <https://github.com/Blei-Lab/lda-bump-cpp>.

## 5 EMPIRICAL STUDY

We apply BUMP-VI to two complex tasks: Bayesian mixture modeling of image histograms and latent Dirichlet allocation (LDA) topic modeling of a scientific text corpus. We compare BUMP-VI to coordinate ascent variational inference. In both examples, BUMP-VI uniformly reaches higher predictive accuracy. We first present both sets of results and then discuss performance.

---

### Algorithm 1: Bumping Variational Inference

---

**Input:** Model  $p(\mathbf{X}, \theta)$ , variational family  $q(\theta; \lambda)$   
**Result:** Optimized  $q(\theta; \lambda_{\dagger}^{(b^*)})$  approximation

Choose the number of bootstraps  $B$   
 Choose a step-size sequence  $\{\rho_{(i)}\}_1^{\infty}$   
 Initialize parameters  $\lambda_{(0)}$ , iteration  $i = 0$

**while**  $\|\lambda_{(i+1)} - \lambda_{(i)}\|$  is above some threshold **do**

**for**  $b = 1$  **to**  $B$  **do**

    Draw a bootstrap sample  $\mathbf{Z}^{(b)} \sim \hat{G}$

    Calculate gradient of parameters  $\lambda$

$$\mathbf{g}_{\lambda}^{(b)} \leftarrow \nabla_{\lambda} \mathcal{L}(\mathbf{Z}^{(b)}, \lambda)$$

**end**

  Choose the bootstrap index that maximizes the Bayesian predictive density on the dataset

$$b^* \leftarrow \arg \max_b \prod_{n=1}^N \int p(x_n | \theta_n) q(\theta_n; \lambda_{(i)} + \rho_{(i)} \mathbf{g}_{\lambda}^{(b)}) d\theta_n$$

  Take a step in direction indexed by  $b^*$

$$\lambda_{(i+1)} \leftarrow \lambda_{(i)} + \rho_{(i)} \mathbf{g}_{\lambda}^{(b^*)}$$

  Update iteration counter

$$i \leftarrow i + 1$$

**end**

Return variational parameters

$$\lambda_{\dagger}^{(b^*)} \leftarrow \lambda_{(i+1)}$$

---

### 5.1 BAYESIAN MIXTURE MODEL

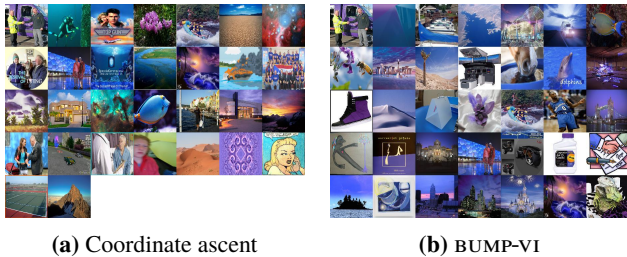

Consider a Gaussian mixture model (GMM) with a Gaussian-Gamma prior on the mixture component means and precisions, and a Dirichlet prior on the proportions. These are conditionally conjugate priors that lead to straightforward coordinate ascent update equations (Bishop, 2006).

The imageCLEF dataset has 576-dimensional color histograms of natural images (Villegas et al., 2013). We randomly select 5 000 images as our dataset and choose another 1 000 images for predictive accuracy tests. We standardize the mean and variance of the set of histograms. Thus, the hyperparameters for the Gaussian-Gamma prior are zero on the component means and one on the precisions. The hyperparameter on the Dirichlet is  $1/K$  where  $K$  is the number of components. We set the number of bootstrap samples to  $B = 10$  and the step-size to  $\rho = 0.1$ .

We compare coordinate ascent to BUMP-VI across a range of components. Figure 5 displays these results. BUMP-VI attains a higher average log predictive evaluated on the held-out set. We run each algorithm ten times per configuration to account for random initialization of the initial parameters.

**Figure 5:** Average log-predictive density of 1 000 held-out images. BUMP-VI (orange) reaches a higher predictive accuracy than coordinate ascent (green) across a range of configurations. Boxplots show the median, quartiles, and 1.5 interquartile range of ten repeats per configuration.

**Figure 6:** The “blue-purple” GMM ( $K = 40$ ) coordinate ascent component has some extraneous images. The bumping component is qualitatively more uniform.

Both algorithms converge in fewer than 75 iterations.

Figure 6 presents the effect of reaching higher predictive accuracy. We assign each image to its most probable mixture component and pick the one with “blue-purple” images. Though this is a subjective matter, the BUMP-VI component appears more uniform than its counterpart. The coordinate ascent component seems to have red-toned images that might belong in a different component.

## 5.2 LATENT DIRICHLET ALLOCATION

We study LDA with a corpus of 5 000 randomly selected abstracts from the arXiv repository. The abstracts are short ( $\sim 150$  words) and the vocabulary is large ( $\sim 12\,000$  unique words). The arXiv exhibits jargon-heavy abstracts, which leads to a large vocabulary. This makes for a challenging dataset; because of the vocabulary size, we only expect to identify a few topics in a corpus of size 5 000.

LDA has two Dirichlet priors. We set the hyperparameter on the topics distributions to be  $1/K$  where  $K$  is the number of topics. The hyperparameter on the topics is 0.005, which is approximately  $60/V$  where  $V$  is the vocabulary size. We set the number of bootstrap samples to  $B = 10$  and the

**Figure 7:** Average per-word log-predictive density of 1 000 held-out abstracts. BUMP-VI (orange) reaches a higher predictive accuracy than coordinate ascent (green) across a range of model configurations.

step-size to  $\rho = 0.05$ .

We study BUMP-VI across a range of topics. Figure 7 plots a comparison to coordinate ascent. BUMP-VI attains a higher average per-word log predictive evaluated on the held-out set. Tables 3 and 4 show how this difference affects the topics. While six of the topics are similar, BUMP-VI finds two topics with higher predictive power. As with mixture components, examining topics is a subjective activity. Both algorithms converged in fewer than 150 iterations.

## 5.3 MITIGATING MODEL MISMATCH

There is no reason to believe that natural images are truly distributed as a mixture of Gaussians. The same holds for the “bag of words” assumption that underlies LDA. With real data, there is always some level of inherent model mismatch. BUMP-VI attempts to mitigate this effect.

The performance gap widens with the number of components. We might expect a simpler model to be more severely mismatched. This demonstrates that POP-EB cannot rectify the choice of an inappropriate model. For example, two topics are simply too few to accurately model our arXiv corpus; both algorithms do poorly. However, with twelve topics, coordinate ascent does even worse. This may be due to other effects, such as local maxima in the variational objective function (Wainwright and Jordan, 2008).

Does BUMP-VI outperform classical techniques because it reaches a better local maximum of the ELBO? The answer is no. Evaluating the ELBO on the observed dataset gives similar numerical values for both methods. (In our experiments, coordinate ascent usually reaches a slightly higher number than BUMP-VI.) This is not surprising, as BUMP-VI solves a different optimization problem than coordinate ascent variational inference; it approximates the POP-EB MAP predictive density instead of the Bayesian predictive density.

**Figure 8:** BUMP-VI sensitivity study with the GMM ( $K = 40$ ) model. Average log-predictive density of 1 000 held-out images, over ten repeats.

**Table 2:** Runtime ratios of BUMP-VI compared to coordinate ascent. An efficient re-weighting strategy gives ratios that are less than  $B$ . (See supplementary note.)

| $B$     | 2    | 5    | 10   | 15   | 30    |
|---------|------|------|------|------|-------|
| BUMP-VI | 1.8× | 3.2× | 5.6× | 7.7× | 15.1× |

#### 5.4 SENSITIVITY TO BOOTSTRAP SAMPLES AND COMPUTATIONAL COST

We also study the sensitivity of BUMP-VI to the number of bootstrap samples  $B$  (Figure 8). Tibshirani and Knight (1999) recommend using 20-30 bootstrap samples for bumping, but as few as five appear to perform well. This is because BUMP-VI, in a loose sense, re-samples the dataset  $B$  times the number of iterations. For completeness, we also compare the case of  $B = 1$ . This is equivalent to stochastic variational inference (SVI) with “minibatch” size equal to  $N$  (Hoffman et al., 2013). This shows that the performance gain in BUMP-VI is not due to stochastic escapes from local maxima. (Though, it likely benefits from it.)

The POP-EB framework incurs a computational cost proportional to the choice of  $B$ . BUMP-VI reduces this cost in two ways. The first is due to the iterative resampling effect mentioned above. The second is due to an efficient calculation of the  $B$  gradients at each iteration. (See supplementary note.) Table 2 shows that BUMP-VI is less than  $B$  times the cost of coordinate ascent variational inference.

## 6 CONCLUSION

Mismatched models exhibit poor predictive performance. The POP-EB predictive density mitigates this effect by incorporating the population  $F$  into Bayesian analysis. The POP-EB MAP predictive density is attractively simple; it explores the space of bootstrapped dataset to find the one with highest predictive power. BUMP-VI extends this idea to variational

inference; it delivers an efficient algorithm with promising results on real-world datasets.

POP-EB, like EB, uses the dataset twice: once to estimate the prior and again during inference. There are alternatives to consider, such as cross-validation and bias correction (Efron and Tibshirani, 1997; Gelman et al., 2013). Directly modeling the expected predictive performance of future data should also improve POP-EB.

**Table 3:** Coordinate ascent LDA topics ( $K = 8$ ).

| Topic 1      | Topic 2       | Topic 3      | Topic 4    |
|--------------|---------------|--------------|------------|
| charge       | gravitational | et           | knowledge  |

## Abstract

Markov logic uses weighted formulas to compactly encode a probability distribution over possible worlds. Despite the use of logical formulas, Markov logic networks (MLNs) can be difficult to interpret, due to the often counter-intuitive meaning of their weights. To address this issue, we propose a method to construct a possibilistic logic theory that exactly captures what can be derived from a given MLN using maximum a posteriori (MAP) inference. Unfortunately, the size of this theory is exponential in general. We therefore also propose two methods which can derive compact theories that still capture MAP inference, but only for specific types of evidence. These theories can be used, among others, to make explicit the hidden assumptions underlying an MLN or to explain the predictions it makes.

## 1 INTRODUCTION

Markov logic [22] and possibilistic logic [9] are two popular logics for modelling uncertain beliefs. Both logics share a number of important characteristics. At the syntactic level, formulas correspond to pairs  $(\alpha, \lambda)$ , consisting of a classical formula  $\alpha$  and a certainty weight  $\lambda$ , while at the semantic level, sets of these formulas induce a mapping from possible worlds to  $[0, 1]$ , encoding the relative plausibility of each possible world.

Despite their close similarities, however, Markov logic and possibilistic logic have been developed in different communities and for different purposes: Markov logic has mainly been studied in a machine learning context whereas possibilistic logic has been studied as a knowledge representation language. This reflects the complementary strengths and weaknesses of these logics. On the one hand, the qualitative nature of possibilistic logic makes it challenging to use for learning; although a few interesting approaches for

learning possibilistic logic theories from data have been explored (e.g. [24]), their impact on applications to date has been limited. On the other hand, the intuitive meaning of Markov logic theories is often difficult to grasp, which limits the potential of Markov logic for knowledge representation. The main culprit is that the meaning of a theory can often not be understood by looking at the individual formulas in isolation. This issue, among others, has been highlighted in [26], where coherence measures are proposed that evaluate to what extent the formulation of a Markov logic theory is misleading.

**Example 1.** Consider the following Markov logic formulas:

$$\begin{aligned} +\infty : & \quad \text{antarctic-bird}(X) \rightarrow \text{bird}(X) \\ 10 : & \quad \text{bird}(X) \rightarrow \text{flies}(X) \\ 5 : & \quad \text{antarctic-bird}(X) \rightarrow \neg \text{flies}(X) \end{aligned}$$

While the last formula might appear to suggest that antarctic birds cannot fly, in combination with the other two formulas, it merely states that antarctic birds are less likely to fly than birds in general.

Possibilistic logic is based on a purely qualitative, comparative model of uncertainty: while a Markov logic theory compactly encodes a probability distribution over the set of possible worlds, a possibilistic logic theory merely encodes a ranking of these possible worlds. Even though a probability distribution offers a much richer uncertainty model, many applications of Markov logic are based on MAP inference, which only relies on the ranking induced by the probability distribution.

In this paper, we first show how to construct a possibilistic logic theory  $\Theta$ , given a Markov logic theory  $\mathcal{M}$ , such that the conclusions that we can infer from  $\Theta$  are exactly those conclusions that we can obtain from  $\mathcal{M}$  using MAP inference. Our construction can be seen as the syntactic counterpart of the probability-possibility transformation from [10]. In principle, it allows us to combine the best of both worlds, using  $\mathcal{M}$  for making predictions while using  $\Theta$  for elucidating the knowledge that is captured by  $\mathcal{M}$  (e.g. to verify

that the theory  $\mathcal{M}$  is sensible). However, the size of  $\Theta$  can be exponential in the size of  $\mathcal{M}$ , which is unsurprising given that the computational complexity of MAP inference is higher than the complexity of inference in possibilistic logic. To overcome this problem, we begin by studying ground (i.e. propositional) theories and propose two novel approaches for transforming a ground MLN into a compact ground possibilistic logic theory that still correctly captures MAP inference, but only for specific types of evidence (e.g. sets of at most  $k$  literals). Then we lift one of these approaches such that it can transform a first-order MLN into a first-order possibilistic logic theory. Finally, we present several examples that illustrate how the transformation process can be used to help identify unintended consequences of a given MLN, and more generally, to better understand its behaviour.

The remainder of the paper is structured as follows. In the next section, we provide some background on Markov logic and possibilistic logic. In Section 3, we analyse the relation between MAP inference in ground Markov logic networks and possibilistic logic inference, introducing in particular two methods for deriving compact theories. Section 4 then discusses how we can exploit the symmetries in the case of an ungrounded Markov logic network, while Section 5 provides some illustrative examples. Finally, we provide an overview of related work in Section 6.

Due to space limitations, some of the proofs have been omitted from this paper. These proofs can be found in an online appendix.<sup>1</sup>

## 2 BACKGROUND

### 2.1 MARKOV LOGIC

A Markov logic network (MLN) [22] is a set of pairs  $(F, w_F)$ , where  $F$  is a formula in first-order logic and  $w_F$  is a real number, intuitively reflecting a penalty that is applied to possible worlds (i.e. logical interpretations) that violate  $F$ . In examples, we will also use the notation  $w_F : F$  to denote the formula  $(F, w_F)$ . An MLN serves as a template for constructing a propositional Markov network. In particular, given a set of constants  $C$ , an MLN  $\mathcal{M}$  induces the following probability distribution on possible worlds  $\omega$ :

$$p_{\mathcal{M}}(\omega) = \frac{1}{Z} \exp \left( \sum_{(F, w_F) \in \mathcal{M}} w_F n_F(\omega) \right), \quad (1)$$

where  $n_F(x)$  is the number of true groundings of  $F$  in the possible world  $\omega$ , and  $Z$  is a normalization constant to ensure that  $p_{\mathcal{M}}$  can be interpreted as a probability distribution. Sometimes, formulas  $(F, w_F)$  are considered where  $w_F = +\infty$ , to represent hard constraints. In such cases,

we define  $p_{\mathcal{M}}(\omega) = 0$  for all possible worlds that do not satisfy all of the hard constraints, and only formulas with a real-valued weight are considered in (1) for the possible worlds that do. Note that a Markov logic network can be seen as a weighted set of propositional formulas, which are obtained by grounding the formulas in  $\mathcal{M}$  w.r.t. the set of constants  $C$  in the usual way. In the particular case that all formulas in  $\mathcal{M}$  are already grounded,  $\mathcal{M}$  corresponds to a theory in penalty logic [13].

One common inference task in MLNs is full MAP inference. In this setting, given a set of ground literals (the evidence) the goal is to compute the most probable configuration of all unobserved variables (the queries). Two standard approaches for performing MAP inference in MLNs are to employ a strategy based on MaxWalkSAT [22] or to use a cutting plane based strategy [23, 18]. Given a set of ground formulas  $E$ , we write  $\max(\mathcal{M}, E)$  for the set of most probable worlds of the MLN that satisfy  $E$ . For each  $\omega \in \max(\mathcal{M}, E)$ ,  $\sum_{(F, w_F) \in \mathcal{M}} w_F n_F(\omega)$  evaluates to the same value, which we will refer to as  $\text{sat}(\mathcal{M}, E)$ . We define the penalty  $\text{pen}(\mathcal{M}, E)$  of  $E$  as follows:

$$\text{pen}(\mathcal{M}, E) = \text{sat}(\mathcal{M}, \emptyset) - \text{sat}(\mathcal{M}, E)$$

We will sometimes identify possible worlds with the set of literals they make true, writing  $\text{pen}(\mathcal{M}, \omega)$ . We will also write  $\text{pen}(\mathcal{M}, \alpha)$ , with  $\alpha$  a ground formula, as a shorthand for  $\text{pen}(\mathcal{M}, \{\alpha\})$ . We will consider the following inference relation, which has been considered among others in [13]:

$$(\mathcal{M}, E) \vdash_{\text{MAP}} \alpha \quad \text{iff} \quad \forall \omega \in \max(\mathcal{M}, E) : \omega \models \alpha \quad (2)$$

with  $\mathcal{M}$  an MLN,  $\alpha$  a ground formula and  $E$  a set of ground formulas. It can be shown that checking  $(\mathcal{M}, E) \vdash_{\text{MAP}} \alpha$  for a ground network  $\mathcal{M}$  is  $\Delta_2^P$ -complete<sup>2</sup> [4].

### 2.2 POSSIBILISTIC LOGIC

A possibility distribution in a universe  $\Omega$  is a mapping  $\pi$  from  $\Omega$  to  $[0, 1]$ , encoding our knowledge about the possible values that a given variable  $X$  can take; throughout this paper, we will assume that all universes are finite. For each  $x \in \Omega$ ,  $\pi(x)$  is called the possibility degree of  $x$ . By convention, in a state of complete ignorance, we have  $\pi(x) = 1$  for all  $x \in \Omega$ ; conversely, if  $X = x_0$  is known, we have  $\pi(x_0) = 1$  and  $\pi(x) = 0$  for  $x \neq x_0$ . Possibility theory [27, 12] is based on the possibility measure  $\Pi$  and dual necessity measure  $N$ , induced by a possibility distribution  $\pi$  as follows ( $A \subseteq \Omega$ ):

$$\Pi(A) = \max_{a \in A} \pi(a)$$

$$N(A) = 1 - \Pi(\Omega \setminus A)$$

<sup>2</sup>The complexity class  $\Delta_2^P$  contains those decision problems that can be solved in polynomial time on a deterministic Turing machine with access to an NP oracle.

<sup>1</sup><http://arxiv.org/abs/1506.01432>

Intuitively,  $\Pi(A)$  is the degree to which available evidence is compatible with the view that  $X$  belongs to  $A$ , whereas  $N(A)$  is the degree to which available evidence implies that  $X$  belongs to  $A$ , i.e. the degree to which it is certain that  $X$  belongs to  $A$ .

A theory in possibilistic logic [9] is a set of formulas of the form  $(\alpha, \lambda)$ , where  $\alpha$  is a propositional formula and  $\lambda \in [0, 1]$  is a certainty weight. A possibility distribution  $\pi$  satisfies  $(\alpha, \lambda)$  iff  $N(\llbracket \alpha \rrbracket) \geq \lambda$ , with  $N$  the necessity measure induced by  $\pi$  and  $\llbracket \alpha \rrbracket$  the set of propositional models of  $\alpha$ . We say that a possibilistic logic theory  $\Theta$  entails  $(\alpha, \lambda)$ , written  $\Theta \models (\alpha, \lambda)$ , if every possibility distribution which satisfies all the formulas in  $\Theta$  also satisfies  $(\alpha, \lambda)$ . A possibility distribution  $\pi_1$  is called less specific than a possibility distribution  $\pi_2$  if  $\pi_1(\omega) \geq \pi_2(\omega)$  for every  $\omega$ . It can be shown that the set of models of  $\Theta$  always has a least element w.r.t. the minimal specificity ordering, which is called the least specific model  $\pi^*$  of  $\Theta$ . It is easy to see that  $\Theta \models (\alpha, \lambda)$  iff  $\pi^*$  satisfies  $(\alpha, \lambda)$ .

Even though the semantics of possibilistic logic is defined at the propositional level, we will also use first-order formulas such as  $(p(X) \rightarrow q(X, Y), \lambda)$  throughout the paper. As in Markov logic, we will interpret these formulas as abbreviations for a set of propositional formulas, obtained using grounding in the usual way. In particular, we will always assume that first-order formulas are defined w.r.t. a finite set of constants.

The  $\lambda$ -cut  $\Theta_\lambda$  of a possibilistic logic theory  $\Theta$  is defined as follows:

$$\Theta_\lambda = \{\alpha \mid (\alpha, \mu) \in \Theta, \mu \geq \lambda\}$$

It can be shown that  $\Theta \models (\alpha, \lambda)$  iff  $\Theta_\lambda \models \alpha$ , which means that inference in possibilistic logic can straightforwardly be implemented using a SAT solver.

An inconsistency-tolerant inference relation  $\vdash_{poss}$  for possibilistic logic can be defined as follows:

$$\Theta \vdash_{poss} \alpha \quad \text{iff} \quad \Theta_{con(\Theta)} \models \alpha$$

where the consistency level  $con(\Theta)$  of  $\Theta$  is the lowest certainty level  $\lambda$  for which  $\Theta_\lambda$  is satisfiable (among the certainty levels that occur in  $\Theta$ ). Note that all formulas with a certainty level below  $con(\Theta)$  are ignored, even if they are unrelated to any inconsistency in  $\Theta$ . This observation is known as the drowning effect.

We will write  $(\Theta, E) \vdash_{poss} \alpha$ , with  $E$  a set of propositional formulas, as an abbreviation for  $\Theta \cup \{(e, 1) \mid e \in E\} \vdash_{poss} \alpha$ . Despite its conceptual simplicity,  $\vdash_{poss}$  has many desirable properties. Among others, it is closely related to AGM belief revision [8] and default reasoning [2]. It can be shown that checking  $\Theta \vdash_{poss} (\alpha, \lambda)$  is a  $\Theta_2^P$  complete problem<sup>3</sup> [17]. In this paper,  $\vdash_{poss}$  will allow us to capture the non-monotonicity of MAP inference.

<sup>3</sup>The complexity class  $\Theta_2^P$  contains those decision problems

**Example 2.** Let  $\Theta$  consist of the following formulas:

$$\begin{aligned} &(penguin(X) \rightarrow bird(X), 1) \\ &(penguin(X) \rightarrow \neg flies(X), 1) \\ &(bird(X) \rightarrow flies(X), 0.5) \end{aligned}$$

Then we find:

$$\begin{aligned} &(\Theta, \{bird(tweety)\}) \vdash_{poss} flies(tweety) \\ &(\Theta, \{bird(tweety), penguin(tweety)\}) \vdash_{poss} \neg flies(tweety) \end{aligned}$$

In general,  $\vdash_{poss}$  allows us to model rules with exceptions, by ensuring that rules about specific contexts have a higher certainty weight than rules about general contexts.

### 3 ENCODING GROUND NETWORKS

Throughout this section, we will assume that  $\mathcal{M}$  is a ground MLN in which all the weights are strictly positive. This can always be guaranteed for ground MLNs by replacing formulas  $(\alpha, \lambda)$  with  $\lambda < 0$  by  $(\neg\alpha, -\lambda)$ , and by discarding any formula whose weight is 0. For a subset  $X \subseteq \mathcal{M}$ , we write  $X^*$  for the set of corresponding classical formulas, e.g. for  $X = \{(F_1, w_1), \dots, (F_n, w_n)\}$  we have  $X^* = \{F_1, \dots, F_n\}$ . In particular,  $\mathcal{M}^*$  are the classical formulas appearing in the MLN  $\mathcal{M}$ .

The following transformation constructs a possibilistic logic theory that is in some sense equivalent to a given MLN. It is inspired by the probability-possibility transformation from [10].

**Transformation 1.** We define the possibilistic logic theory  $\Theta_{\mathcal{M}}$  corresponding to an MLN  $\mathcal{M}$  as follows:

$$\{(\bigvee X^*, \phi(\neg \bigvee X^*)) \mid X \subseteq \mathcal{M}, \phi(\neg \bigvee X^*) > 0\} \quad (3)$$

where for a propositional formula  $\alpha$ :

$$\phi(\alpha) = \begin{cases} \frac{K + pen(\mathcal{M}, \alpha)}{L} & \text{if } \alpha \text{ satisfies the hard constraints} \\ 1 & \text{otherwise} \end{cases}$$

and the constants  $K$  and  $L$  are chosen such that  $0 = \phi(\top) \leq \phi(\alpha) < 1$  for every  $\alpha$  that satisfies the hard constraints (i.e. the formulas with weight  $+\infty$ ).

In the following we will use the notations  $\phi(\omega)$  for a possible world  $\omega$  and  $\phi(E)$  for a set of formulas  $E$ , defined entirely analogously. Throughout the paper we will also write  $(-K < x < L - K)$ :

$$\lambda_x = \frac{K + x}{L}$$

The correctness of Transformation 1 follows from the next proposition, which is easy to show.

that can be solved in polynomial time on a deterministic Turing machine, by making at most a logarithmic number of calls to an NP oracle.

**Proposition 1.** Let  $\mathcal{M}$  be a ground MLN and  $\Theta_{\mathcal{M}}$  the corresponding possibilistic logic theory. Let  $\pi$  be the least specific model of  $\Theta_{\mathcal{M}}$ . It holds that:

$$\pi(\omega) = 1 - \phi(\omega)$$

**Corollary 1.** Let  $\mathcal{M}$  be a ground MLN and  $\Theta_{\mathcal{M}}$  the corresponding possibilistic logic theory. It holds that for  $\lambda < 1$ :

$$\Theta_{\mathcal{M}} \models (\alpha, \lambda) \quad \text{iff} \quad \text{pen}(\mathcal{M}, \neg\alpha) \geq \lambda L - K$$

and

$$\Theta_{\mathcal{M}} \models (\alpha, 1) \quad \text{iff} \quad \text{pen}(\mathcal{M}, \neg\alpha) = +\infty$$

**Corollary 2.** Let  $\mathcal{M}$  be a ground MLN and  $\Theta_{\mathcal{M}}$  the corresponding possibilistic logic theory. For  $p_{\mathcal{M}}$  the probability distribution induced by  $\mathcal{M}$  and  $\pi$  the least specific model of  $\Theta_{\mathcal{M}}$ , it holds that

$$p_{\mathcal{M}}(\omega_1) > p_{\mathcal{M}}(\omega_2) \quad \text{iff} \quad \pi(\omega_1) > \pi(\omega_2)$$

for all possible worlds  $\omega_1$  and  $\omega_2$ . In particular, it follows that for every propositional formula  $\alpha$  and every set of propositional formulas  $E$ :

$$(\mathcal{M}, E) \vdash_{\text{MAP}} \alpha \quad \text{iff} \quad (\Theta, E) \vdash_{\text{poss}} \alpha \quad (4)$$

**Example 3.** Consider the MLN  $\mathcal{M}$  containing the following formulas:

$$5 : a \rightarrow x \quad 5 : a \rightarrow y \quad 10 : a \wedge b \rightarrow \neg y$$

Then  $\Theta_{\mathcal{M}}$  contains the following formulas:

$$\begin{aligned} \lambda_5 : a \rightarrow x & & \lambda_5 : a \rightarrow y \\ \lambda_{10} : a \wedge b \rightarrow \neg y & & \lambda_{10} : a \rightarrow x \vee y \\ \lambda_{15} : a \wedge b \rightarrow x \vee \neg y & & \end{aligned}$$

It can be verified that:

$$(\Theta_{\mathcal{M}}, \{a\}) \vdash_{\text{poss}} x \wedge y \quad (\Theta_{\mathcal{M}}, \{a, b\}) \vdash_{\text{poss}} x \wedge \neg y$$

An important drawback of the transformation to possibilistic logic is that the number of formulas in  $\Theta_{\mathcal{M}}$  is exponential in  $|\mathcal{M}|$ . This makes the transformation inefficient, and moreover limits the interpretability of the possibilistic logic theory. In general, the exponential size of  $\Theta_{\mathcal{M}}$  cannot be avoided if we want (4) to hold for any  $E$  and  $\alpha$ . However, more compact theories can be found if we focus on specific types of evidence. Sections 3.1 and 3.2 introduce two practical methods to accomplish this.

### 3.1 SELECTIVELY AVOIDING DROWNING

In many applications, we are only interested in particular types of evidence sets  $E$ . For example, we may only

be interested in evidence sets that contain at most  $k$  literals, or in evidence sets that only contain positive literals. In such cases, we can often derive a more compact possibilistic logic theory  $\Theta^{\mathcal{E}}$  as follows. Let  $\mathcal{E}$  be the set of evidence sets that we wish to consider, where each  $E \in \mathcal{E}$  is a set of ground formulas. Given  $E \in \mathcal{E}$  we write  $\mathcal{S}_E$  for the set of all minimal subsets  $\{F_1, \dots, F_l\}$  of  $\mathcal{M}_E^* = \{F \mid F \in \mathcal{M}^*, \text{pen}(\mathcal{M}, \neg F) < \text{pen}(\mathcal{M}, E)\}$  s.t.

$$\text{pen}(\mathcal{M}, \bigwedge E \wedge \neg F_1 \wedge \dots \wedge \neg F_l) > \text{pen}(\mathcal{M}, E) \quad (5)$$

The following transformation constructs a possibilistic logic theory that correctly captures MAP inference for evidence sets in  $\mathcal{E}$ . The basic intuition is that we want to weaken the formulas in  $\mathcal{M}^*$  just enough to ensure that the resulting certainty level prevents them from drowning when the evidence  $E$  becomes available.

**Transformation 2.** Given a ground MLN  $\mathcal{M}$  and a set of evidence sets  $\mathcal{E}$ , we define the possibilistic logic theory  $\Theta_{\mathcal{M}}^{\mathcal{E}}$  as follows:

$$\{(F_1, \phi(\neg F_1)) \mid F_1 \in \mathcal{M}^*\} \quad (6)$$

$$\cup \{(\neg \bigwedge E \vee \bigvee Z, \phi(\bigwedge E \wedge \neg \bigwedge Z)) \mid Z \in \mathcal{S}_E, \quad (7)$$

$$E \in \mathcal{E}\} \cup \{(\neg \bigwedge E, \phi(\bigwedge E)) \mid E \in \mathcal{E}\} \quad (8)$$

If  $\mathcal{M}$  is clear from the context, we will omit the subscript in  $\Theta_{\mathcal{M}}^{\mathcal{E}}$ . The formulas in (6) are the direct counterpart of the MLN. Intuitively, there are two reasons why these formulas are not sufficient. First, due to the drowning effect, formulas  $F$  such that  $\text{pen}(\mathcal{M}, \neg F) < \text{pen}(\mathcal{M}, E)$  will be ignored under the evidence  $E$ . In such cases we should look at minimal ways to weaken these formulas such that the certainty level of the resulting formula is sufficient to avoid drowning under the evidence  $E$ . This is accomplished by adding the formulas in (7). Second, as  $\Theta^{\mathcal{E}}$  contains less information than  $\Theta_{\mathcal{M}}$ , we need to ensure that the consistency level for  $\Theta^{\mathcal{E}}$  is never lower than the consistency level for  $\Theta_{\mathcal{M}}$ , given an evidence set  $E \in \mathcal{E}$ . To this end,  $\Theta^{\mathcal{E}}$  includes the formulas in (8). The following example illustrates why these formulas are needed.

**Example 4.** Consider the following MLN  $\mathcal{M}$ :

$$\begin{aligned} 3 : u & & 2 : a & & 10 : (a \vee b) \wedge (u \vee v) \rightarrow \neg x \\ 2 : b & & 1 : v & & \end{aligned}$$

and let  $\mathcal{E} = \{\{x\}\}$ , i.e. the only evidence set in which we are interested is  $\{x\}$ . It holds that

$$\mathcal{S}_E = \{\{a, u\}, \{b, u\}, \{a, v\}, \{b, v\}\} \quad (9)$$

and  $\Theta^{\mathcal{E}} = \Theta \cup \Psi \cup \Gamma$ , where:

$$\Theta = \{(u, \lambda_3), (a, \lambda_2), ((a \vee b) \wedge (u \vee v) \rightarrow \neg x, \lambda_{10}), (b, \lambda_2), (v, \lambda_1)\}$$

$$\Psi = \{(a \vee u \vee \neg x, \lambda_6), (b \vee u \vee \neg x, \lambda_6), (a \vee v \vee \neg x, \lambda_5), (b \vee v \vee \neg x, \lambda_5)\}$$

$$\Gamma = \{(\neg x, \lambda_4)\}$$

It is easy to verify that  $(\Theta \cup \Psi, \{x\}) \vdash_{poss} u$  whereas  $(\mathcal{M}, \{x\}) \not\vdash_{MAP} u$  and  $(\Theta \cup \Psi \cup \Gamma, \{x\}) \not\vdash_{poss} u$ .

We now prove the correctness of Transformation 2.

**Proposition 2.** *For any formula  $\alpha$  and any evidence set  $E \in \mathcal{E}$ , it holds that  $(\Theta_{\mathcal{M}}, E) \vdash_{poss} \alpha$  iff  $(\Theta^{\mathcal{E}}, E) \vdash_{poss} \alpha$ .*

*Proof.* Let us introduce the following notation:

$$\begin{aligned}\lambda_E &= \text{con}(\Theta_{\mathcal{M}} \cup \{(e, 1) \mid e \in E\}) \\ \lambda_E^{\mathcal{E}} &= \text{con}(\Theta^{\mathcal{E}} \cup \{(e, 1) \mid e \in E\}) \\ A &= (\Theta_{\mathcal{M}} \cup \{(e, 1) \mid e \in E\})_{\lambda_E} \\ A^E &= (\Theta^{\mathcal{E}} \cup \{(e, 1) \mid e \in E\})_{\lambda_E^{\mathcal{E}}}\end{aligned}$$

We need to show that  $A$  is equivalent to  $A^E$ , for any  $E \in \mathcal{E}$ .

By Corollary 1, we know that every formula  $(\alpha, \lambda)$  in  $\Theta_{\mathcal{M}}^{\mathcal{E}}$  is entailed by  $\Theta_{\mathcal{M}}$ , hence  $\lambda_E^{\mathcal{E}} \leq \lambda_E$ . Since  $\lambda_E$  is the smallest certainty level from  $\Theta_{\mathcal{M}}$  which is strictly higher than  $\phi(E)$ , it follows that  $A^E$  contains every formula which appears in  $\Theta^{\mathcal{E}}$  with a weight that is strictly higher than  $\phi(E)$ . Moreover, since  $\Theta^{\mathcal{E}}$  by construction contains  $(\neg \wedge E, \phi(\wedge E))$ , we find that  $A^E$  can only contain such formulas:

$$A^E = E \cup \{\alpha \mid (\alpha, \lambda) \in \Theta^{\mathcal{E}}, \lambda > \phi(E)\} \quad (10)$$

It follows that  $A \models A^E$ .

Let  $G_1 \vee \dots \vee G_s$  be a formula from  $A$ . From Corollary 1 we know that:

$$\text{pen}(\mathcal{M}, \neg G_1 \wedge \dots \wedge \neg G_s) > \text{pen}(\mathcal{M}, E)$$

and a fortiori

$$\text{pen}(\mathcal{M}, E \wedge \neg G_1 \wedge \dots \wedge \neg G_s) > \text{pen}(\mathcal{M}, E)$$

This means that for any formula  $G_1 \vee \dots \vee G_s$  in  $A$ , either  $\text{pen}(\mathcal{M}, \neg G_i) > \text{pen}(\mathcal{M}, E)$  for some  $i$  or  $\mathcal{S}_E$  contains a subset  $\{H_1, \dots, H_r\}$  of  $\{G_1, \dots, G_s\}$ . Then  $\Theta^{\mathcal{E}}$  contains either  $G_i$  or the formula  $\neg E \vee H_1 \dots \vee H_r$  with a weight which is strictly higher than  $\phi(E)$  and thus either  $G_i$  or  $\neg E \vee H_1 \dots \vee H_r$  belongs to  $A^E$ . In both cases we find  $A^E \models G_1 \vee \dots \vee G_s$ . We conclude  $A^E \models A$ .  $\square$

An alternative, which would make the approach in this section closer to the standard encoding in (1), is to define  $\mathcal{S}'_E$  as the set of minimal subsets  $\{F_1, \dots, F_l\}$  of  $\mathcal{M}_E^*$  such that

$$\text{pen}(\mathcal{M}, \neg F_1 \wedge \dots \wedge \neg F_l) > \text{pen}(\mathcal{M}, E) \quad (11)$$

and then replace the formulas in (7) by

$$\{(\bigvee Z, \phi(\neg \bigwedge Z)) \mid Z \in \mathcal{S}'_E\} \quad (12)$$

The advantage of (7), however, is that we can expect many of the sets in  $\mathcal{S}_E$  to be singletons. To see why this is

the case, first note that for each world  $\omega$  in  $\max(\mathcal{M}, E)$ , the set of formulas  $\mathcal{Y} \subseteq \mathcal{M}^*$  satisfied by  $\omega$  is such that  $\text{pen}(\mathcal{M}, \neg \bigvee (\mathcal{M}^* \setminus \mathcal{Y}))$  is minimal among all sets  $\mathcal{Y}' \subseteq \mathcal{M}^*$  for which  $E \wedge \bigwedge \mathcal{Y}'$  is consistent. Let us write  $\text{Cons}_E(\mathcal{M})$  for the set of all these maximally consistent subsets of  $\mathcal{M}^*$ . Note that  $\max(\mathcal{M}, E) = \llbracket \bigvee \{ \bigwedge \mathcal{Y} \mid \mathcal{Y} \in \text{Cons}_E(\mathcal{M}) \} \rrbracket$ .

**Lemma 1.** *For a set of formulas  $\{F_1, \dots, F_l\} \subseteq \mathcal{M}^*$  it holds that  $\text{pen}(\mathcal{M}, E \wedge \neg F_1 \wedge \dots \wedge \neg F_l) > \text{pen}(\mathcal{M}, E)$  iff  $\{F_1, \dots, F_l\} \cap \mathcal{Y} \neq \emptyset$  for every  $\mathcal{Y}$  in  $\text{Cons}_E(\mathcal{M})$ .*

**Corollary 3.** *Let  $\text{Cons}_E(\mathcal{M}) = \{\mathcal{Y}_1, \dots, \mathcal{Y}_s\}$ . It holds that  $\mathcal{S}_E$  consists of the subset-minimal elements of  $\{\{y_1, \dots, y_s\} \mid y_1 \in \mathcal{Y}_1 \cap \mathcal{M}_E^*, \dots, y_s \in \mathcal{Y}_s \cap \mathcal{M}_E^*\}$ .*

**Example 5.** *Consider again the MLN  $\mathcal{M}$  from Example 4 and let  $E = \{x\}$ . It holds that  $\text{Cons}_E(\mathcal{M}) = \{\mathcal{Y}_1, \mathcal{Y}_2\}$ , where*

$$\begin{aligned}\mathcal{Y}_1 &= \{(a \vee b) \wedge (u \vee v) \rightarrow \neg x, a, b\} \\ \mathcal{Y}_2 &= \{(a \vee b) \wedge (u \vee v) \rightarrow \neg x, u, v\} \\ \mathcal{M}_E^* &= \{a, b, u, v\}\end{aligned}$$

From Corollary 3, it follows that  $\mathcal{S}_E$  is given by (9).

In practice,  $\text{Cons}_E(\mathcal{M})$  will often contain a single element, in which case all the elements of  $\mathcal{S}_E$  will be singletons.

### 3.2 MAP INFERENCE AS DEFAULT REASONING

A large number of approaches has been proposed for reasoning with a set of default rules of the form “if  $\alpha$  then typically  $\beta$ ” [15, 19, 14]. At the core, each of the proposed semantics corresponds to the intuition that a set of default rules imposes a preference order on possible worlds, where “if  $\alpha$  then  $\beta$ ” means that  $\beta$  is true in the most preferred models of  $\alpha$ . The approaches from [15] and [19] can be elegantly captured in possibilistic logic [2], by interpreting the default rule as the constraint  $\Pi(\alpha \wedge \beta) > \Pi(\alpha \wedge \neg \beta)$ . In Markov logic, the same constraint on the ordering of possible worlds can be expressed by imposing the constraint  $(\mathcal{M}, \alpha) \vdash_{MAP} \beta$ . In other words, we can view the MAP consequences of an MLN as a set of default rules, and encode these default rules in possibilistic logic. The following transformation is based on this idea.

**Transformation 3.** *Given a ground MLN  $\mathcal{M}$  and a positive integer  $k$ , we construct a possibilistic logic theory  $\Theta_{\mathcal{M}}^k$  as follows:*

- For each hard rule  $F$  from  $\mathcal{M}$ , add  $(F, 1)$  to  $\Theta_{\mathcal{M}}^k$ .
- For each set of literals  $E$  such that  $0 \leq |E| \leq k$ , let  $X = \{x \mid (\mathcal{M}, E) \vdash_{MAP} x\}$  be the set of literals that are true in all the most plausible models of  $E$ . Unless there is a literal  $y \in E$  such that  $\bigwedge (E \setminus \{y\}) \vdash_{MAP} y$ , add

$$\left( \bigwedge E \rightarrow \bigwedge X, \lambda_E \right)$$

to  $\Theta_{\mathcal{M}}^k$ , where  $\lambda_E = \phi(\bigwedge E)$ . If  $\text{pen}(\mathcal{M}, E) > \text{pen}(\mathcal{M}, \emptyset)$ , add also

$$(\neg(\bigwedge E \wedge \bigwedge X), \lambda'_E) \quad (13)$$

where  $\lambda'_E$  is the certainty level just below  $\lambda_E$  in  $\Theta_{\mathcal{M}}^k$ , i.e.  $\lambda_{E'} = \max\{\lambda_F \mid \lambda_F < \lambda_E, |F| \leq k\}$ .

If  $\mathcal{M}$  is clear from the context, we will omit the subscript in  $\Theta_{\mathcal{M}}^k$ . The possibilistic encoding of default rules used in Transformation 3 is similar in spirit to the method from [2], which is based on the Z-ranking from [19]. However, because  $p_{\mathcal{M}}$  already provides us with a model of the default rules, we can directly encode default rules in possibilistic logic, without having to rely on the Z-ranking. Also note that although the method is described in terms of an MLN, it can be used for encoding any ranking on possible worlds (assuming a finite set of atoms).

As illustrated in the following example, (13) is needed to avoid deriving too much, serving a similar purpose to (8) in the approach from Section 3.1.

**Example 6.** Consider the following MLN  $\mathcal{M}$ :

$$2 : \neg a \vee b \quad 2 : a \vee b \quad 1 : a \vee \neg b$$

Then  $\Theta^1 = \Theta \cup \Psi$ , where

$$\begin{aligned} \Theta &= \{(\top \rightarrow a \wedge b, \lambda_0), (\neg a \rightarrow b, \lambda_1), (\neg b \rightarrow \top, \lambda_2)\} \\ \Psi &= \{(b, \lambda_1), (a \vee \neg b, \lambda_0)\} \end{aligned}$$

We find  $(\Theta, \{\neg b\}) \vdash_{\text{poss}} a$  while  $(\mathcal{M}, \{\neg b\}) \not\vdash_{\text{MAP}} a$ . Accordingly, we have  $(\Theta \cup \Psi, \{\neg b\}) \not\vdash_{\text{poss}} a$ .

Transformations 2 and 3 have complementary strengths. For example, Transformation 2 may lead to more compact theories for relatively simple MLNs, e.g. if for most of the considered evidence sets, there is a unique set of formulas from the MLN that characterizes the most probable models of the evidence (cf. Lemma 1). On the other hand, Transformation 3 may lead to substantially more compact theories in cases where the number of formulas is large relative to the number of atoms.

We now show the correctness of Transformation 3.

**Proposition 3.** Let  $\mathcal{M}$  be an MLN,  $k$  a positive integer and  $\Theta^k$  the proposed possibilistic logic encoding of  $\mathcal{M}$ . Furthermore, let  $E$  and  $C$  be sets of literals such that  $|E| + |C| \leq k + 1$ . It holds that  $(\mathcal{M}, E) \vdash_{\text{MAP}} \bigvee C$  if and only if  $(\Theta^k, E) \vdash_{\text{poss}} \bigvee C$ .

Before we prove Proposition 3, we present a number of lemmas. In the lemmas and proofs below,  $\mathcal{M}$  will always be an MLN,  $\Theta^k$  will be the corresponding possibilistic logic theory and  $k$  will be the maximum size of the evidence sets considered in the translation.

**Lemma 2.** If  $E$  is a set of literals,  $|E| \leq k$ ,  $\lambda = \phi(E)$  and  $(\mathcal{M}, E) \vdash_{\text{MAP}} x$  then

$$\left\{ \left( \bigwedge E' \rightarrow \bigwedge X \right) \in \Theta_{\lambda}^k \text{ s.t. } |E'| \leq |E| \right\} \vdash \bigwedge E \rightarrow x$$

**Lemma 3.** If  $\phi(\omega) \leq \lambda$  then  $\omega$  is a model of  $\Theta_{\lambda}^k$ .

*Proof.* If there were a formula  $F = (\bigwedge E) \rightarrow (\bigwedge X)$  in  $\Theta_{\lambda}^k$  that was not satisfied by  $\omega$ , then its body would have to be true in  $\omega$  but then necessarily

$$\lambda \leq \phi(E) \leq \phi(\omega) \leq \lambda.$$

The first inequality follows from the fact that, by the construction of  $\Theta^k$ , if the certainty weight of  $F$  is at least  $\lambda$  then it must be the case that  $\phi(E) \geq \lambda$ . The second inequality follows from the fact that  $\omega$  was assumed to be a model of  $\bigwedge E$ . It follows that:

$$\text{pen}(\mathcal{M}, \omega) = \text{pen}(\mathcal{M}, E).$$

However, this would mean that  $\omega$  is also a most probable world of  $(\mathcal{M}, E)$ , but then  $\omega \models F$  by construction of  $\Theta^k$ .

If there were an unsatisfied formula  $F = \neg(\bigwedge E \wedge \bigwedge X)$  in  $\Theta_{\lambda}^k$  then by construction we would have  $\phi(E \cup X) > \lambda$ . However, from  $\omega \models \bigwedge E \wedge \bigwedge X$  we find  $\phi(E \cup X) \leq \phi(\omega) \leq \lambda$ , a contradiction.

Since all formulas in  $\Theta^k$  are of the two considered types, it follows that all formulas from  $\Theta^k$  whose certainty weight is at least  $\lambda$  must be satisfied in  $\omega$ .  $\square$

**Lemma 4.** If  $(\mathcal{M}, E) \vdash_{\text{MAP}} (y_1 \vee \dots \vee y_m)$  then

- (i) for any  $i$ , either  $(\mathcal{M}, E \cup \{\neg y_i\}) \vdash_{\text{MAP}} (y_1 \vee \dots \vee y_{i-1} \vee y_{i+1} \vee \dots \vee y_m)$  or  $(\mathcal{M}, E) \vdash_{\text{MAP}} y_i$ ,
- (ii) there exist a  $j$  and a set  $\{y'_1, \dots, y'_m\} \subseteq \{y_1, \dots, y_m\} \setminus \{y_j\}$  such that  $(\mathcal{M}, E \cup \{\neg y'_1, \dots, \neg y'_m\}) \vdash_{\text{MAP}} y_j$ .

**Lemma 5.** If  $|C| + |E| \leq k + 1$ , and  $\lambda = \phi(E)$  then  $\Theta_{\lambda}^k \cup E \vdash \bigvee C$  if and only if  $(\mathcal{M}, E) \vdash_{\text{MAP}} \bigvee C$ .

We now turn to the proof of Proposition 3.

*Proof of Proposition 3.* Let  $E$  be an evidence set such that  $|E| \leq k$  and let  $\lambda = \phi(E)$ . Given Lemma 5, it is sufficient to show that  $\text{con}(\Theta^k, E) = \lambda$ . It follows from Lemma 3 that  $\text{con}(\Theta^k, E) \leq \lambda$ . Let  $X = \{x \mid (\mathcal{M}, E) \vdash_{\text{MAP}} x\}$  be the set of literals which can be derived from  $(\mathcal{M}, E)$  using MAP inference. By construction,  $\Theta^k$  contains a formula  $\neg(\bigwedge E \wedge \bigwedge X)$  with a certainty weight which is just below  $\lambda$ . Specifically, for  $\lambda' < \lambda$  we either have  $\Theta_{\lambda'}^k = \Theta_{\lambda}^k$ , or  $\Theta_{\lambda'}^k \models \neg \bigwedge E$ , from which we find  $\text{con}(\Theta^k, E) = \lambda$ .  $\square$

It is of interest to remove any formulas in  $\Theta^k$  that are redundant, among others because this is likely to make the theory easier to interpret. Although we can use possibilistic logic inference to identify redundant formulas, in some cases we can avoid adding the redundant formulas altogether. For example, in the transformation procedure, we do not add any rules for  $E$  if it holds that  $E \setminus \{y\} \vdash_{MAP} y$  for some  $y \in E$ . This pruning rule is the counterpart of the cautious monotonicity property, which is well-known in the context of default reasoning [15]. Any ranking on possible worlds also satisfies the stronger rational monotonicity property, which translated to our setting states that when  $(\mathcal{M}, E \setminus \{y\}) \vdash_{MAP} x$  and  $(\mathcal{M}, E \setminus \{y\}) \not\vdash_{MAP} \neg y$  it holds that  $(\mathcal{M}, E) \vdash_{MAP} x$ . Accordingly, when processing the evidence set  $E$  in the transformation procedure, instead of  $(\bigwedge E \rightarrow \bigwedge X, \lambda_E)$  it is sufficient to add the following rule:

$$\left( \bigwedge E \rightarrow \bigwedge (X \setminus X_0), \lambda_E \right)$$

where

$$X_0 = \{x \mid E \setminus \{y\} \vdash_{MAP} x \text{ and } E \setminus \{y\} \not\vdash_{MAP} \neg y\}$$

The correctness of this pruning step follows from the following proposition.

**Proposition 4.** *Let  $x$  and  $y$  be literals. If  $|E| < k$ ,  $(\mathcal{M}, E) \vdash_{MAP} x$  and  $(\mathcal{M}, E) \not\vdash_{MAP} \neg y$  then:*

$$\Theta^k \setminus \{F\} \models \left( \bigwedge E \wedge y \rightarrow x, \lambda_{E \cup \{y\}} \right)$$

where  $F$  is the formula in  $\Theta^k$  corresponding to the evidence set  $E \cup \{y\}$ , i.e.:

$$F = \bigwedge (E \cup \{y\}) \rightarrow \bigwedge \{x \mid (\mathcal{M}, E \cup \{y\}) \vdash_{MAP} x\}$$

*Proof.* If  $(\mathcal{M}, E) \vdash_{MAP} x$  and  $(\mathcal{M}, E) \not\vdash_{MAP} \neg y$  then  $(\mathcal{M}, E \cup \{y\}) \vdash_{MAP} x$  and  $pen(\mathcal{M}, E) = pen(\mathcal{M}, E \cup \{y\}) = pen(\mathcal{M}, E \cup \{x, y\})$ . Therefore using Lemma 2, we find that  $\Theta^k_{\lambda_{E \cup \{y\}}} \vdash \bigwedge E \rightarrow x$ . From Lemma 2, it furthermore follows that  $\bigwedge E \rightarrow x$  can be derived from rules with antecedents of length at most  $|E|$ . In particular, we find that  $\bigwedge E \rightarrow x$  can be derived without using the formula  $\bigwedge E \wedge y \rightarrow \bigwedge X$ .  $\square$

Finally, note that formulas of the form (13) can be omitted when  $\lambda'_E = \lambda_{(E \setminus \{y\})}$  for some  $y \in E$ . Indeed, in such a case we find from  $pen(\mathcal{M}, E \setminus \{y\}) < pen(\mathcal{M}, E)$  that  $(\mathcal{M}, E \setminus \{y\}) \vdash_{MAP} \neg y$ , hence (13) will be entailed by a formula of the form  $(\bigwedge (E \setminus \{y\}) \rightarrow \bigwedge X, \lambda_{E \setminus \{y\}})$  in  $\Theta^k$ .

## 4 ENCODING NON-GROUND NETWORKS

We now provide the counterpart to the construction from Section 3.2 for non-ground MLNs. The first-order nature

of MLNs often leads to distributions with many symmetries which can be exploited by lifted inference methods [20]. We can similarly exploit these symmetries for constructing more compact possibilistic logic theories from MLNs.

For convenience, in the possibilistic logic theories, we will use *typed* formulas. For instance, when we have the formula  $\alpha = owns(person : X, thing : Y)$  and the set of constants of the type *person* is  $\{alice, bob\}$  and the set of constants of the type *thing* is  $\{car\}$  then  $\alpha$  corresponds to the ground formulas  $owns(alice, car)$  and  $owns(bob, car)$ . In cases where there is only one type, we will not write it explicitly.

Two typed formulas  $F_1$  and  $F_2$  are said to be isomorphic when there is a type-respecting substitution  $\theta$  of the variables of  $F_1$  such that  $F_1\theta \equiv F_2$  (where  $\equiv$  denotes equivalence of logical formulas). Two MLNs  $\mathcal{M}_1$  and  $\mathcal{M}_2$  are said to be isomorphic, denoted by  $\mathcal{M}_1 \approx \mathcal{M}_2$ , if there is a bijection  $i$  from formulas of  $\mathcal{M}_1$  to formulas of  $\mathcal{M}_2$  such that for  $i(F, w) = (F', w')$  it holds that  $w = w'$  and the formulas  $F$  and  $F'$  are isomorphic. When  $j$  is a permutation of a subset of constants from  $\mathcal{M}$  then  $j(\mathcal{M})$  denotes the MLN obtained by replacing any constant  $c$  from the subset by its image  $j(c)$ .

Given a non-ground MLN  $\mathcal{M}$ , we can first identify sets of constants which are *interchangeable*, where a set of constants  $\mathcal{C}_t$  is said to be interchangeable if  $j(\mathcal{M}) \approx \mathcal{M}$  for any permutation  $j$  of the constants in  $\mathcal{C}_t$ . Note that to check whether a set of constants  $\mathcal{C}_t$  is interchangeable, it is sufficient to check that  $j(\mathcal{M}) \approx \mathcal{M}$  for those permutations which swap just two constants from  $\mathcal{C}_t$ . For every maximal set  $\mathcal{C}_t$  of interchangeable constants, we introduce a new type  $t$ . For a constant  $c$ , we write  $\tau(c)$  to denote its type. When  $F$  is a ground formula, *variabilize*( $F$ ) denotes the following formula:

$$\bigwedge \{V_c \neq V_d \mid c, d \in const(F), \tau(c) = \tau(d)\} \rightarrow F'$$

where  $const(F)$  is the set of constants appearing in  $F$  and  $F'$  is obtained from  $F$  by replacing all constants  $c$  by a new variable  $V_c$  of type  $\tau(c)$ .

**Transformation 4.** *Given an MLN  $\mathcal{M}$  and a positive integer  $k$ , we construct a possibilistic logic theory  $\Theta^k_{\mathcal{M}}$  as follows:*

- For each hard rule  $F$  from  $\mathcal{M}$ , add  $(F, 1)$  to  $\Theta^k_{\mathcal{M}}$ .
- For each set of literals  $E$  such that  $0 \leq |E| \leq k$ , let  $X = \{x \mid (\mathcal{M}, E) \vdash_{MAP} x\}$ . For all  $x \in X$ , unless there is a literal  $y \in E$  such that  $(\mathcal{M}, E \setminus \{y\}) \vdash_{MAP} y$  and unless  $\Theta^k_{\mathcal{M}}$  already contains a formula isomorphic to *variabilize*( $\bigwedge E \rightarrow x$ ), add

$$\left( \text{variabilize} \left( \bigwedge E \rightarrow x \right), \lambda_E \right)$$

to  $\Theta_{\mathcal{M}}^k$ . If  $\text{pen}(\mathcal{M}, E) > \text{pen}(\mathcal{M}, \emptyset)$  and  $\Theta_{\mathcal{M}}^k$  does not already contain a formula isomorphic to  $\text{variabilize}(\neg(\bigwedge E \wedge \bigwedge X))$ , add also

$$\left(\text{variabilize}\left(\neg\left(\bigwedge E \wedge \bigwedge X\right)\right), \lambda'_E\right) \quad (14)$$

where  $\lambda'_E$  is the certainty level just below  $\lambda_E$  in  $\Theta_{\mathcal{M}}^k$ .

As before, we will usually omit the subscript in  $\Theta_{\mathcal{M}}^k$ . We can show that after grounding,  $\Theta^k$  is equivalent to the theory that would be obtained by first grounding the MLN and then applying the method from Section 3.2. The correctness proof is provided in the online appendix.

Our implementation<sup>4</sup> of Transformation 4 relies on an efficient implementation of inference in possibilistic logic and Markov logic, efficient generation of non-redundant candidate evidence sets and efficient filtering of isomorphic formulas. For MAP inference in MLNs, we used a cutting-plane inference algorithm based on a SAT-based optimization. For inference in possibilistic logic, we also used cutting-plane inference in order to avoid having to ground the whole theory. To find the ground rules that need to be added by the cutting-plane method, we used a modified querying system from [16]. For solving and optimizing the resulting ground programs, we used the SAT4J library [3].

Note that to check whether  $\Theta_{\lambda}^k \vdash F$ , where  $F$  is a (not necessarily ground) clause, it is sufficient to find one (type-respecting) grounding  $\theta$  of  $F$ , and check whether  $\Theta_{\lambda}^k \cup \{\neg(F\theta)\}$  is inconsistent. In this way, we can check whether a rule is implied by  $\Theta^k$  without grounding the whole theory because, as for MLNs, inference in non-ground possibilistic logic theories can be carried out by cutting-plane inference methods.

We implemented the transformation as a modification of the standard best-first search (BFS) algorithm which constructs incrementally larger candidate evidence sets, checks their MAP consequences and adds the respective rules to the possibilistic logic theory being constructed. Like the standard BFS algorithm it uses a hash-table based data structure *closed*, in which already processed evidence sets are stored. In order to avoid having to check isomorphism with every evidence set in *closed*, each time a new evidence set is considered, the stored evidence sets are enriched by fingerprints which contain some invariants, guaranteeing that no two variabilized evidence sets with different fingerprints are isomorphic. In this way, we can efficiently check for a given evidence set  $E$  whether there is a previously generated evidence set  $E'$  such that  $\text{variabilize}(E)$  and  $\text{variabilize}(E')$  are isomorphic.

As a final remark, we note that for the non-ground transformation, it may be preferable to replace any

<sup>4</sup>The implementation can be downloaded from: <https://github.com/supertweety/mln2poss>.

rule  $(\text{variabilize}(\neg(\bigwedge E \wedge \bigwedge X)), \lambda'_E)$  by the rule  $(\text{variabilize}(\neg\bigwedge E), \lambda'_E)$ . The reason is that the former rules may often become too long in the non-ground case. On the other hand, for the ground transformation, the advantage of the longer rules is that they will often be the same for different sets  $E$ , which, in effect, means a smaller number of rules in the possibilistic logic theory. The correctness of this alternative to Transformation 4 is also shown in the online appendix.

## 5 ILLUSTRATIVE EXAMPLES

The first example is a variation on a classical problem from non-monotonic reasoning. Here, we want to express that birds generally fly, but heavy antarctic birds do not fly, unless they have a jet pack. The MLN which we will convert into possibilistic logic contains the following rules:  $10 : \text{bird}(X) \rightarrow \text{flies}(X)$ ,  $1 : \text{antarctic}(X) \rightarrow \neg\text{flies}(X)$ ,  $10 : \text{heavy}(X) \rightarrow \neg\text{flies}(X)$ ,  $100 : \text{hasJetPack}(X) \rightarrow \text{flies}(X)$ . When presented with this MLN, Transformation 4 produces the following possibilistic logic theory.

$$\begin{aligned} &(\neg\text{antarctic}(X) \vee \neg\text{flies}(X), \lambda_0) \\ &(\neg\text{bird}(X) \vee \text{flies}(X), \lambda_0) \\ &(\neg\text{heavy}(X) \vee \neg\text{flies}(X), \lambda_0) \\ &(\text{flies}(X) \vee \neg\text{hasJetPack}(X), \lambda_0) \\ &(\neg\text{bird}(X) \vee \text{flies}(X) \vee \text{hasJetPack}(X), \lambda_1) \\ &(\neg\text{heavy}(X) \vee \text{antarctic}(X) \vee \neg\text{flies}(X), \lambda_1) \\ &(\neg\text{bird}(X) \vee \neg\text{heavy}(X), \lambda_1) \\ &(\neg\text{antarctic}(X) \vee \neg\text{heavy}(X) \vee \neg\text{flies}(X), \lambda_{10}) \\ &(\text{flies}(X) \vee \neg\text{hasJetPack}(X) \vee \text{bird}(X), \lambda_{11}) \\ &(\neg\text{bird}(X) \vee \text{flies}(X) \vee \neg\text{hasJetPack}(X), \lambda_{100}) \end{aligned}$$

Let us consider the evidence set  $E = \{\text{bird}(\text{tweety}), \text{heavy}(\text{tweety})\}$ . Then the levels  $\lambda_0$  and  $\lambda_1$  drown because of the inconsistency with the rule  $(\neg\text{bird}(X) \vee \neg\text{heavy}(X), \lambda_1)$  which was produced as one of the rules (14). We can see from the rest of the possibilistic logic theory that unless we add either  $\text{antarctic}(\text{tweety})$  or  $\text{hasJetPack}(\text{tweety})$ , we cannot say anything about whether *tweety* flies or not. It can be verified that the same is true also for the respective MLN.

The second example consists of formulas from a classical MLN about smokers. There are three predicates in this MLN: a binary predicate  $f(A, B)$  denoting that  $A$  and  $B$  are friends, and two unary predicates  $s(A)$  and  $c(A)$  denoting that  $A$  smokes and that  $A$  has cancer, respectively. The MLN contains the following hard rules:  $\neg f(A, B) \vee f(B, A)$  and  $\neg f(A, A)$ . In addition, we have two soft rules. The first soft rule  $10 : \neg s(A) \vee \neg f(A, B) \vee s(B)$  states that if  $A$  and  $B$  are friends and  $A$  smokes then  $B$  is more likely to smoke too. The second rule  $10 : \neg s(A) \vee c(A)$  states that smoking increases the likelihood of cancer. The following possi-

bilistic logic theory was obtained using Transformation 4 with  $k = 4$ .

$$\begin{aligned}
& (s(B) \vee \neg f(A, B) \vee \neg s(A) \vee \neg \text{alldiff}(A, B), \lambda_0) \\
& \quad (\neg s(A) \vee c(A), \lambda_0) \\
& (\neg f(C, B) \vee \neg f(A, B) \vee s(A) \vee s(C) \\
& \quad \vee \neg \text{alldiff}(A, B, C) \vee \neg s(B), \lambda_{10}) \\
& (\neg f(C, B) \vee \neg s(A) \vee \neg f(A, C) \vee s(C) \\
& \quad \vee \neg \text{alldiff}(A, B, C) \vee \neg s(B), \lambda_{10}) \\
& (\neg s(A) \vee \neg f(C, A) \vee s(C) \vee c(B) \\
& \quad \vee \neg \text{alldiff}(A, B, C) \vee \neg s(B), \lambda_{10}) \\
& (\neg s(A) \vee c(A) \vee c(B) \vee \neg s(B) \vee \neg \text{alldiff}(A, B), \lambda_{10}) \\
& (s(B) \vee \neg f(A, B) \vee \neg s(A) \vee c(A) \vee \neg \text{alldiff}(A, B), \lambda_{10}) \\
& \quad (\neg f(A, B) \vee f(B, A), 1) \\
& \quad (\neg f(A, A), 1)
\end{aligned}$$

At the lowest level  $\lambda_0$  we find the counterparts of the soft rules from the MLN, whereas at level 1 we find the hard rules. At the intermediate level we intuitively find weakened rules from the MLN. For instance, the rule  $(\neg s(A) \vee c(A) \vee c(B) \vee \neg s(B) \vee \neg \text{alldiff}(A, B), \lambda_1)$  can be interpreted as: if  $A$  and  $B$  smoke then at least one of them has cancer. It is quite natural that this rule has higher certainty weight than the rule: if  $A$  smokes then  $A$  has cancer.

A final, more elaborate example is provided in the online appendix.

## 6 RELATED WORK

One line of related work focuses on extracting a comprehensible model from another learned model that is difficult or impossible to interpret. A seminal work in this area is the TREPAN [5] algorithm. Given a trained neural network and a data set, TREPAN learns a decision tree to mimic the predictions of the neural network. In addition to producing interpretable output, this algorithm was shown to learn accurate models that faithfully mimicked the neural network's predictions. More recent research has focused on approximating complex ensemble classifiers with a single model. For example, Popovic et al. [21] proposed a method for learning a single decision tree that mimics the predictions of a random forest.

While, to the best of our knowledge, this is the first paper that studies the relation between Markov logic and possibilistic logic, the links between possibility theory and probability theory have been widely studied. For example, [10] has proposed a probability-possibility transformation based on the view that a possibility measure corresponds to a particular family of probability measures. Dempster-Shafer evidence theory [25] has also been used to provide a probabilistic interpretation to possibility degrees. In particular, a possibility distribution can be interpreted as the contour

function of a mass assignment; see [11] for details. In [13] it is shown how the probability distribution induced by a penalty logic theory corresponds to the contour function of a mass assignment, which suggests that it is indeed natural to interpret this probability distribution as a possibility distribution. Several other links between possibility theory and probability theory have been discussed in [6].

In this paper, we have mainly focused on MAP inference. An interesting question is whether it would be possible to construct a (possibilistic) logic base that captures the set of accepted beliefs encoded by a probability distribution, where  $A$  is accepted if  $P(A) > P(\neg A)$ . Unfortunately, the results in [7] show that this is only possible for the limited class of so-called big-stepped probability distributions. In practice, this means that we would have to define a partition of the set of possible worlds, such that the probability distribution over the partition classes is big-stepped, and only capture the beliefs that are encoded by the latter, less informative, probability distribution. A similar approach was taken in [1] to learn default rules from data.

## 7 CONCLUSIONS

This paper has focused on how a Markov logic network  $\mathcal{M}$  can be encoded in possibilistic logic. We started from the observation that it is always possible to construct a possibilistic logic theory  $\Theta_{\mathcal{M}}$  that is equivalent to  $\mathcal{M}$ , in the sense that the probability distribution induced by  $\mathcal{M}$  is isomorphic to the possibility distribution induced by  $\Theta_{\mathcal{M}}$ . As a result, applying possibilistic logic inference to  $\Theta_{\mathcal{M}}$  yields the same conclusions as applying MAP inference to  $\mathcal{M}$ . Although the size of  $\Theta_{\mathcal{M}}$  is exponential in the number of formulas in  $\mathcal{M}$ , we have shown how more compact theories can be obtained in cases where we can put restrictions on the types of evidence that need to be considered (e.g. small sets of literals).

Our main motivation has been to use possibilistic logic as a way to make explicit the assumptions encoded in a given MLN. Among others, the possibilistic logic theory could be used to generate explanations for predictions made by the MLN, to gain insight into the data from which the MLN was learned, or to identify errors in the structure or weights of the MLN. Taking this last idea one step further, our aim for future work is to study methods for repairing a given MLN, based on the mistakes that have thus been identified.

## Abstract

How could we solve the machine learning and the artificial intelligence problem if we had infinite computation? Solomonoff induction and the reinforcement learning agent AIXI are proposed answers to this question. Both are known to be incomputable. In this paper, we quantify this using the arithmetical hierarchy, and prove upper and corresponding lower bounds for incomputability. We show that AIXI is not limit computable, thus it cannot be approximated using finite computation. Our main result is a limit-computable  $\varepsilon$ -optimal version of AIXI with infinite horizon that maximizes expected rewards.

**Keywords.** AIXI, Solomonoff induction, general reinforcement learning, computability, complexity, arithmetical hierarchy, universal Turing machine.

## 1 INTRODUCTION

Given infinite computation power, many traditional AI problems become trivial: playing chess, go, or backgammon can be solved by exhaustive expansion of the game tree. Yet other problems seem difficult still; for example, predicting the stock market, driving a car, or babysitting your nephew. How can we solve these problems in theory? A proposed answer to this question is the agent AIXI [Hut00, Hut05]. As a *reinforcement learning agent*, its goal is to maximize cumulative (discounted) rewards obtained from the environment [SB98].

The basis of AIXI is Solomonoff's theory of learning [Sol64, Sol78, LV08], also called *Solomonoff induction*. It arguably solves the induction problem [RH11]: for data drawn from a computable measure  $\mu$ , Solomonoff induction will converge to the correct belief about any hypothesis [BD62, RH11]. Moreover, convergence is extremely fast in the sense that Solomonoff induction will make a total of at most  $E + O(\sqrt{E})$  errors when predicting

the next data points, where  $E$  is the number of errors of the informed predictor that knows  $\mu$  [Hut01]. While learning the environment according to Solomonoff's theory, AIXI selects actions by running an expectimax-search for maximum cumulative discounted rewards. It is clear that AIXI can only serve as an ideal, yet recently it has inspired some impressive applications [VNH<sup>+</sup>11].

Both Solomonoff induction and AIXI are known to be incomputable. But not all incomputabilities are equal. The *arithmetical hierarchy* specifies different levels of computability based on *oracle machines*: each level in the arithmetical hierarchy is computed by a Turing machine which may query a halting oracle for the respective lower level.

We posit that any ideal for a 'perfect agent' needs to be *limit computable* ( $\Delta_2^0$ ). The class of limit computable functions is the class of functions that admit an *anytime algorithm*. It is the highest level of the arithmetical hierarchy which can be approximated using a regular Turing machine. If this criterion is not met, our model would be useless to guide practical research.

For MDPs, planning is already P-complete for finite and infinite horizons [PT87]. In POMDPs, planning is undecidable [MHC99, MHC03]. The existence of a policy whose expected value exceeds a given threshold is PSPACE-complete [MGLA00], even for purely epistemic POMDPs in which actions do not change the hidden state [SLR07]. In this paper we derive hardness results for planning in general semicomputable environments; this environment class is even more general than POMDPs. We show that finding an optimal policy is  $\Pi_2^0$ -hard and finding an  $\varepsilon$ -optimal policy is undecidable.

Moreover, we show that by default, AIXI is not limit computable. The reason is twofold: First, when picking the next action, two or more actions might have the same value (expected future rewards). The choice between them is easy, but determining whether such a tie exists is difficult. Second, in case of an infinite horizon (using discounting), the iterative definition of the value function [Hut05, Def. 5.30] conditions on surviving forever. The first problem

|                | LT       | $\Delta_3^0, \Sigma_1^0$ -hard | $\Delta_2^0, \Sigma_1^0$ -hard |
| Recursive AIMU | DC       | $\Delta_2^0$                   | $\Delta_1^0$                   |
|                | LT       | $\Delta_2^0$                   | $\Delta_1^0$                   |

Table 1: Computability results for different agent models derived in Section 3. DC means general discounting, a lower semicomputable discount function  $\gamma$ ; LT means finite lifetime, undiscounted rewards up to a fixed lifetime  $m$ . Hardness results for AIXI are with respect to a specific universal Turing machine; hardness results for AINU are with respect to a specific environment  $\nu \in \mathcal{M}$ .

can be circumvented by settling for an  $\varepsilon$ -optimal agent. We show that the second problem can be solved by using the recursive instead of the iterative definition of the value function. With this we get a limit-computable agent with infinite horizon. Table 1 and Table 3 summarize our computability results.

## 2 PRELIMINARIES

### 2.1 THE ARITHMETICAL HIERARCHY

A set  $A \subseteq \mathbb{N}$  is  $\Sigma_n^0$  iff there is a computable relation  $S$  such that

$$k \in A \iff \exists k_1 \forall k_2 \dots Q_n k_n S(k, k_1, \dots, k_n) \quad (1)$$

where  $Q_n = \forall$  if  $n$  is even,  $Q_n = \exists$  if  $n$  is odd [Nie09, Def. 1.4.10]. A set  $A \subseteq \mathbb{N}$  is  $\Pi_n^0$  iff its complement  $\mathbb{N} \setminus A$  is  $\Sigma_n^0$ . We call the formula on the right hand side of (1) a  $\Sigma_n^0$ -formula, its negation is called  $\Pi_n^0$ -formula. It can be shown that we can add any bounded quantifiers and duplicate quantifiers of the same type without changing the classification of  $A$ . The set  $A$  is  $\Delta_n^0$  iff  $A$  is  $\Sigma_n^0$  and  $A$  is  $\Pi_n^0$ . We get that  $\Sigma_1^0$  as the class of recursively enumerable sets,  $\Pi_1^0$  as the class of co-recursively enumerable sets and  $\Delta_1^0$  as the class of recursive sets.

We say the set  $A \subseteq \mathbb{N}$  is  $\Sigma_n^0$ -hard ( $\Pi_n^0$ -hard,  $\Delta_n^0$ -hard) iff for any set  $B \in \Sigma_n^0$  ( $B \in \Pi_n^0$ ,  $B \in \Delta_n^0$ ),  $B$  is many-one reducible to  $A$ , i.e., there is a computable function  $f$  such that  $k \in B \leftrightarrow f(k) \in A$  [Nie09, Def. 1.2.1]. We get  $\Sigma_n^0 \subseteq$

$\Delta_{n+1}^0 \subseteq \Sigma_{n+1}^0 \subseteq \dots$  and  $\Pi_n^0 \subseteq \Delta_{n+1}^0 \subseteq \Pi_{n+1}^0 \subseteq \dots$ . This hierarchy of subsets of natural numbers is known as the *arithmetical hierarchy*.

By Post's Theorem [Nie09, Thm. 1.4.13], a set is  $\Sigma_n^0$  if and only if it is recursively enumerable on an oracle machine with an oracle for a  $\Sigma_{n-1}^0$ -complete set.

### 2.2 STRINGS

Let  $\mathcal{X}$  be some finite set called *alphabet*. The set  $\mathcal{X}^* := \bigcup_{n=0}^{\infty} \mathcal{X}^n$  is the set of all finite strings over the alphabet  $\mathcal{X}$ , the set  $\mathcal{X}^\infty$  is the set of all infinite strings over the alphabet  $\mathcal{X}$ , and the set  $\mathcal{X}^\# := \mathcal{X}^* \cup \mathcal{X}^\infty$  is their union. The empty string is denoted by  $\epsilon$ , not to be confused with the small positive real number  $\varepsilon$ . Given a string  $x \in \mathcal{X}^*$ , we denote its length by  $|x|$ . For a (finite or infinite) string  $x$  of length  $\geq k$ , we denote with  $x_{1:k}$  the first  $k$  characters of  $x$ , and with  $x_{<k}$  the first  $k-1$  characters of  $x$ . The notation  $x_{1:\infty}$  stresses that  $x$  is an infinite string. We write  $x \sqsubseteq y$  iff  $x$  is a prefix of  $y$ , i.e.,  $x = y_{1:|x|}$ .

### 2.3 COMPUTABILITY OF REAL-VALUED FUNCTIONS

We fix some encoding of rational numbers into binary strings and an encoding of binary strings into natural numbers. From now on, this encoding will be done implicitly wherever necessary.

**Definition 1** ( $\Sigma_n^0$ -,  $\Pi_n^0$ -,  $\Delta_n^0$ -computable). A function  $f : \mathcal{X}^* \rightarrow \mathbb{R}$  is called  $\Sigma_n^0$ -computable ( $\Pi_n^0$ -computable,  $\Delta_n^0$ -computable) iff the set  $\{(x, q) \in \mathcal{X}^* \times \mathbb{Q} \mid f(x) > q\}$  is  $\Sigma_n^0$  ( $\Pi_n^0$ ,  $\Delta_n^0$ ).

A  $\Delta_1^0$ -computable function is called *computable*, a  $\Sigma_1^0$ -computable function is called *lower semicomputable*, and a  $\Pi_1^0$ -computable function is called *upper semicomputable*. A  $\Delta_2^0$ -computable function  $f$  is called *limit computable*, because there is a computable function  $\phi$  such that

$$\lim_{k \rightarrow \infty} \phi(x, k) = f(x).$$

The program  $\phi$  that limit computes  $f$  can be thought of as an *anytime algorithm* for  $f$ : we can stop  $\phi$  at any time  $k$  and get a preliminary answer. If the program  $\phi$  ran long enough (which we do not know), this preliminary answer will be close to the correct one.

Limit-computable sets are the highest level in the arithmetical hierarchy that can be approached by a regular Turing machine. Above limit-computable sets we necessarily need some form of halting oracle. See Table 2 for the definition of lower/upper semicomputable and limit-computable functions in terms of the arithmetical hierarchy.

**Lemma 2** (Computability of Arithmetical Operations). *Let  $n > 0$  and let  $f, g : \mathcal{X}^* \rightarrow \mathbb{R}$  be two  $\Delta_n^0$ -computable functions. Then*

|                                 | $f_>$        | $f_<$        |
|---------------------------------|--------------|--------------|
| $f$ is computable               | $\Delta_1^0$ | $\Delta_1^0$ |
| $f$ is lower semicomputable     | $\Sigma_1^0$ | $\Pi_1^0$    |
| $f$ is upper semicomputable     | $\Pi_1^0$    | $\Sigma_1^0$ |
| $f$ is limit computable         | $\Delta_2^0$ | $\Delta_2^0$ |
| $f$ is $\Delta_n^0$ -computable | $\Delta_n^0$ | $\Delta_n^0$ |
| $f$ is $\Sigma_n^0$ -computable | $\Sigma_n^0$ | $\Pi_n^0$    |
| $f$ is $\Pi_n^0$ -computable    | $\Pi_n^0$    | $\Sigma_n^0$ |

Table 2: Connection between the computability of real-valued functions and the arithmetical hierarchy. We use the shorthand  $f_> := \{(x, q) \mid f(x) > q\}$  and  $f_< := \{(x, q) \mid f(x) < q\}$ .

- (i)  $\{(x, y) \mid f(x) > g(y)\}$  is  $\Sigma_n^0$ ,
- (ii)  $\{(x, y) \mid f(x) \leq g(y)\}$  is  $\Pi_n^0$ ,
- (iii)  $f + g$ ,  $f - g$ , and  $f \cdot g$  are  $\Delta_n^0$ -computable, and
- (iv)  $f/g$  is  $\Delta_n^0$ -computable if  $g(x) \neq 0$  for all  $x$ .

## 2.4 ALGORITHMIC INFORMATION THEORY

A *semimeasure* over the alphabet  $\mathcal{X}$  is a function  $\nu : \mathcal{X}^* \rightarrow [0, 1]$  such that (i)  $\nu(\epsilon) \leq 1$ , and (ii)  $\nu(x) \geq \sum_{a \in \mathcal{X}} \nu(xa)$  for all  $x \in \mathcal{X}^*$ . A semimeasure is called (probability) *measure* iff for all  $x$  equalities hold in (i) and (ii). *Solomonoff's prior*  $M$  [Sol64] assigns to a string  $x$  the probability that the reference universal monotone Turing machine  $U$  [LV08, Ch. 4.5.2] computes a string starting with  $x$  when fed with uniformly random bits as input. The *measure mixture*  $\bar{M}$  [Gá83, p. 74] removes the contribution of programs that do not compute infinite strings; it is a measure except for a constant factor. Formally,

$$M(x) := \sum_{p: x \sqsubseteq U(p)} 2^{-|p|}, \quad \bar{M}(x) := \lim_{n \rightarrow \infty} \sum_{y \in \mathcal{X}^n} M(xy)$$

Equivalently, the Solomonoff prior  $M$  can be defined as a mixture over all lower semicomputable semimeasures [WSH11]. The function  $M$  is a lower semicomputable semimeasure, but not computable and not a measure [LV08, Lem. 4.5.3]. A semimeasure  $\nu$  can be turned into a measure  $\nu_{\text{norm}}$  using *Solomonoff normalization*:  $\nu_{\text{norm}}(\epsilon) := 1$  and for all  $x \in \mathcal{X}^*$  and  $a \in \mathcal{X}$ ,

$$\nu_{\text{norm}}(xa) := \nu_{\text{norm}}(x) \frac{\nu(xa)}{\sum_{b \in \mathcal{X}} \nu(xb)}. \quad (2)$$

## 2.5 GENERAL REINFORCEMENT LEARNING

In general reinforcement learning the agent interacts with an environment in cycles: at time step  $t$  the agent chooses an *action*  $a_t \in \mathcal{A}$  and receives a *percept*  $e_t = (o_t, r_t) \in \mathcal{E}$  consisting of an *observation*  $o_t \in \mathcal{O}$  and a real-valued

*reward*  $r_t \in \mathbb{R}$ ; the cycle then repeats for  $t + 1$ . A *history* is an element of  $(\mathcal{A} \times \mathcal{E})^*$ . We use  $\mathfrak{x} \in \mathcal{A} \times \mathcal{E}$  to denote one interaction cycle, and  $\mathfrak{x}_{1:t}$  to denote a history of length  $t$ . The goal in reinforcement learning is to maximize total discounted rewards. A *policy* is a function  $\pi : (\mathcal{A} \times \mathcal{E})^* \rightarrow \mathcal{A}$  mapping each history to the action taken after seeing this history.

The environment can be stochastic, but is assumed to be semicomputable. In accordance with the AIXI literature [Hut05], we model environments as lower semicomputable *chronological conditional semimeasures* (LSCCCSs). A *conditional semimeasure*  $\nu$  takes a sequence of actions  $a_{1:t}$  as input and returns a semimeasure  $\nu(\cdot \parallel a_{1:t})$  over  $\mathcal{E}^\#$ . A conditional semimeasure  $\nu$  is *chronological* iff percepts at time  $t$  do not depend on future actions, i.e.,  $\nu(e_{1:t} \parallel a_{1:k}) = \nu(e_{1:t} \parallel a_{1:t})$  for all  $k > t$ . Despite their name, conditional semimeasures do *not* specify conditional probabilities; the environment  $\nu$  is *not* a joint probability distribution on actions and percepts. Here we only care about the computability of the environment  $\nu$ ; for our purposes, chronological conditional semimeasures behave just like semimeasures.

## 2.6 THE UNIVERSAL AGENT AIXI

Our environment class  $\mathcal{M}$  is the class of all LSCCCSs. Typically, Bayesian agents such as AIXI only function well if the true environment is in their hypothesis class. Since the hypothesis class  $\mathcal{M}$  is extremely large, the assumption that it contains the true environment is rather weak. We fix the *universal prior*  $(w_\nu)_{\nu \in \mathcal{M}}$  with  $w_\nu > 0$  for all  $\nu \in \mathcal{M}$  and  $\sum_{\nu \in \mathcal{M}} w_\nu \leq 1$ , given by the reference machine  $U$ . The universal prior  $w$  gives rise to the *universal mixture*  $\xi$ , which is a convex combination of all LSCCCSs  $\mathcal{M}$ :

$$\xi(e_{<t} \parallel a_{<t}) := \sum_{\nu \in \mathcal{M}} w_\nu \nu(e_{<t} \parallel a_{<t})$$

It is analogous to the Solomonoff prior  $M$  but defined for reactive environments. Like  $M$ , the universal mixture  $\xi$  is lower semicomputable [Hut05, Sec. 5.10].

We fix a *discount function*  $\gamma : \mathbb{N} \rightarrow \mathbb{R}$  with  $\gamma_t := \gamma(t) \geq 0$  and  $\sum_{t=1}^\infty \gamma_t < \infty$  and make the following assumptions.

**Assumption 3.** (a) *The discount function  $\gamma$  is lower semicomputable.*

(b) *Rewards are bounded between 0 and 1.*

(c) *The set of actions  $\mathcal{A}$  and the set of percepts  $\mathcal{E}$  are both finite.*

Assumption 3 (b) could be relaxed to bounded rewards because we can rescale rewards  $r \mapsto cr + d$  for any  $c, d \in \mathbb{R}$  without changing optimal policies if the environment  $\nu$  is a measure. However, for our value-related results, we require that rewards are nonnegative.

We define the *discount normalization factor*  $\Gamma_t := \sum_{i=t}^{\infty} \gamma_i$ . There is no requirement that  $\Gamma_t > 0$ . In fact, we use  $\gamma$  for both, AIXI with discounted infinite horizon ( $\Gamma_t > 0$  for all  $t$ ), and AIXI with finite lifetime  $m$ . In the latter case we set

$$\gamma_{\text{LT}m}(t) := \begin{cases} 1 & \text{if } t \leq m \\ 0 & \text{if } t > m. \end{cases}$$

If we knew the true environment  $\nu \in \mathcal{M}$ , we would choose the  $\nu$ -optimal agent known as AINU that maximizes  $\nu$ -expected value (if  $\nu$  is a measure). Since we do not know the true environment, we use the universal mixture  $\xi$  over all environments in  $\mathcal{M}$  instead. This yields the Bayesian agent AIXI: it weighs every environment  $\nu \in \mathcal{M}$  according to its prior probability  $w_\nu$ .

**Definition 4** (Iterative Value Function [Hut05, Def. 5.30]). The *value* of a policy  $\pi$  in an environment  $\nu$  given history  $\mathbf{x}_{<t}$  is

$$V_\nu^\pi(\mathbf{x}_{<t}) := \frac{1}{\Gamma_t} \lim_{m \rightarrow \infty} \sum_{e_{t:m}} R(e_{t:m}) \nu(e_{1:m} \mid e_{<t} \parallel a_{1:m})$$

if  $\Gamma_t > 0$  and  $V_\nu^\pi(\mathbf{x}_{<t}) := 0$  if  $\Gamma_t = 0$  where  $a_i := \pi(e_{<i})$  for all  $i \geq t$  and  $R(e_{t:m}) := \sum_{k=t}^m \gamma_k r_k$ . The *optimal value* is defined as  $V_\nu^*(h) := \sup_\pi V_\nu^\pi(h)$ .

Let  $\mathbf{x}_{<t} \in (\mathcal{A} \times \mathcal{E})^*$  be some history. We extend the value functions  $V_\nu^\pi$  to include initial interactions (in reinforcement learning literature on MDPs these are called  $Q$ -values),  $V_\nu^\pi(\mathbf{x}_{<t} a_t) := V_\nu^{\pi'}(\mathbf{x}_{<t})$  where  $\pi'$  is the policy  $\pi$  except that it takes action  $a_t$  next, i.e.,  $\pi'(\mathbf{x}_{<t}) := a_t$  and  $\pi'(h) := \pi(h)$  for all  $h \neq \mathbf{x}_{<t}$ . We define  $V_\nu^*(\mathbf{x}_{<t} a_t) := \sup_\pi V_\nu^\pi(\mathbf{x}_{<t} a_t)$  analogously.

**Definition 5** (Optimal Policy [Hut05, Def. 5.19 & 5.30]). A policy  $\pi$  is *optimal in environment  $\nu$*  ( $\nu$ -optimal) iff for all histories the policy  $\pi$  attains the optimal value:  $V_\nu^\pi(h) = V_\nu^*(h)$  for all  $h \in (\mathcal{A} \times \mathcal{E})^*$ .

Since the discount function is summable, rewards are bounded (Assumption 3b), and actions and percepts spaces are both finite (Assumption 3c), an optimal policy exists for every environment  $\nu \in \mathcal{M}$  [LH14, Thm. 10]. For a fixed environment  $\nu$ , an explicit expression for the optimal value function is

$$V_\nu^*(\mathbf{x}_{<t}) = \frac{1}{\Gamma_t} \lim_{m \rightarrow \infty} \mathop{\text{m}\max}_{\mathbf{x}_{t:m}} \sum R(e_{t:m}) \nu(e_{1:m} \mid e_{<t} \parallel a_{1:m}), \quad (3)$$

where  $\mathop{\text{m}\max}$  denotes the expectimax operator:

$$\mathop{\text{m}\max}_{\mathbf{x}_{t:m}} := \max_{a_t \in \mathcal{A}} \sum_{e_t \in \mathcal{E}} \dots \max_{a_m \in \mathcal{A}} \sum_{e_m \in \mathcal{E}}$$

For an environment  $\nu \in \mathcal{M}$  (an LSCCCS), AINU is defined as a  $\nu$ -optimal policy  $\pi_\nu^* = \arg \max_\pi V_\nu^\pi(\epsilon)$ . To

|                              | Plain  | Conditional                                      |
|------------------------------|--|--|
| $M$                          | $\Sigma_1^0 \setminus \Delta_1^0$                | $\Delta_2^0 \setminus (\Sigma_1^0 \cup \Pi_1^0)$ |
| $M_{\text{norm}}$            | $\Delta_2^0 \setminus (\Sigma_1^0 \cup \Pi_1^0)$ | $\Delta_2^0 \setminus (\Sigma_1^0 \cup \Pi_1^0)$ |
| $\overline{M}$               | $\Pi_2^0 \setminus \Delta_2^0$                   | $\Delta_3^0 \setminus (\Sigma_2^0 \cup \Pi_2^0)$ |
| $\overline{M}_{\text{norm}}$ | $\Delta_3^0 \setminus (\Sigma_2^0 \cup \Pi_2^0)$ | $\Delta_3^0 \setminus (\Sigma_2^0 \cup \Pi_2^0)$ |

Table 3: The complexity of the set  $\{(x, q) \in \mathcal{X}^* \times \mathbb{Q} \mid f(x) > q\}$  where  $f \in \{M, M_{\text{norm}}, \overline{M}, \overline{M}_{\text{norm}}\}$  is one of the various versions of Solomonoff’s prior. Lower bounds on the complexity of  $\overline{M}$  and  $\overline{M}_{\text{norm}}$  hold only for specific universal Turing machines.

stress that the environment is given by a measure  $\mu \in \mathcal{M}$  (as opposed to a semimeasure), we use AIMU. AIXI is defined as a  $\xi$ -optimal policy  $\pi_\xi^*$  for the universal mixture  $\xi$  [Hut05, Ch. 5]. Since  $\xi \in \mathcal{M}$  and every measure  $\mu \in \mathcal{M}$  is also a semimeasure, both AIMU and AIXI are a special case of AINU. However, AIXI is not a special case of AIMU since the mixture  $\xi$  is not a measure.

Because there can be more than one optimal policy, the definitions of AINU, AIMU and AIXI are not unique. More specifically, a  $\nu$ -optimal policy maps a history  $h$  to

$$\pi_\nu^*(h) := \arg \max_{a \in \mathcal{A}} V_\nu^*(ha). \quad (4)$$

If there are multiple actions  $\alpha, \beta \in \mathcal{A}$  that attain the optimal value,  $V_\nu^*(h\alpha) = V_\nu^*(h\beta)$ , we say there is an *argmax tie*. Which action we settle on in case of a tie (how we break the tie) is irrelevant and can be arbitrary.

### 3 THE COMPLEXITY OF AINU, AIMU, AND AIXI

#### 3.1 THE COMPLEXITY OF SOLOMONOFF INDUCTION

AIXI uses an analogue to Solomonoff’s prior on all possible environments  $\mathcal{M}$ . Therefore we first state computability results for *Solomonoff’s prior*  $M$  and the *measure mixture*  $\overline{M}$  in Table 3 [LH15b]. Notably,  $M$  is lower semicomputable and its conditional is limit computable. However, neither the measure mixture  $\overline{M}$  nor any of its variants are limit computable.

#### 3.2 UPPER BOUNDS

In this section, we derive upper bounds on the computability of AINU, AIMU, and AIXI. Except for Corollary 13, all results in this section apply generally to any LSCCCS  $\nu \in \mathcal{M}$ , hence they apply to AIXI even though they are stated for AINU.

For a fixed lifetime  $m$ , only the first  $m$  interactions matter. There is a finite number of policies that are different for

the first  $m$  interactions, and the optimal policy  $\pi_\xi^*$  can be encoded in a finite number of bits and is thus computable. To make a meaningful statement about the computability of  $\text{AINU}_{\text{LT}}$ , we have to consider it as the function that takes the lifetime  $m$  and outputs a policy  $\pi_\xi^*$  that is optimal in the environment  $\xi$  using the discount function  $\gamma_{\text{LT}m}$ . In contrast, for infinite lifetime discounting we just consider the function  $\pi_\xi^* : (\mathcal{A} \times \mathcal{E})^* \rightarrow \mathcal{A}$ .

In order to position AINU in the arithmetical hierarchy, we need to identify these functions with sets of natural numbers. In both cases, finite and infinite lifetime, we represent these functions as relations over  $\mathbb{N} \times (\mathcal{A} \times \mathcal{E})^* \times \mathcal{A}$  and  $(\mathcal{A} \times \mathcal{E})^* \times \mathcal{A}$  respectively. These relations are easily identified with sets of natural numbers by encoding the tuple with their arguments into one natural number. From now on this translation of policies (and  $m$ ) into sets of natural numbers will be done implicitly wherever necessary.

**Lemma 6** (Policies are in  $\Delta_n^0$ ). *If a policy  $\pi$  is  $\Sigma_n^0$  or  $\Pi_n^0$ , then  $\pi$  is  $\Delta_n^0$ .*

*Proof.* Let  $\varphi$  be a  $\Sigma_n^0$ -formula ( $\Pi_n^0$ -formula) defining  $\pi$ , i.e.,  $\varphi(h, a)$  holds iff  $\pi(h) = a$ . We define the formula  $\varphi'$ ,

$$\varphi'(h, a) := \bigwedge_{a' \in \mathcal{A} \setminus \{a\}} \neg \varphi(h, a').$$

The set of actions  $\mathcal{A}$  is finite, hence  $\varphi'$  is a  $\Pi_n^0$ -formula ( $\Sigma_n^0$ -formula). Moreover,  $\varphi'$  is equivalent to  $\varphi$ .  $\square$

To compute the optimal policy, we need to compute the value function. The following lemma gives an upper bound on the computability of the value function for environments in  $\mathcal{M}$ .

**Lemma 7** (Complexity of  $V_\nu^*$ ). *For every LSCCCS  $\nu \in \mathcal{M}$ , the function  $V_\nu^*$  is  $\Pi_2^0$ -computable. For  $\gamma = \gamma_{\text{LT}m}$  the function  $V_\nu^*$  is  $\Delta_2^0$ -computable.*

*Proof.* Multiplying (3) with  $\Gamma_t \nu(e_{<t} \parallel a_{<t})$  yields  $V_\nu^*(\mathbf{x}_{<t}) > q$  if and only if

$$\lim_{m \rightarrow \infty} \bigvee_{\mathbf{x}_{t:m}} \nu(e_{1:m} \parallel a_{1:m}) R(e_{t:m}) > q \Gamma_t \nu(e_{<t} \parallel a_{<t}). \quad (5)$$

The inequality's right side is lower semicomputable, hence there is a computable function  $\psi$  such that  $\psi(\ell) \nearrow q \Gamma_t \nu(e_{<t} \parallel a_{<t}) =: q'$  for  $\ell \rightarrow \infty$ . For a fixed  $m$ , the left side is also lower semicomputable, therefore there is a computable function  $\phi$  such that  $\phi(m, k) \nearrow \bigvee_{\mathbf{x}_{t:m}} \nu(e_{1:m} \parallel a_{1:m}) R(e_{t:m}) =: f(m)$  for  $k \rightarrow \infty$ . We already know that the limit of  $f(m)$  for  $m \rightarrow \infty$  exists (uniquely), hence we

can write (5) as

$$\begin{aligned} & \lim_{m \rightarrow \infty} f(m) > q' \\ \iff & \forall m_0 \exists m \geq m_0. f(m) > q' \\ \iff & \forall m_0 \exists m \geq m_0 \exists k. \phi(m, k) > q' \\ \iff & \forall \ell \forall m_0 \exists m \geq m_0 \exists k. \phi(m, k) > \psi(\ell), \end{aligned}$$

which is a  $\Pi_2^0$ -formula. In the finite lifetime case where  $m$  is fixed, the value function  $V_\nu^*(\mathbf{x}_{<t})$  is  $\Delta_2^0$ -computable by Lemma 2 (iv), since  $V_\nu^*(\mathbf{x}_{<t}) = f(m)q/q'$ .  $\square$

From the optimal value function  $V_\nu^*$  we get the optimal policy  $\pi_\nu^*$  according to (4). However, in cases where there is more than one optimal action, we have to break an argmax tie. This happens iff  $V_\nu^*(h\alpha) = V_\nu^*(h\beta)$  for two potential actions  $\alpha \neq \beta \in \mathcal{A}$ . This equality test is more difficult than determining which is larger in cases where they are unequal. Thus we get the following upper bound.

**Theorem 8** (Complexity of Optimal Policies). *For any environment  $\nu \in \mathcal{M}$ , if  $V_\nu^*$  is  $\Delta_n^0$ -computable, then there is an optimal policy  $\pi_\nu^*$  for the environment  $\nu$  that is  $\Delta_{n+1}^0$ .*

*Proof.* To break potential ties, we pick an (arbitrary) total order  $\succ$  on  $\mathcal{A}$  that specifies which actions should be preferred in case of a tie. We define

$$\begin{aligned} \pi_\nu(h) = a \iff & \bigwedge_{a': a' \succ a} V_\nu^*(ha) > V_\nu^*(ha') \\ & \wedge \bigwedge_{a': a' \succ a'} V_\nu^*(ha) \geq V_\nu^*(ha'). \end{aligned} \quad (6)$$

Then  $\pi_\nu$  is a  $\nu$ -optimal policy according to (4). By assumption,  $V_\nu^*$  is  $\Delta_n^0$ -computable. By Lemma 2 (i) and (ii)  $V_\nu^*(ha) > V_\nu^*(ha')$  is in  $\Sigma_n^0$  and  $V_\nu^*(ha) \geq V_\nu^*(ha')$  is  $\Pi_n^0$ . Therefore the policy  $\pi_\nu$  defined in (6) is a conjunction of a  $\Sigma_n^0$ -formula and a  $\Pi_n^0$ -formula and thus in  $\Delta_{n+1}^0$ .  $\square$

**Corollary 9** (Complexity of AINU).  *$\text{AINU}_{\text{LT}}$  is  $\Delta_3^0$  and  $\text{AINU}_{\text{DC}}$  is  $\Delta_4^0$  for every environment  $\nu \in \mathcal{M}$ .*

*Proof.* From Lemma 7 and Theorem 8.  $\square$

Usually we do not mind taking slightly suboptimal actions. Therefore actually trying to determine if two actions have the exact same value seems like a waste of resources. In the following, we consider policies that attain a value that is always within some  $\varepsilon > 0$  of the optimal value.

**Definition 10** ( $\varepsilon$ -Optimal Policy). *A policy  $\pi$  is  $\varepsilon$ -optimal in environment  $\nu$  iff  $V_\nu^*(h) - V_\nu^\pi(h) < \varepsilon$  for all histories  $h \in (\mathcal{A} \times \mathcal{E})^*$ .*

**Theorem 11** (Complexity of  $\varepsilon$ -Optimal Policies). *For any environment  $\nu \in \mathcal{M}$ , if  $V_\nu^*$  is  $\Delta_n^0$ -computable, then there is an  $\varepsilon$ -optimal policy  $\pi_\nu^\varepsilon$  for the environment  $\nu$  that is  $\Delta_n^0$ .*

*Proof.* Let  $\varepsilon > 0$  be given. Since the value function  $V_\nu^*(h)$  is  $\Delta_n^0$ -computable, the set  $V_\varepsilon := \{(ha, q) \mid |q - V_\nu^*(ha)| < \varepsilon/2\}$  is in  $\Delta_n^0$  according to Definition 1. Hence we compute the values  $V_\nu^*(ha')$  until we get within  $\varepsilon/2$  for every  $a' \in \mathcal{A}$  and then choose the action with the highest value so far. Formally, let  $\succ$  be an arbitrary total order on  $\mathcal{A}$  that specifies which actions should be preferred in case of a tie. Without loss of generality, we assume  $\varepsilon = 1/k$ , and define  $Q$  to be an  $\varepsilon/2$ -grid on  $[0, 1]$ , i.e.,  $Q := \{0, 1/2k, 2/2k, \dots, 1\}$ . We define

$$\begin{aligned} \pi_\nu^\varepsilon(h) = a &: \iff \\ \exists (q_{a'})_{a' \in \mathcal{A}} \in Q^{\mathcal{A}}. & \bigwedge_{a' \in \mathcal{A}} (ha', q_{a'}) \in V_\varepsilon \\ & \wedge \bigwedge_{a': a' \succ a} q_a > q_{a'} \wedge \bigwedge_{a': a \succ a'} q_a \geq q_{a'} \\ & \wedge \text{the tuple } (q_{a'})_{a' \in \mathcal{A}} \text{ is minimal with} \\ & \text{respect to the lex. ordering on } Q^{\mathcal{A}}. \end{aligned} \quad (7)$$

This makes the choice of  $a$  unique. Moreover,  $Q^{\mathcal{A}}$  is finite since  $\mathcal{A}$  is finite, and hence (7) is a  $\Delta_n^0$ -formula.  $\square$

**Corollary 12** (Complexity of  $\varepsilon$ -Optimal AINU). *For any environment  $\nu \in \mathcal{M}$ , there is an  $\varepsilon$ -optimal policy for  $\text{AINU}_{LT}$  that is  $\Delta_2^0$  and there is an  $\varepsilon$ -optimal policy for  $\text{AINU}_{DC}$  that is  $\Delta_3^0$ .*

*Proof.* From Lemma 7 and Theorem 11.  $\square$

If the environment  $\nu \in \mathcal{M}$  is a measure, i.e.,  $\nu$  assigns zero probability to finite strings, then we get computable  $\varepsilon$ -optimal policies.

**Corollary 13** (Complexity of AIMU). *If the environment  $\mu \in \mathcal{M}$  is a measure and the discount function  $\gamma$  is computable, then  $\text{AIMU}_{LT}$  and  $\text{AIMU}_{DC}$  are limit computable ( $\Delta_2^0$ ), and  $\varepsilon$ -optimal  $\text{AIMU}_{LT}$  and  $\text{AIMU}_{DC}$  are computable ( $\Delta_1^0$ ).*

*Proof.* In the discounted case, we can truncate the limit  $m \rightarrow \infty$  in (3) at the  $\varepsilon/2$ -effective horizon  $m_{\text{eff}} := \min\{k \mid \Gamma_k/\Gamma_t < \varepsilon/2\}$ , since everything after  $m_{\text{eff}}$  can contribute at most  $\varepsilon/2$  to the value function. Any lower semicomputable measure is computable [LV08, Lem. 4.5.1]. Therefore  $V_\mu^*$  as given in (3) is composed only of computable functions, hence it is computable according to Lemma 2. The claim now follows from Theorem 8 and Theorem 11.  $\square$

### 3.3 LOWER BOUNDS

We proceed to show that the bounds from the previous section are the best we can hope for. In environment classes where ties have to be broken,  $\text{AIMU}_{DC}$  has to solve  $\Sigma_3^0$ -hard problems (Theorem 15), and  $\text{AIMU}_{LT}$  has to solve

$\Pi_2^0$ -hard problems (Theorem 16). These lower bounds are stated for particular environments  $\nu \in \mathcal{M}$ .

We also construct universal mixtures that yield bounds on  $\varepsilon$ -optimal policies. In the finite lifetime case, there is an  $\varepsilon$ -optimal  $\text{AIXI}_{LT}$  that solves  $\Sigma_1^0$ -hard problems (Theorem 17), and for general discounting, there is an  $\varepsilon$ -optimal  $\text{AIXI}_{DC}$  that solves  $\Pi_2^0$ -hard problems (Theorem 18). For arbitrary universal mixtures, we prove the following weaker statement that only guarantees incomputability.

**Theorem 14** (No AIXI is computable).  *$\text{AIXI}_{LT}$  and  $\text{AIXI}_{DC}$  are not computable for any universal Turing machine  $U$ .*

This theorem follows from the incomputability of Solomonoff induction. Since AIXI uses an analogue of Solomonoff's prior for learning, it succeeds to predict the environment's behavior for its own policy [Hut05, Thm. 5.31]. If AIXI were computable, then there would be computable environments more powerful than AIXI: they can simulate AIXI and anticipate its prediction, which leads to a contradiction.

*Proof.* Assume there is a computable policy  $\pi_\xi^*$  that is optimal in  $\xi$ . We define a deterministic environment  $\mu$ , the adversarial environment to  $\pi_\xi^*$ . The environment  $\mu$  gives rewards 0 as long as the agent follows the policy  $\pi_\xi^*$ , and rewards 1 once the agent deviates. Formally, we ignore observations by setting  $\mathcal{O} := \{0\}$ , and define

$$\begin{aligned} \mu(r_{1:t} \parallel a_{1:t}) &:= \\ \begin{cases} 1 & \text{if } \forall k \leq t. a_k = \pi_\xi^*((ar)_{<k}) \text{ and } r_k = 0 \\ 1 & \text{if } \forall k \leq t. r_k = \mathbb{1}_{k \geq i} \\ & \text{where } i := \min\{j \mid a_j \neq \pi_\xi^*((ar)_{<j})\} \\ 0 & \text{otherwise.} \end{cases} \end{aligned}$$

The environment  $\mu$  is computable because the policy  $\pi_\xi^*$  was assumed to be computable. Suppose  $\pi_\xi^*$  acts in  $\mu$ , then by [Hut05, Thm. 5.36], AIXI learns to predict perfectly on policy:

$$V_\xi^*(\mathbf{x}_{<t}) = V_\xi^{\pi_\xi^*}(\mathbf{x}_{<t}) \rightarrow V_\mu^{\pi_\xi^*}(\mathbf{x}_{<t}) = 0 \text{ as } t \rightarrow \infty,$$

since both  $\pi_\xi^*$  and  $\mu$  are deterministic. Therefore we find a  $t$  large enough such that  $V_\xi^*(\mathbf{x}_{<t}) < w_\mu$  (in the finite lifetime case we choose  $m > t$ ) where  $\mathbf{x}_{<t}$  is the interaction history of  $\pi_\xi^*$  in  $\mu$ . A policy  $\pi$  with  $\pi(\mathbf{x}_{<t}) \neq \pi_\xi^*(\mathbf{x}_{<t})$ , gets a reward of 1 in environment  $\mu$  for all time steps after  $t$ , hence  $V_\mu^\pi(\mathbf{x}_{<t}) = 1$ . With linearity of  $V_\xi^\pi(\mathbf{x}_{<t})$  in  $\xi$  [Hut05, Thm. 5.31],

$$V_\xi^\pi(\mathbf{x}_{<t}) \geq w_\mu \frac{\mu(e_{1:t} \parallel a_{1:t})}{\xi(e_{1:t} \parallel a_{1:t})} V_\mu^\pi(\mathbf{x}_{<t}) \geq w_\mu,$$

since  $\mu(e_{1:t} \parallel a_{1:t}) = 1$  ( $\mu$  is deterministic),  $V_\mu^\pi(\mathbf{x}_{<t}) = 1$ , and  $\xi(e_{1:t} \parallel a_{1:t}) \leq 1$ . Now we get a contradiction:

$$w_\mu > V_\xi^*(\mathbf{x}_{<t}) = \max_{\pi'} V_\xi^{\pi'}(\mathbf{x}_{<t}) \geq V_\xi^\pi(\mathbf{x}_{<t}) \geq w_\mu \quad \square$$

For the remainder of this section, we fix the action space to be  $\mathcal{A} := \{\alpha, \beta\}$  with action  $\alpha$  favored in ties. The percept space is fixed to a tuple of binary observations and rewards,  $\mathcal{E} := \mathcal{O} \times \{0, 1\}$  with  $\mathcal{O} := \{0, 1\}$ .

**Theorem 15** (AINU<sub>DC</sub> is  $\Sigma_3^0$ -hard). *If  $\Gamma_t > 0$  for all  $t$ , there is an environment  $\nu \in \mathcal{M}$  such that AINU<sub>DC</sub> is  $\Sigma_3^0$ -hard.*

*Proof.* Let  $A$  be any  $\Sigma_3^0$  set, then there is a computable relation  $S$  such that

$$n \in A \iff \exists i \forall t \exists k S(n, i, t, k). \quad (8)$$

We define a class of environments  $\mathcal{M}' = \{\rho_0, \rho_1, \dots\} \subseteq \mathcal{M}$  where each environment  $\rho_i$  is defined by

$$\rho_i((or)_{1:t} \parallel a_{1:t}) := \begin{cases} 2^{-t}, & \text{if } o_{1:t} = 1^t \text{ and } \forall t' \leq t. r_{t'} = 0 \\ 2^{-n-1}, & \text{if } \exists n. 1^n 0 \sqsubseteq o_{1:t} \sqsubseteq 1^n 0^\infty \text{ and } a_{n+2} = \alpha \\ & \text{and } \forall t' \leq t. r_{t'} = 0 \\ 2^{-n-1}, & \text{if } \exists n. 1^n 0 \sqsubseteq o_{1:t} \sqsubseteq 1^n 0^\infty \text{ and } a_{n+2} = \beta \\ & \text{and } \forall t' \leq t. r_{t'} = \mathbb{1}_{t' > n+1} \\ & \text{and } \forall t' \leq t \exists k S(n, i, t', k) \\ 0, & \text{otherwise.} \end{cases}$$

Every  $\rho_i$  is a chronological conditional semimeasure by definition, so  $\mathcal{M}' \subseteq \mathcal{M}$ . Furthermore, every  $\rho_i$  is lower semicomputable since  $S$  is computable.

We define our environment  $\nu$  as a mixture over  $\mathcal{M}'$ ,

$$\nu := \sum_{i \in \mathbb{N}} 2^{-i-1} \rho_i;$$

the choice of the weights on the environments  $\rho_i$  is arbitrary but positive. Let  $\pi_\nu^*$  be an optimal policy for the environment  $\nu$  and recall that the action  $\alpha$  is preferred in ties. We claim that for the  $\nu$ -optimal policy  $\pi_\nu^*$ ,

$$n \in A \iff \pi_\nu^*(1^n 0) = \beta. \quad (9)$$

This enables us to decide whether  $n \in A$  given the policy  $\pi_\nu^*$ , hence proving (9) concludes this proof.

Let  $n, i \in \mathbb{N}$  be given, and suppose we are in environment  $i$  and observe  $1^n 0$ . Taking action  $\alpha$  next yields rewards 0 forever; taking action  $\beta$  next yields a reward of 1 for those time steps  $t \geq n + 2$  for which  $\forall t' \leq t \exists k S(n, i, t', k)$ , after that the semimeasure assigns probability 0 to all next observations. Therefore, if for some  $t_0$  there is no  $k$  such that  $S(n, i, t_0, k)$ , then  $\rho_i(e_{1:t_0} \parallel \dots \beta \dots) = 0$ , and hence

$$V_{\rho_i}^*(1^n 0 \beta) = 0 = V_{\rho_i}^*(1^n 0 \alpha),$$

and otherwise  $\rho_i$  yields reward 1 for every time step after  $n + 1$ , therefore

$$V_{\rho_i}^*(1^n 0 \beta) = \Gamma_{n+2} > 0 = V_{\rho_i}^*(1^n 0 \alpha)$$

(omitting the first  $n + 1$  actions and rewards in the argument of the value function). We can now show (9): By (8),  $n \in A$  if and only if there is an  $i$  such that for all  $t$  there is a  $k$  such that  $S(n, i, t, k)$ , which happens if and only if there is an  $i \in \mathbb{N}$  such that  $V_{\rho_i}^*(1^n 0 \beta) > 0$ , which is equivalent to  $V_\nu^*(1^n 0 \beta) > 0$ , which in turn is equivalent to  $\pi_\nu^*(1^n 0) = \beta$  since  $V_\nu^*(1^n 0 \alpha) = 0$  and action  $\alpha$  is favored in ties.  $\square$

**Theorem 16** (AINU<sub>LT</sub> is  $\Pi_2^0$ -hard). *There is an environment  $\nu \in \mathcal{M}$  such that AINU<sub>LT</sub> is  $\Pi_2^0$ -hard.*

The proof of Theorem 16 is analogous to the proof of Theorem 15. The notable difference is that we replace  $\forall t' \leq t \exists k S(n, i, t', k)$  with  $\exists k S(n, i, k)$ . Moreover, we swap actions  $\alpha$  and  $\beta$ : action  $\alpha$  ‘checks’ the relation  $S$  and action  $\beta$  gives a sure reward of 1.

**Theorem 17** (Some  $\varepsilon$ -optimal AIXI<sub>LT</sub> are  $\Sigma_1^0$ -hard). *There is a universal Turing machine  $U'$  and an  $\varepsilon > 0$  such that any  $\varepsilon$ -optimal policy for AIXI<sub>LT</sub> is  $\Sigma_1^0$ -hard.*

*Proof.* Let  $\xi$  denote the universal mixture derived from the reference universal monotone Turing machine  $U$ . Let  $A$  be a  $\Sigma_1^0$ -set and  $S$  computable relation such that  $n + 1 \in A$  iff  $\exists k S(n, k)$ . We define the environment

$$\nu((or)_{1:t} \parallel a_{1:t}) := \begin{cases} \xi((or)_{1:n} \parallel a_{1:n}), & \text{if } \exists n. o_{1:n} = 1^{n-1} 0 \\ & \text{and } a_n = \alpha \\ & \text{and } \forall t' > n. e_{t'} = (0, \frac{1}{2}) \\ \xi((or)_{1:n} \parallel a_{1:n}), & \text{if } \exists n. o_{1:n} = 1^{n-1} 0 \\ & \text{and } a_n = \beta \\ & \text{and } \forall t' > n. e_{t'} = (0, 1) \\ & \text{and } \exists k S(n-1, k). \\ \xi((or)_{1:t} \parallel a_{1:t}), & \text{if } \nexists n. o_{1:n} = 1^{n-1} 0 \\ 0, & \text{otherwise.} \end{cases}$$

The environment  $\nu$  mimics the universal environment  $\xi$  until the observation history is  $1^{n-1} 0$ . Taking the action  $\alpha$  next gives rewards  $1/2$  forever. Taking the action  $\beta$  next gives rewards 1 forever if  $n \in A$ , otherwise the environment  $\nu$  ends at some future time step. Therefore we want to take action  $\beta$  if and only if  $n \in A$ . We have that  $\nu$  is an LSCCCS since  $\xi$  is an LSCCCS and  $S$  is computable.

We define the universal lower semicomputable semimeasure  $\xi' := \frac{1}{2}\nu + \frac{1}{8}\xi$ . Choose  $\varepsilon := 1/9$ . Let  $n \in A$  be given and define the lifetime  $m := n + 1$ . Let  $h \in (\mathcal{A} \times \mathcal{E})^n$  be any history with observations  $o_{1:n} = 1^{n-1} 0$ . Since  $\nu(1^{n-1} 0 \mid a_{1:n}) = \xi(1^{n-1} 0 \mid a_{1:n})$  by definition, the posterior weights of  $\nu$  and  $\xi$  in  $\xi'$  are equal to the prior weights, analogously to [LH15a, Thm. 7]. In the following, we use the linearity of  $V_\rho^{\pi_{\xi'}}^*$  in  $\rho$  [Hut05, Thm. 5.21], and the fact that values are bounded between 0 and 1. If there is a  $k$

such that  $S(n-1, k)$ ,

$$\begin{aligned} & V_{\xi'}^*(h\beta) - V_{\xi'}^*(h\alpha) \\ &= \frac{1}{2}V_{\nu}^{\pi_{\xi'}^*}(h\beta) - \frac{1}{2}V_{\nu}^{\pi_{\xi'}^*}(h\alpha) + \frac{1}{8}V_{\xi}^{\pi_{\xi'}^*}(h\beta) - \frac{1}{8}V_{\xi}^{\pi_{\xi'}^*}(h\alpha) \\ &\geq \frac{1}{2} - \frac{1}{4} + 0 - \frac{1}{8} = \frac{1}{8}, \end{aligned}$$

and similarly if there is no  $k$  such that  $S(n-1, k)$ , then

$$\begin{aligned} & V_{\xi'}^*(h\alpha) - V_{\xi'}^*(h\beta) \\ &= \frac{1}{2}V_{\nu}^{\pi_{\xi'}^*}(h\alpha) - \frac{1}{2}V_{\nu}^{\pi_{\xi'}^*}(h\beta) + \frac{1}{8}V_{\xi}^{\pi_{\xi'}^*}(h\alpha) - \frac{1}{8}V_{\xi}^{\pi_{\xi'}^*}(h\beta) \\ &\geq \frac{1}{4} - 0 + 0 - \frac{1}{8} = \frac{1}{8}. \end{aligned}$$

In both cases  $|V_{\xi'}^*(h\beta) - V_{\xi'}^*(h\alpha)| > 1/9$ . Hence we pick  $\varepsilon := 1/9$  and get for every  $\varepsilon$ -optimal policy  $\pi_{\xi'}^{\varepsilon}$ , that  $\pi_{\xi'}^{\varepsilon}(h) = \beta$  if and only if  $n \in A$ .  $\square$

**Theorem 18** (Some  $\varepsilon$ -optimal  $\text{AIXI}_{\text{DC}}$  are  $\Pi_2^0$ -hard). *There is a universal Turing machine  $U'$  and an  $\varepsilon > 0$  such that any  $\varepsilon$ -optimal policy for  $\text{AIXI}_{\text{DC}}$  is  $\Pi_2^0$ -hard.*

The proof of Theorem 18 is analogous to the proof of Theorem 17 except that we choose  $\forall m' \leq m \exists k S(x, m, k)$  as a condition for reward 1 after playing action  $\beta$ .

## 4 ITERATIVE VS. RECURSIVE AINU

Generally, our environment  $\nu \in \mathcal{M}$  is only a semimeasure and not a measure. I.e., there is a history  $\mathbf{x}_{<t}$  such that

$$1 > \sum_{e_t \in \mathcal{E}} \nu(e_t \mid e_{<t} \parallel a_{1:t}).$$

In such cases, with positive probability the environment  $\nu$  does not produce a new percept  $e_t$ . If this occurs, we shall use the informal interpretation that the environment  $\nu$  *ended*, but our formal argument does not rely on this interpretation.

The following proposition shows that for a semimeasure  $\nu \in \mathcal{M}$  that is not a measure, the iterative definition of AINU does not maximize  $\nu$ -expected rewards. Recall that  $\gamma_1$  states the discount of the first reward. In the following, we assume without loss of generality that  $\gamma_1 > 0$ , i.e., we are not indifferent about the reward received in time step 1.

**Proposition 19** (Iterative AINU is not a  $\nu$ -Expected Rewards Maximizer). *For any  $\varepsilon > 0$  there is an environment  $\nu \in \mathcal{M}$  that is not a measure and a policy  $\pi$  that receives a total of  $\gamma_1$  rewards in  $\nu$ , but AINU receives only  $\varepsilon\gamma_1$  rewards in  $\nu$ .*

Informally, the environment  $\nu$  is defined as follows. In the first time step, the agent chooses between the two actions  $\alpha$  and  $\beta$ . Taking action  $\alpha$  gives a reward of 1, and subsequently the environment ends. Action  $\beta$  gives a reward of  $\varepsilon$ , but the environment continues forever. There are no

other rewards in this environment. From the perspective of  $\nu$ -expected reward maximization, it is better to take action  $\alpha$ , however AINU takes action  $\beta$ .

*Proof.* Let  $\varepsilon > 0$ . We ignore observations and set  $\mathcal{E} := \{0, \varepsilon, 1\}$ ,  $\mathcal{A} := \{\alpha, \beta\}$ . The environment  $\nu$  is formally defined by

$$\nu(r_{1:t} \parallel a_{1:t}) := \begin{cases} 1 & \text{if } a_1 = \alpha \text{ and } r_1 = 1 \text{ and } t = 1 \\ 1 & \text{if } a_1 = \beta \text{ and } r_1 = \varepsilon \text{ and } r_k = 0 \forall 1 < k \leq t \\ 0 & \text{otherwise.} \end{cases}$$

Taking action  $\alpha$  first, we have  $\nu(r_{1:t} \parallel \alpha a_{2:t}) = 0$  for  $t > 1$  (the environment  $\nu$  ends in time step 2 given history  $\alpha$ ). Hence we use (3) to conclude

$$V_{\nu}^*(\alpha) = \frac{1}{\Gamma_t} \lim_{m \rightarrow \infty} \sum_{r_{1:m}} \nu(r_{1:m} \parallel \alpha a_{2:m}) \sum_{i=1}^m r_i = 0.$$

Taking action  $\beta$  first we get

$$V_{\nu}^*(\beta) = \frac{1}{\Gamma_t} \lim_{m \rightarrow \infty} \sum_{r_{1:m}} \nu(r_{1:m} \parallel \beta a_{2:m}) \sum_{i=1}^m r_i = \frac{\gamma_1}{\Gamma_1} \varepsilon.$$

Since  $\gamma_1 > 0$  and  $\varepsilon > 0$ , we have  $V_{\nu}^*(\beta) > V_{\nu}^*(\alpha)$ , and thus AINU will use a policy that plays action  $\beta$  first, receiving a total discounted reward of  $\varepsilon\gamma_1$ . In contrast, any policy  $\pi$  that takes action  $\alpha$  first receives a larger total discounted reward of  $\gamma_1$ .  $\square$

Whether it is reasonable to assume that our environment has a nonzero probability of ending is a philosophical debate we do not want to engage in here. Instead, we have a different motivation to use the recursive value function: we get an improved computability result. Concretely, we show that for all environments  $\nu \in \mathcal{M}$ , there is a limit-computable  $\varepsilon$ -optimal policy maximizing  $\nu$ -expected rewards using an infinite horizon. According to Theorem 18, this does not hold for all  $V_{\nu}^*$ -maximizing agents AINU.

In order to maximize  $\nu$ -expected rewards in case  $\nu$  is not a measure, we need the recursive definition of the value function (analogously to [Hut05, Eq. 4.12]). To avoid confusion, we denote it  $W_{\nu}^{\pi}$ :

$$\begin{aligned} W_{\nu}^{\pi}(\mathbf{x}_{<t}) &= \frac{1}{\Gamma_t} \sum_{e_t} (\gamma_t r_t \\ &\quad + \Gamma_{t+1} W_{\nu}^{\pi}(\mathbf{x}_{1:t})) \nu(e_t \mid e_{<t} \parallel a_{1:t}) \end{aligned}$$

where  $a_t := \pi(\mathbf{x}_{<t})$ . In the following we write it in non-recursive form.

**Definition 20** ( $\nu$ -Expected Value Function). The  $\nu$ -expected value of a policy  $\pi$  in an environment  $\nu$  given

history  $\mathbf{x}_{<t}$  is

$$W_\nu^\pi(\mathbf{x}_{<t}) := \frac{1}{\Gamma_t} \sum_{m=t}^{\infty} \sum_{e_{t:m}} \gamma_m r_m \nu(e_{1:m} \parallel a_{1:m})$$

if  $\Gamma_t > 0$  and  $W_\nu^\pi(\mathbf{x}_{<t}) := 0$  if  $\Gamma_t = 0$  where  $a_i := \pi(e_{<i})$  for all  $i \geq t$ . The *optimal  $\nu$ -expected value* is defined as  $W_\nu^*(h) := \sup_\pi W_\nu^\pi(h)$ .

The difference between  $V_\nu^\pi$  and  $W_\nu^\pi$  is that for  $W_\nu^\pi$  all obtained rewards matter, but for  $V_\nu^\pi$  only the rewards in timelines that continue indefinitely. In this sense the value function  $V_\nu^\pi$  conditions on surviving forever. If the environment  $\mu$  is a measure, then the history is infinite with probability one, and so  $V_\nu^\pi$  and  $W_\nu^\pi$  coincide. Hence this distinction is not relevant for AIMU, only for AINU and AIXI.

So why use  $V_\nu^\pi$  in the first place? Historically, this is how infinite-horizon AIXI has been defined [Hut05, Def. 5.30]. This definition is the natural adaptation of (optimal) minimax search in zero-sum games to the (optimal) expectimax algorithm for stochastic environments. It turns out to be problematic only because semimeasures have positive probability of ending prematurely.

**Lemma 21** (Complexity of  $W_\nu^*$ ). *For every LSCCCS  $\nu \in \mathcal{M}$ , and every lower semicomputable discount function  $\gamma$ , the function  $W_\nu^*$  is  $\Delta_2^0$ -computable.*

*Proof.* The proof is analogous to the proof of Lemma 7. We expand Definition 20 using the expectimax operator analogously to (3). This gives a quotient with numerator

$$\lim_{m \rightarrow \infty} \max_{\mathbf{x}_{t:m}} \sum_{i=t}^m \gamma_i r_i \nu(e_{1:i} \parallel a_{1:i}),$$

and denominator  $\nu(e_{<t} \parallel a_{<t}) \cdot \Gamma_t$ . In contrast to the iterative value function, the numerator is now nondecreasing in  $m$  because we assumed rewards to be nonnegative (Assumption 3b). Hence both numerator and denominator are lower semicomputable functions, so Lemma 2 (iv) implies that  $W_\nu^*$  is  $\Delta_2^0$ -computable.  $\square$

Now we can apply our results from Section 3.2 to show that using the recursive value function  $W_\nu^\pi$ , we get a universal AI model with an infinite horizon whose  $\varepsilon$ -approximation is limit computable. Moreover, in contrast to iterative AINU, recursive AINU actually maximizes  $\nu$ -expected rewards.

**Corollary 22** (Complexity of Recursive AINU/AIXI). *For any environment  $\nu \in \mathcal{M}$ , recursive AINU is  $\Delta_3^0$  and there is an  $\varepsilon$ -optimal recursive AINU that is  $\Delta_2^0$ . In particular, for any universal Turing machine, recursive AIXI is  $\Delta_3^0$  and there is an  $\varepsilon$ -optimal recursive AIXI that is limit computable.*

*Proof.* From Theorem 8, Theorem 11, and Lemma 21.  $\square$

Analogously to Theorem 14, Theorem 16, and Theorem 17 we can show that recursive AIXI is not computable, recursive AINU is  $\Pi_2^0$ -hard, and for some universal Turing machines,  $\varepsilon$ -optimal recursive AIXI is  $\Sigma_1^0$ -hard.

## 5 DISCUSSION

We set out with the goal of finding a limit-computable perfect agent. Table 3 on page 4 summarizes our computability results regarding Solomonoff's prior  $M$ : conditional  $M$  and  $M_{\text{norm}}$  are limit computable, while  $\overline{M}$  and  $\overline{M}_{\text{norm}}$  are not. Table 1 on page 2 summarizes our computability results for AINU, AIXI, and AINU: iterative AINU with finite lifetime is  $\Delta_3^0$ . Having an infinite horizon increases the level by one, while restricting to  $\varepsilon$ -optimal policies decreases the level by one. All versions of AINU are situated between  $\Delta_2^0$  and  $\Delta_4^0$  (Corollary 9 and Corollary 12). For environments that almost surely continue forever (semimeasure that are measures), AIMU is limit-computable and  $\varepsilon$ -optimal AIMU is computable. We proved that these computability bounds on iterative AINU are generally unimprovable (Theorem 15 and Theorem 16). Additionally, we proved weaker lower bounds for AIXI independent of the universal Turing machine (Theorem 14) and for  $\varepsilon$ -optimal AIXI for specific choices of the universal Turing machine (Theorem 17 and Theorem 18).

We considered  $\varepsilon$ -optimality in order to avoid having to break argmax ties. This  $\varepsilon$  does not have to be constant over time, instead we may let  $\varepsilon \rightarrow 0$  as  $t \rightarrow \infty$  at any computable rate. With this we retain the computability results of  $\varepsilon$ -optimal policies and get that the value of the  $\varepsilon(t)$ -optimal policy  $\pi_\nu^{\varepsilon(t)}$  converges rapidly to the  $\nu$ -optimal value:  $V_\nu^*(\mathbf{x}_{<t}) - V_\nu^{\pi_\nu^{\varepsilon(t)}}(\mathbf{x}_{<t}) \rightarrow 0$  as  $t \rightarrow \infty$ . Therefore the limitation to  $\varepsilon$ -optimal policies is not very restrictive.

When the environment  $\nu$  has nonzero probability of not producing a new percept, the iterative definition (Definition 4) of AINU fails to maximize  $\nu$ -expected rewards (Proposition 19). We introduced a recursive definition of the value function for infinite horizons (Definition 20), which correctly returns  $\nu$ -expected value. The difference between the iterative value function  $V$  and recursive value function  $W$  is readily exposed in the difference between  $M$  and  $\overline{M}$ . Just like  $V$  conditions on surviving forever, so does  $\overline{M}$  eliminate the weight of programs that do not produce infinite strings. Both  $\overline{M}$  and  $V$  are not limit computable for this reason.

Our main motivation for the introduction of the recursive value function  $W$  is the improvement of the computability of optimal policies. Recursive AINU is  $\Delta_3^0$  and admits a limit-computable  $\varepsilon$ -optimal policy (Corollary 22). In this sense our goal to find a limit-computable perfect agent has been accomplished.

## Abstract

We present a novel graphical model approach for a problem not previously considered in the machine learning literature: that of tracking with ranked signals. The problem consists of tracking a single target given observations about the target that consist of ranked continuous signals, from unlabeled sources in a cluttered environment. We introduce appropriate factors to handle the imposed ordering assumption, and also incorporate various systematic errors that can arise in this problem, particularly clutter or noise signals as well as missing signals. We show that inference in the obtained graphical model can be simplified by adding bipartite structures with appropriate factors. We apply a hybrid approach consisting of belief propagation and particle filtering in this mixed graphical model for inference and validate the approach on simulated data. We were motivated to formalize and study this problem by a key task in Oceanography, that of tracking the motion of RAFOS ocean floats, using range measurements sent from a set of fixed beacons, but where the identities of the beacons corresponding to the measurements are not known. However, unlike the usual tracking problem in artificial intelligence, there is an implicit ranking assumption among signal arrival times. Our experiments show that the proposed graphical model approach allows us to effectively leverage the problem constraints and improve tracking accuracy over baseline tracking methods yielding results similar to the ground truth hand-labeled data.

## 1 INTRODUCTION

We consider the problem of tracking a single target where the observations, concerning the position of the target, consist of ranked continuous signals from unlabeled sources in

a cluttered environment. We allow for various types of error that may occur in these observations: (a) a recorded signal may correspond to a spurious signal instead of a true signal, and (b) a signal may be lost and never recorded. We present a novel graphical model approach for this problem. Our graphical model is a mixed or hybrid model with both discrete and continuous components. To perform probabilistic inference in this mixed graphical model, we use particle filtering for the continuous component which represents the location of the target, and belief propagation for the discrete component which represents the data association between the signals and the signals' sources.

We were motivated to study the above problem formalism by a mathematical abstraction of a key problem in Oceanography: that of tracking RAFOS floats using ranked range measurements. RAFOS floats (Rossby *et al.*, 1986; Hancock & Speer, 2013) are low cost acoustically tracked subsurface floating devices used to study ocean currents by measuring the paths taken by fluid parcels in the ocean. They also measure temperature and pressure along the way. The typical mission times for these floats are on the order of a few months to a few of years during which they don't surface, and hence it is not possible to **locate or track** these floats via satellite (GPS) position fixes. In order to solve this location or tracking problem, a moored (fixed) array of sound sources, also known as *beacons* are used. These moored sound sources or beacons produce and transmit one sound signal per tracking cycle. The floats then record the **arrival times** of these signals transmitted from the beacons. These arrival times depend on the distance from the sound source and the velocity of sound in the ocean, and thus provide information about the location of the float (since the sound sources or beacons are fixed and their locations are known). At any given instant, if distances of the float from three beacons are known, this suffices to determine the position of the float. Thus if we could identify the beacons corresponding to the received signals, we can then track the course of the float.

The caveat is that while the arrival times are stored, the beacons from which the respective signals originated is **not**

known. In addition, the storage capacity of each float is limited and it only records a small number of these signal arrival times each day. These signals have a natural ordering in that the beacon signals most likely to be stored originate from the closest beacons and are received (and stored) in distance order. We are interested in inferring the identity of the beacons at each time step corresponding to the few received ordered or “ranked” signals. This is a challenging task and currently, this information is hand-labeled by oceanography researchers, with many months of effort. Our paper provides an automated solution for this interesting problem, and moreover provides a novel machine learning problem abstraction of tracking with ranked signals, which would be of interest even from a purely machine learning standpoint.

We will nonetheless anchor our discussion of the tracking with ranked signals problem to the RAFOS float tracking problem for presentational reasons. Let us consider the setup and assumptions of the above RAFOS float tracking problem in greater detail. Each float’s tracking data consists of its initial and final positions, and a fixed number of earliest signal arrival times for each day. Figure 1 shows the observed signal arrival times for a particular float over the entire tracking period. There are  $s$  fixed beacons with known positions. Each float in the ocean is equipped with a receiver. Every day at a specified time, a float starts listening for sound signals transmitted by the beacons. The float stores the arrival times of the first  $r (< s)$  signals it receives and a confidence value for each signal, then shuts off its receiver. Our goal is to use these arrival times to track the position of the float over time. The model we present includes the following kinds of errors that capture key characteristics of this problem:

- The arrival times are subject to noise due to environmental factors and recording equipment
- Signals from a beacon may never reach or be dropped by the receiver, we call these errors *missing values*.
- The receiver may erroneously record ambient noise as a signal from a beacon, and store that value. We call these errors *junk values* or *clutter*. Figure 1 and our analysis in the experiments section show that junk values are very common and outnumber true signals in the data.

While our focus is on the beacon association problem, it should be noted that there are additional sources of error such as those due to the Doppler effect, variations in the speed of sound due to temperature and beacon depth or clock drift in the receiver which have been investigated in prior work (Wooding *et al.*, 2005; Hancock & Speer, 2013). These would change the conditional probability distributions in the model we introduce in Figure 2 and incorporating these in our model is left as future work.

**Contributions** The main contributions of this work are as follows:

- Our setting differs from prior work from a machine learning standpoint due to the ordering condition imposed on the received signals, as described earlier. Our model introduces novel ranking based factors to enforce this condition, and we present an equivalent bipartite model similar in structure to that used in the data association literature (Williams & Lau, 2010) which can then be used for inference via message passing. This contribution should be valuable for other graphical model problems where ranking based factors are involved.
- RAFOS float tracking has not previously been considered from a graphical model perspective; indeed, (Hancock & Speer, 2013; Wooding *et al.*, 2005) label data by hand. Our model in Figure 2 captures several important characteristics of this problem and is also of practical importance from an application standpoint.
- We evaluate our algorithm on simulated data and show that our algorithm performs better than a baseline model which does not take the ranking of signal arrival times into account. We also present the results of our algorithm on real world RAFOS float data and demonstrate good agreement with hand-labeled data.

## 1.1 RELATED WORK

We now review prior work on tracking, and specifically contrast our problem with the classical tracking problem. A tracking algorithm can be viewed as computing the probability distribution of a system’s state  $x_t$  given observations  $y_t$ . A common model for this is a Hidden Markov model with hidden states  $x_t$ . Inference using message passing for this model leads to the well known Kalman filtering and smoothing algorithms or the forward-backward algorithm under different distributional assumptions. Another common class of approaches to perform inference on such models are particle filtering and other MCMC-based approaches (Oh *et al.*, 2009; Chertkov *et al.*, 2010).

In the RAFOS float tracking problem, from the perspective of the float, the problem resembles a multi-target tracking or data association problem, where the beacons are the targets. In multi-target tracking, we try to track a number of moving targets over time given some noisy information about the set of observed locations at each time step, and the challenge is to link the locations over time to obtain the trajectory for each target. Classical approaches to multi-target tracking assign a probability to each possible association of targets across time steps. The inference problem  $p(x_t|y_t)$  then requires summing over all possible such associations and reduces to computing the permanent of a matrix (Oh *et al.*, 2009; Chertkov *et al.*, 2010), which is

Figure 1: Observed signal arrival times for float #767 and #811 over the entire tracking period

known to be #P-complete (Valiant, 1979). The probabilistic data association filter (Bar-Shalom, 1987; Bar-Shalom *et al.*, 2009) collapses this state into a single Gaussian at each time step to make the problem tractable. Another interesting line of work is multiple hypothesis tracking (Blackman, 2004). At each time step the algorithm maintains a mixture of Gaussians for each target representing a distribution over its possible positions, and updates the state by summing over all possible associations while discarding components with low probability to make computation tractable. Message passing algorithms which have been shown to converge (Vontobel, 2013; Huang & Jebara, 2009) have also been proposed. (Cevher *et al.*, 2006) developed a particle filtering approach which uses only range measurements, while MCMC algorithms that are fully polynomial-time randomized approximation schemes (Jerum *et al.*, 2004) have also been studied. Other approaches include greedy approaches widely used in robotics, which include choosing the data association with the maximum likelihood (Thrun *et al.*, 2005), and nearest-neighbor methods where observations “closest” to expected observations are kept and others are discarded. While simple, such greedy approaches work poorly under relatively high noise levels (Bar-Shalom *et al.*, 2009). Yet another interesting line of work represents the state  $x_t$  of the system using distributions over permutations and uses group-theoretic methods to approximate these distributions (Kondor *et al.*, 2007; Huang *et al.*, 2009). Such approaches have been investigated in the contexts of radar tracking, computer vision, and robotics.

We cannot directly apply these methods to the RAFOS float tracking problem because the number of observed targets (beacon arrival times) is small compared to the number of beacons and thus most beacons are unobserved at each time step. This is because if we can identify the beacons corre-

sponding to each arrival time, only a small number (three in 2D space) of beacons are required to track the float’s position, and thus the float need only store the first few arrival times while the number of beacons may be much larger. Further, there may be regime changes, where a beacon goes out of range and a previously unobserved beacon appears in range which these methods cannot directly handle. However, since the closest beacons are the ones most likely to be recorded and their values are received in order, the provided information may be sufficient for tracking. We show in this paper that explicitly modeling the ordering assumption among beacon times and the fact that there is an underlying latent variable – the float’s position – which connects the targets, allows us to track the float.

We also note that multiple hypothesis tracking approaches which maintain a mixture over the potential associations are not required for our model for tracking with ranked signals. In a sense, in the RAFOS float tracking problem the only true latent variable is the float’s position and the others such as the beacon arrival times are derived from this. In particular, the additional ordering assumption provides a strong helpful constraint, since the only way the closest beacon’s signal is not received first is if two signals were close together and their ordering was changed due to ambient noise, if that signal is lost or if a junk signal was recorded as the first. The first possibility does not affect tracking since the two signals were already close, while the probabilities of the latter two systematic errors can be modeled in a principled manner with a graphical model approach. Thus, in the RAFOS tracking problem knowing the initial position allows us to continue tracking the float without needing a mixture model and in this sense, our model for tracking with ranked signals is (computationally and statistically) easier than the standard multiple-target tracking problem.

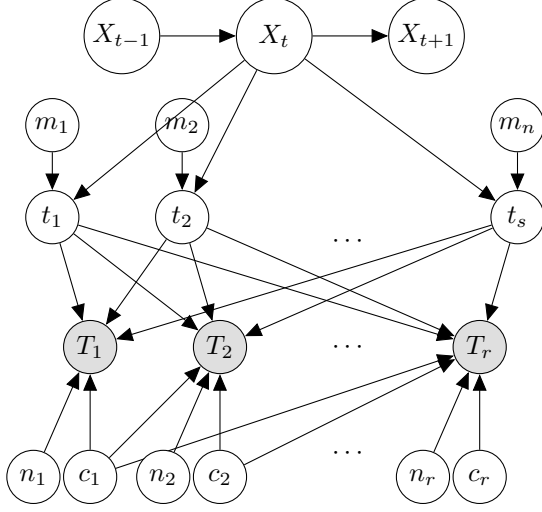

Figure 2: Graphical Model for tracking with ranked signals

To investigate the question of the practical advantage of our ordering constraint, which is a key difference from previous work, we consider a baseline model by dropping the ranking assumption. Thus, any permutation is allowed as a possible signal to signal source assignment, and is given the same weight. This approach leads to a mixture over possible assignments and we compare against this baseline in our experiments.

## 2 GRAPHICAL MODEL

Our proposed graphical model for tracking with ranked signals is shown in Figure 2. While Figure 2 expresses our model as a directed graphical model (also known as a Bayesian network), we will specify the probability distribution not in terms of conditional probabilities but in terms of local factors in the corresponding factor graph (see Figure 9 in appendix), since these will be used for inference in the sequel. For simplicity of description, we assume that target is in a 2-dimensional space, however it must be noted that our model applies to the general case when the target is in a  $d$ -dimensional space. We now describe each node and factor in Figure 2.

At each time step, the target records the first  $r$  signals emitted from  $s$  signal sources. It is possible that a signal from a particular signal source may be lost and not detectable at the target for the target to record. It is also possible that the target may record a spurious signal if the spurious signal is ranked higher than a true signal.

We indicate the position of the target by  $X_t \in \mathbb{R}^2$ . We model the system's dynamics as  $X_{t+1} \sim \mathcal{N}(X_t, \Sigma)$ , so that we have the corresponding factor  $f(X_t, X_{t+1})$  given by

$$f(X_t, X_{t+1}) = (2\pi)^{-1} |\Sigma|^{-1/2} \exp\left(-\frac{1}{2} \Delta_t^T \Sigma^{-1} \Delta_t\right) \quad (1)$$

where  $\Delta_t = X_{t+1} - X_t$ .

We denote the signal characteristic (providing information about the target) from signal source  $i$  by  $t_i \in \mathbb{R}$ , ( $1 \leq i \leq s$ ). Note that in the context of RAFOS float tracking, this would correspond to the arrival time of the sound signal from beacon  $i$ . Some of these signals might be lost as noted in the introduction, so that we use Bernoulli random variables  $m_i \in \{0, 1\}$  to indicate whether or not the signal from signal source  $i$  was lost. Thus, if  $m_i = 1$ , the signal was lost and  $t_i$  is set to  $\infty$  (so that signal source  $i$  will be ignored in (3)). Otherwise,  $t_i$  follows some given distribution depending on signal source  $i$  and current the target location  $X_t$ . For example, in the RAFOS tracking problem,  $t_i$  follows a Gaussian distribution centered on the time taken for a sound signal to travel from location  $b_i$  to location  $X_t$ , given by  $\frac{\|X_t - b_i\|_2}{v_s}$ , where  $b_i$  is the beacon's location and  $v_s$  is the speed of sound. We capture this interaction between the state  $X_t$ , the estimated arrival time  $t_i$ , and the lost signal indicator  $m_i$  via the factors  $g_i(X_t, t_i, m_i)$  ( $1 \leq i \leq s$ ):

$$g_i(X_t, t_i, m_i) = \begin{cases} \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(t_i - \frac{\|X_t - b_i\|_2}{v_s})^2}{2\sigma^2}} & \text{if } m_i = 0 \\ 1 & \text{if } m_i = 1 \end{cases} \quad (2)$$

Note that  $t_i \in \mathbb{R}$ , ( $1 \leq i \leq s$ ) are not directly observed, and hence latent variables in the model. Next, we consider the *observed* signals which we denote by  $T_i$  ( $1 \leq i \leq r$ ). Since these signals are stored sequentially, we have that  $T_1 < T_2 < \dots < T_r$  by our ranking assumption. But some of these signals may not correspond to signals from actual signal sources at all, and could be purely due to *clutter*, as noted in the introduction. We thus use Bernoulli random variables  $c_i \in \{0, 1\}$  to indicate whether or not the signal  $T_i$  corresponds to clutter. By the assumptions made in the previous section, if the signal from the signal source that is supposed to be recorded first is not lost, i.e.  $t_i < \infty$ , and moreover the value stored as  $T_i$  is not junk, i.e.  $c_i = 1$  then  $T_i$  *must* be the minimum of  $\{t_j\}_{j=1}^i$ . Otherwise, a junk clutter value is recorded. We assume these clutter values follow some fixed distribution, which we denote using the random variables  $n_i$ . For instance, in the RAFOS float tracking problem we assume junk clutter value are distributed *uniformly* over a specified interval.

We represent this interaction of  $T_j$  with the clutter, lost/missing, and signal variables, via the factor  $f(T_j, c_1, c_2, \dots, c_j, n_j, t_1, m_1, t_2, m_2, \dots, t_s, m_s)$ :

$$f(T_j, c_1, c_2, \dots, c_j, n_j, t_1, m_1, t_2, m_2, \dots, t_s, m_s) = \begin{cases} \delta(T_j - t_{(j)}) & \text{if } c_j = 0 \\ \delta(T_j - n_j) & \text{if } c_j = 1 \end{cases} \quad (3)$$

where we use  $t_{(j)}$  to denote the  $(j - \sum_{l=1}^{j-1} c_l)^{\text{th}}$  smallest element of the set  $\{t_l\}$ . This is a degenerate conditional

probability distribution for  $T_i$  with mass only at the appropriate  $t_i$  or  $n_i$ . Recall that  $\delta$  is the Dirac delta function, which has the following properties:

$$\delta(x) = \begin{cases} 0 & \text{if } x \neq 0 \\ \text{undefined} & \text{if } x = 0 \end{cases}, \int \delta(x)dx = 1, \\ \int f(x)\delta(x)dx = f(0) \quad (4)$$

## 2.1 INFERENCE WITH $\min$ FACTORS

The key novelty of our graphical model are the high order factors  $f_j$ , which depend on the  $r$  first ranked signals. We consider this model in the simplified case, with no missing signals and no clutter, and show how inference via message passing can be performed in this model. In this setting, the factor  $f_j(T_j, t_1, t_2, \dots, t_s)$  is given by

$$f_j(T_j, t_1, t_2, \dots, t_s) = \delta(T_j - t_{(j)}) \quad (5)$$

where  $t_{(j)}$  is the  $j^{\text{th}}$  minimum element of  $\{t_1, t_2, \dots, t_s\}$ .

Direct computation of messages for high order factors in general requires computing an  $s - 1$ -dimensional integral. However, our  $f_j$ , which correspond to the  $j$ -th minimum function, can be rewritten as a sum of products as,

$$f_j = \sum_{k=1}^s \delta(t_k - T_j) \\ \sum_{(A,B) \in \mathcal{S}_k} \prod_{a \in A} \mathbf{1}(t_a < T_j) \prod_{b \in B} \mathbf{1}(t_b > T_j) \quad (6)$$

where  $\mathcal{S}_k = \{(A, B) \subseteq [s] \times [s] : A \cup B = [s] \setminus \{k\}, A \cap B = \emptyset, |A| = j - 1, |B| = s - j\}$  and  $[s] = \{1, 2, \dots, s\}$

Then, as we show in the appendix, the multidimensional integral, comprising messages in a message passing inference algorithm, can be computed using only one-dimensional integrals and turn out to have the form:

$$\mu_{f_j \rightarrow t_i}(t_i) = \delta(t_i - T_j)h_1(T_j) + \mathbf{1}(t_i < T_j)h_2(T_j) \\ + \mathbf{1}(t_i > T_j)h_3(T_j) \quad (7)$$

where each  $h_j$  can be computed in  $O(s^r)$  time via dynamic programming. When  $r$  is fixed, as in the RAFOS float tracking problem – since with  $r = 3$  at most three known nearest beacons we can obtain the floats position and the overall number of beacons  $s$  is irrelevant – these messages can effectively be computed in polynomial time. This result is in the vein of previous work on reductions for high order potentials such as (Tarlow *et al.*, 2010). Handling high order min factors in this way is a novel result and can potentially be applied to other problems where such ranking factors are involved. Due to their technical complexity however, we defer further discussion of these factors and the details of the message passing algorithm to Appendix A.2. Instead, in the next section, we consider a reduction of our

graphical model, with many such min factors, to an auxiliary model with a bipartite graph structure, which results in easier to implement algorithms.

## 2.2 REDUCTION TO BIPARTITE FACTORS

In this section, we show that our Bayesian network can be represented via a simpler conditional random field with factors that enforce a bipartite matching constraint. We do this by introducing latent variables  $S_i, R_j$  (Figure 3) to represent the association between signal sources and signals.

**One large factor.** First, consider the simplified case with no clutter and no missing signals. In this case, our graphical model is equivalent to one with the following large factor  $f$  connecting the  $t_1, t_2, \dots, t_s$  and  $T_1, T_2, \dots, T_r$  (instead of the  $f_j$  of (3) connecting  $t_j$  to the  $\{T_i\}$ ,  $f(t_1, t_2, \dots, t_s, T_1, T_2, \dots, T_r)$  as

$$f(t_1, t_2, \dots, t_s, T_1, T_2, \dots, T_r) \\ = \sum_{\substack{\Pi \in \{\text{r-permutations} \\ \text{of } \{1, 2, \dots, s\}\}}} \left\{ \prod_{j=1}^r \delta(t_{\Pi(j)} - T_j) \prod_{k \notin \Pi} \mathbf{1}(t_k > T_r) \right\} \quad (8)$$

We prove this by showing that the factor  $f$  defined in (8) above satisfies:

$$f = \prod_{j=1}^r f_j \quad (9)$$

where  $f_1, f_2, \dots, f_j$  are the factors in eq (3). For any  $\{t_1, t_2, \dots, t_s\}$ , if the  $r$  smallest elements are not  $T_1, T_2, \dots, T_r$  then we can see that  $f = 0$  and  $\prod_{j=1}^r f_j = 0$ . When the  $r$  smallest elements of  $\{t_1, t_2, \dots, t_s\}$  are  $T_1, T_2, \dots, T_r$ , where  $t_{i_1} = T_1, t_{i_2} = T_2, \dots, t_{i_r} = T_r$ , then we can see that  $f = \prod_{j=1}^r \delta(t_{i_j} - T_j) = \prod_{j=1}^r f_j$ .

**Auxiliary Bipartite Graph.**  $f$  has a special structure in that it sums over *partial* matchings and for each matching, it can be written as a product of pairwise factors, represented by the snippet of a pairwise conditional random field shown in Figure 3. To represent the matching, we use variables  $S_i$  ( $1 \leq i \leq s$ ) corresponding to signal sources: these take values in  $\{1, 2, \dots, r, \perp\}$ , indicating which of the  $r$  received signals  $S_i$  corresponds to, or a value of  $\perp$  if the signal was *late*, i.e. not in the first  $r$  and was thus not received. On the other side of the matching, we have variables  $R_j$  ( $1 \leq j \leq r$ ) corresponding to received signals  $T_j$ : these take values in  $\{1, 2, \dots, s\}$  indicating which of the signal sources  $T_j$  originated from. Thus,  $T_j$  is the signal corresponding to source  $R_j$ , while  $T_{S_i}$  is the signal corresponding to source  $i$ .

The factors  $f(S_i, R_j)$  enforce these bipartite matching con-

straint:

$$f(S_i, R_j) = \begin{cases} 0 & \text{if } S_i = j, R_j \neq i \text{ or} \\ & S_i \neq j, R_j = i \\ 1 & \text{otherwise} \end{cases} \quad (10)$$

And the factor  $f(S_i)$  is given by

$$f(S_i) = \begin{cases} \delta(t_i - T_{S_i}) & \text{if } S_i \neq \mathbb{L} \\ \mathbf{1}(t_i > T_r) & \text{if } S_i = \mathbb{L} \end{cases} \quad (11)$$

Then, on marginalizing  $S_i$  and  $R_j$ , we obtain the factor  $f$  as in equation (8). Thus, we can replace the factor  $f$  of equation (8) by this auxiliary graphical model and perform message passing on this graphical model. This leads to a model similar to the pairwise models proposed to approximate the permanent, which shows up in the usual data association problem (Pasula *et al.*, 1999; Huang & Jebara, 2009; Oh *et al.*, 2009; Chertkov *et al.*, 2010; Vontobel, 2013). We can now consider the difference between our bipartite model and the one used to approximate the permanent (in (Huang & Jebara, 2009)): the sum in eq (8) is over partial permutations while that in (Huang & Jebara, 2009) involves full permutations. Our model consequently involves an additional value  $L$  to indicate that a signal is ‘‘late’’, leading to the node factors as shown in eq (11) which use indicator functions to indicate that a sent signal may not be in the top  $r$  ranked signals, and thus encodes the min factors required by our model.

**Generalization to Factors with Missing Values, Clutter.** We now generalize this argument to yield a similar conditional random field with pairwise factors for the complete model with missing values and clutter. Each  $S_i$  ( $1 \leq i \leq s$ ) takes values  $1, 2, \dots, r, \mathbb{L}, \mathbb{M}$ , where a number indicates which signal it corresponds to,  $\mathbb{L}$  indicates that the signal is ranked too low to be observed, and  $\mathbb{M}$  indicates that the signal is missing and undetectable at the receiver. Each  $R_j$  ( $1 \leq j \leq r$ ) takes values  $1, 2, \dots, s, \mathbb{C}$ , where a number indicates the signal’s source, and  $\mathbb{C}$  indicates it’s clutter. The factors  $f(S_i, R_j)$  still enforce the bipartite matching constraint of equation (10). The factors  $f(n_j, R_j)$  are given by

$$f(n_j, R_j) = \begin{cases} P_C \delta(n_j - T_j) & \text{if } R_j = \mathbb{C} \\ 1 - P_C & \text{otherwise} \end{cases} \quad (12)$$

where  $P_N$  is the probability that the signal is clutter.

And the factor  $f(t_i, S_i)$  is given by

$$f(t_i, S_i) = \begin{cases} 1 - P_D & \text{if } S_i = \mathbb{M} \\ P_D \mathbf{1}(t_i > T_r) & \text{if } S_i = \mathbb{L} \\ P_D \delta(t_i - T_{S_i}) & \text{otherwise} \end{cases} \quad (13)$$

where  $P_D$  is the probability that the signal can be detected

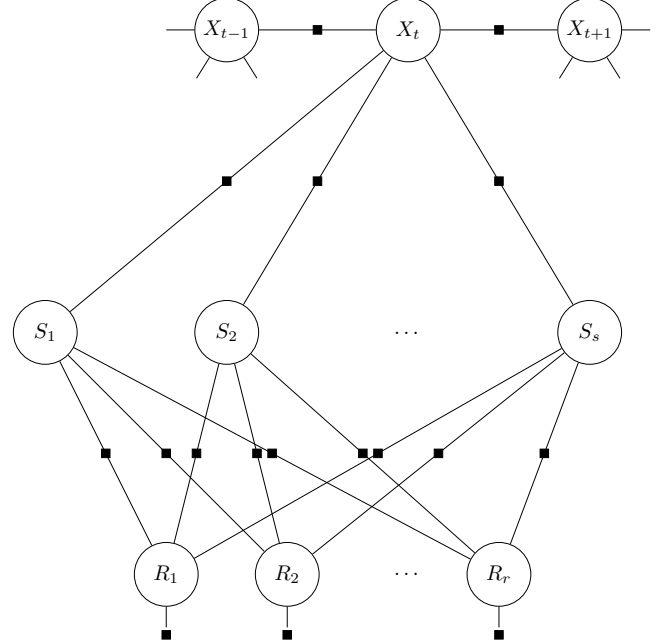

Figure 3: A conditional random field representing the distribution of  $r$  earliest arriving signals

Finally, we marginalize out  $t_1, t_2, \dots, t_s$  and  $n_1, n_2, \dots, n_r$ , so that we can represent the conditional distribution as a simpler pairwise conditional random field as in Figure 3, where no factor uses the delta function, simplifying computation.

In the conditional random field shown in Figure 3, the factor  $f(X_t, S_i)$  is given by

$$f(X_t, S_i) = \begin{cases} 1 - P_D & \text{if } S_i = \mathbb{M} \\ P_D \int_{T_r}^{+\infty} p_i(T|X_t) dT & \text{if } S_i = \mathbb{L} \\ P_D p_i(T_{S_i}|X_t) & \text{otherwise} \end{cases} \quad (14)$$

In the RAFOS tracking problem  $p_i(T|X_t) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left\{-\frac{(T - \frac{\|X_t - b_i\|_2}{v_s})^2}{2\sigma^2}\right\}$  is the distribution of signal arrival time  $T$  given the location  $X_t$  of the target, and the factor  $f(X_t, R_j)$  is given by

$$f(R_j) = \begin{cases} P_C p_N(T_j) & \text{if } R_j = \mathbb{C} \\ 1 - P_C & \text{otherwise} \end{cases} \quad (15)$$

where  $p_N(T)$  is the distribution of clutter signal arrival time.

**Alternative Derivation of the Bipartite Model** Here we show an alternative and more intuitive derivation of the bipartite model assuming that the number of clutter signals follows a Poisson distribution with parameter  $\lambda$  and clutter signals are independent and identically distributed. We also assume that the distribution of signals from different

signal sources are independent, and whether or not a signal is missing and non-detectable at the target is independent of all other signals.

Assume that the target's location is  $X$ , and there are  $N$  clutter signals, the likelihood of observing  $T_1 \leq T_2 \leq \dots \leq T_r$  with labels  $S_1, S_r, \dots, S_s$  and  $R_1, R_2, \dots, R_r$  is proportional to

$$\ell_N = \frac{N!}{(N - \sum \mathbf{1}(R_j = C))!} (1 - P_D)^{\sum \mathbf{1}(S_i = M)} P_D^{\sum \mathbf{1}(S_i \neq M)} \left( \int_{T_r}^{+\infty} p_N(t) dt \right)^{N - \sum \mathbf{1}(R_j = C)} \prod_{R_j = C} p_N(T_j) \prod_{S_i \neq L, M} p_i(T_{S_i} | X) \prod_{S_i = L} \int_{T_r}^{+\infty} p_i(t | X) dt \quad (16)$$

Marginalizing out  $N$  we then have

$$\sum_N e^{-\lambda} \frac{\lambda^N}{N!} \ell_N \propto \lambda^{\sum \mathbf{1}(R_j = C)} (1 - P_D)^{\sum \mathbf{1}(S_i = M)} P_D^{\sum \mathbf{1}(S_i \neq M)} \prod_{R_j = C} p_N(T_j) \prod_{S_i \neq L, M} p_i(T_{S_i} | X) \prod_{S_i = L} \int_{T_r}^{+\infty} p_i(t | X) dt \quad (17)$$

Thus if we set

$$P_C = \frac{\lambda}{1 + \lambda} \quad (18)$$

then it is clear that we can represent this distribution using the conditional random field shown in Figure 3.

### 2.3 INFERENCE

We use a hybrid particle filtering and belief propagation approach. For propagating information across time steps, i.e. between the nodes  $X_{t-1}$  and  $X_t$ , we use particle filtering (Doucet & Johansen, 2009). Particle based methods are simple to implement for tracking with range measurements (Cevher *et al.*, 2006). Such methods have also been widely used in robotics (Thrun *et al.*, 2005).

The distribution for each  $X_t$  is represented by a set of particles, we use message passing in the graphical model shown in Figure 3 to compute  $P(T_1, T_2, \dots, T_r | X_t)$ , which is given by the partition function and can be approximated by the Bethe free energy (Huang & Jebara, 2009). In this graphical model, message passing equations have a simple form where each iteration is  $O(sr)$  (Huang & Jebara, 2009; Williams & Lau, 2010), and message passing converges to a unique fixed point (Huang & Jebara, 2009; Williams & Lau, 2010; Vontobel, 2013). Previous work (Huang & Jebara, 2009; Williams & Lau, 2010; Chertkov *et al.*, 2010) has shown this strategy to be very effective.

An implementation of the tracking algorithm to estimate  $X_1, X_2, \dots, X_n$  where we are given the initial position of the target  $X_0$ , and  $n$  observations of ranked signals  $\{T_1^{(i)} \leq T_2^{(i)} \leq \dots \leq T_r^{(i)}\}_{i=1}^n$  is given in Algorithm 1.

## 3 EXPERIMENTS

We present experiments on two kinds of datasets: simulated data generated using our model (Figure 3) and real world data from RAFOS floats.

### 3.1 SIMULATIONS

We simulate tracking RAFOS floats using ranked continuous range measurements with our method. At each time step, the target records the arrival times of the first 4 signals emitted from 10 fixed beacons. There is a fixed probability that a signal may not be detectable at the target, and the target may record the arrival time of a spurious signal (clutter) if the spurious signal arrives before an actual signal.

#### 3.1.1 SIMULATION OF TRACKING DIFFERENT TRAJECTORIES

Figure 4a shows our algorithm tracking a target moving in a straight line: the  $x$  and  $y$  axes correspond to the  $x$  and  $y$  coordinates of the 2D location of the signal. The corresponding signal arrival times are shown in Figure 4b. Similarly, Figure 5a shows our algorithm tracking a target moving in a spiral, signal arrival times are shown in Figure 5b. In the simulations, there are 10 signal sources and 4 signal arrival times. Clutter arrival times are uniformly distributed on a predefined interval, and the number of clutter signals follows a Poisson distribution with parameter 4, so that  $P_C = \frac{4}{1+4} = 0.8$ . The signal arrival time distribution  $p_i$  has parameter  $\sigma = 0.02$ , and  $P_D = 0.7$ . We can see that our algorithm correctly tracks the target when the

Figure 4: Our algorithm tracking a target moving in a straight line

Figure 5: Our algorithm tracking a target moving in a spiral

association between signal arrival times and signal sources changes.

### 3.1.2 COMPARISON WITH THE BASELINE ALGORITHM

We compare our algorithm against a baseline algorithm which does not take into account that signal arrival times are ranked. The overall structure of the baseline model is the same as that of the graphical model shown in Figure 3, however the factor  $f(X_t, S_i)$  is given by

$$f(X_t, S_i) = \begin{cases} P_D p_i(T_{S_i} | X_t) & \text{if } S_i \neq \text{L and } S_i \neq \text{M} \\ 1 - P_D & \text{if } S_i = \text{L or } S_i = \text{M} \end{cases} \quad (19)$$

so that the implicit ranking of signal arrival times is not taken into account.

Figure 6b shows the mean squared error against the noise level when tracking the straight trajectory shown in Figure 6a. The noise level is indicated by a parameter  $\lambda$  such that  $P_C = \frac{\lambda}{1+\lambda}$ . The parameter  $\lambda$  corresponds to the Poisson parameter for the number of clutter signals (see Appendix). Signal arrival time distribution  $p_i$  has parameter  $\sigma = 0.02$ , and  $P_D = 0.7$ . We can see that our algorithm outperforms the baseline algorithm.

## 3.2 RAFOS FLOAT DATA

We present tracking results on real world RAFOS float data which consists of ranked continuous signal arrival times. We compare the results of our algorithm against hand labeled data where each signal is hand labeled with a par-

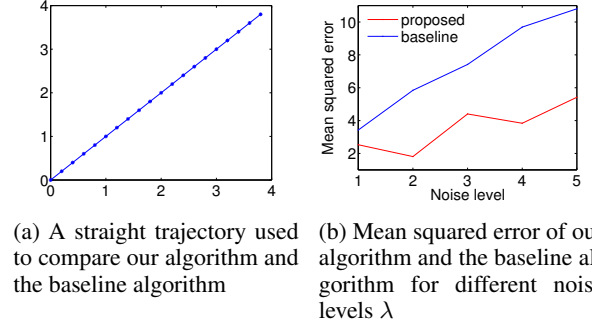

Figure 6: Simulation comparing our proposed algorithm and the baseline

ticular signal source or as clutter. In RAFOS float missions, after a float is released at a known location to start its mission, it records a fixed number of arrival times from a set of beacons whose positions are fixed and known. The dataset presented here are collected in the DIMES (Diapycnal and Isopycnal Mixing Experiment in the Southern Ocean) project (Hancock & Speer, 2013), which is aimed at measuring diapycnal and isopycnal mixing in the Southern Ocean, along the tilting isopycnals of the Antarctic Circumpolar Current. In our dataset, the float records 4 earliest signal arrival times, and there are 10 beacons. The floats are first released off the western coast of South America. There were just two floats — #767 and #811 — for which at least three beacon signals were recorded at all time steps (note that at least three beacon signals are required to uniquely identify the 2D position of the float), and accordingly, we present our results on tracking these two floats. Their signal arrival times are shown in Figure 1. We compare our algorithm's results to a manual tracking procedure where each signal is hand labeled to its source or as noise based on intuition and some apriori knowledge of the physical factors (geometry of ocean basin and acoustic array, basic knowledge of current directions etc.) at play.

Note that the *true* locations of the RAFOS floats are not known and that the hand labeled data only contains the associations between signal arrival times and their corresponding signal sources (or whether they are clutter). Hence, we obtain a trajectory for the hand labeled data using a simple particle filter. At each time step  $T_1 \leq T_2, \dots \leq T_r$  and  $R_1, R_2, \dots, R_r$  are known, so the weight of a particle at  $X$  is given by

$$w(X) \propto \prod_{1 \leq j \leq r} p_{R_j}(T_j | X) \quad (20)$$

When running our proposed algorithm and the one using hand labeled data for RAFOS float tracking, we set  $P_C = 0.5$ ,  $P_D = 0.9$ ,  $\sigma = 5$ . Although in the real environment the speed of sound depends on the depth of the RAFOS float and other environmental factors, in our experiments we set  $v_s = 1.5$  km/s across all cases.

Figure 7: Trajectory of float #767 estimated by our proposed algorithm versus using hand labeled data

Figure 8: Trajectory of float #811 estimated by our proposed algorithm versus using hand labeled data

The results for longitude and latitude of float #767 and #811 estimated by our algorithm versus using hand labeled data are shown in Figure 7 and Figure 8 respectively. Additional results for other floats in the DIMES project are presented in the appendix. We observe good agreement between the tracks estimated using hand labeled data and using our method indicating that our method recovers the associations. We can also see that our algorithm continues to track the target when the set of associated signal sources changes.

#### 4 CONCLUSIONS

We have presented a novel graphical model approach for the problem of tracking with ranked signals which was able to capture certain problem specific features easily. The key novelty in the model, from a machine learning point of view, was the presence of ranking-based factors. We have provided a novel bipartite construction which allows for easy inference via message passing for such factors. While our model and approach were motivated by a particular application, the contributions of this paper should

be applicable to other problems where ranking based high-order factors are involved.

We experimentally showed that our method effectively leverages the varied problem constraints to improve tracking accuracy over baseline tracking methods. We applied our method for tracking with ranked signals to a key Oceanography problem of tracking RAFOS floats in the ocean and thus provide an automated solution to a problem which has previously required significant manual effort.

## Abstract

This paper presents a kernel-based framework for classification of sparse and irregularly sampled time series. The properties of such time series can result in substantial uncertainty about the values of the underlying temporal processes, while making the data difficult to deal with using standard classification methods that assume fixed-dimensional feature spaces. To address these challenges, we propose to first re-represent each time series through the Gaussian process (GP) posterior it induces under a GP regression model. We then define kernels over the space of GP posteriors and apply standard kernel-based classification. Our primary contributions are (i) the development of a kernel between GPs based on the mixture of kernels between their finite marginals, (ii) the development and analysis of extensions of random Fourier features for scaling the proposed kernel to large-scale data, and (iii) an extensive empirical analysis of both the classification performance and scalability of our proposed approach.

## 1 INTRODUCTION

In this paper, we address the problem of classification of sparse and irregularly sampled time series. Irregularly sampled (or non-uniformly sampled) time series are characterized by variable time intervals between successive observations. While all time series in a data set are typically defined on the same continuous-time interval, the number of observations per time series can vary. When the intervals between successive observations are long, the time series are said to be sparsely sampled.

Such time series data arise when sampling complex temporal processes in a number of important areas including climate science [Schulz and Stattegger, 1997], ecology [Clark

and Bjørnstad, 2004], biology [Ruf, 1999], medicine [Marlin et al., 2012] and astronomy [Scargle, 1982]. In domains including medicine, the data are both irregularly sampled and sparsely sampled [Marlin et al., 2012]. Classification in this setting is challenging both because the data cases are not naturally defined in a fixed-dimensional feature space due to irregular sampling and variable time series length, and because there can be substantial uncertainty about the underlying temporal processes due to the sparsity of observations.

To address these challenges, we begin by re-representing each input time series using the Gaussian process (GP) posterior it induces under a GP regression model [Rasmussen and Williams, 2006]. We then define kernels over the space of GP posteriors and apply standard kernel-based classification methods [Cortes and Vapnik, 1995]. We propose a kernel between GPs based on the mixture of kernels between finite dimensional GP marginal distributions defined over sliding time windows. We refer to this as the *mixture of sliding GP marginal kernels (MSM)* framework.

The MSM kernel framework requires a base kernel between finite-dimensional GP marginals, which are Gaussian distributions. While the MSM framework can be used with any valid base kernel between two Gaussian distributions, we propose an uncertainty-aware base kernel that we refer to as the *expected Gaussian kernel* to address the uncertainty that results from sparse sampling. Using the expected Gaussian kernel in the MSM framework yields a kernel between Gaussian processes that we refer to as the *mixture of expected Gaussian kernels (MEG)*.

Next, we consider the problem of scaling our proposed kernel-based time series classification framework to large-scale data. Computing the exact Gram matrix for the proposed MEG kernel with  $n$  time series takes  $\mathcal{O}(n^2 d^3 k)$  time when  $k$  sliding windows of length  $d$  are used. To address this problem, we show how to extend the random Fourier feature kernel approximation framework [Rahimi and Recht, 2007] to the MEG kernel. Using our random feature construction, it takes  $\mathcal{O}(nMd^2)$  time to compute the random feature matrix using  $M$  random features for

each time series. We then show how to use Fastfood [Le et al., 2013] to reduce the random feature computation time to  $\mathcal{O}(nMd \log d)$  when the window size  $d$  is large. With an extra rank- $r$  covariance approximation, we can further reduce this time to  $\mathcal{O}(nMr \log d)$  for  $r \ll d$ . Finally, we provide a convergence analysis of our proposed approximation based on the recently developed matrix Bernstein inequality [Lopez-Paz et al., 2014; Tropp, 2012a].

The primary contributions of this paper are:

1. The development of an uncertainty-aware kernel for GPs based on the mixture of kernels between their finite-dimensional marginals (Section 3).
2. The development and analysis of an extension of random Fourier features for scaling the proposed kernel to large-scale data (Section 4).
3. An extensive empirical analysis of both the classification performance and scalability of our proposed approach (Section 5).

In Section 2, we begin by describing how to represent sparse and irregularly sampled time series using Gaussian processes, which are a fundamental building block of our proposed framework.

## 2 SPARSE AND IRREGULARLY SAMPLED TIME SERIES

Our focus in this paper is classification of time series data in the presence of sparse and irregular sampling. Consider a data set of  $n$  independent time series  $\mathcal{D} = \{\mathcal{S}_1, \dots, \mathcal{S}_n\}$ , where each time series  $\mathcal{S}_i$  is represented as a list of time points  $\mathbf{t}_i = [t_{i1}, \dots, t_{i|\mathcal{S}_i}|]^\top$ , and a list of corresponding values  $\mathbf{y}_i = [y_{i1}, \dots, y_{i|\mathcal{S}_i}|]^\top$ . We assume that each time series is defined over a common continuous-time interval  $[0, T]$ . However, for irregularly sampled time series we do not assume that all of the time series are defined on the same collection of time points (i.e.,  $\mathbf{t}_i \neq \mathbf{t}_j$  in general), we do not assume that the intervals between time points are uniform, and we do not assume that the number of observations in different time series is the same (i.e.,  $|\mathcal{S}_i| \neq |\mathcal{S}_j|$  in general).

Learning in this setting is challenging because the data cases are not naturally defined in a fixed-dimensional feature space due to irregular sampling, and there can be substantial uncertainty about the underlying temporal processes due to the sparsity of observations.

To address these challenges, we begin by re-representing each input time series using the Gaussian process (GP) posterior it induces under a Gaussian process regression model [Rasmussen and Williams, 2006]. This construction naturally accommodates sparse and irregularly sampled time

series. To obtain the posterior GPs, we use a Gaussian likelihood function with noise variance  $\sigma^2$ , and a zero-mean GP prior with the squared exponential covariance function

$$\mathcal{K}_{\text{SE}}(t_i, t_j) = a \exp(-b(t_i - t_j)^2), \text{ for } a, b > 0.$$

We learn the hyperparameters  $a, b, \sigma$  of the GP regression model by maximizing the marginal likelihood of the data.<sup>1</sup> Under this model, the posterior distribution induced by each time series  $\mathcal{S}$  is also a Gaussian process. By definition, any finite marginal of a GP is Gaussian distributed. Let  $\mathcal{GP}(\mathbf{u} | \mathcal{S} = \{\mathbf{t}, \mathbf{y}\}) = \mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$  denote the posterior GP marginal of  $\mathcal{S}$  over a collection of time points  $\mathbf{u}$ . The mean and covariance of the Gaussian posterior marginal  $\mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$  is given below where  $[K(\mathbf{u}, \mathbf{t})]_{ij} = \mathcal{K}_{\text{SE}}(u_i, t_j)$ .

$$\begin{aligned} \boldsymbol{\mu} &= K(\mathbf{u}, \mathbf{t}) (K(\mathbf{t}, \mathbf{t}) + \sigma^2 \mathbf{I})^{-1} \mathbf{y}, \\ \boldsymbol{\Sigma} &= K(\mathbf{u}, \mathbf{u}) - K(\mathbf{u}, \mathbf{t}) (K(\mathbf{t}, \mathbf{t}) + \sigma^2 \mathbf{I})^{-1} K(\mathbf{t}, \mathbf{u}). \end{aligned} \quad (1)$$

Applying GP regression requires  $\mathcal{O}(|\mathcal{S}|^3)$  time due to the matrix inversion in (1). We note that efficient approximation algorithms are available when working with long time series [Hensman et al., 2013; Quiñero-Candela and Rasmussen, 2005].

In the next section, we describe our proposed framework for defining kernels between time series based on Gaussian processes.

## 3 KERNELS FOR TIME SERIES

In this section, we first introduce the general mixture of sliding GP marginal kernels (MSM) framework for sparse and irregularly sampled data. We then introduce the expected Gaussian kernel, which serves as an uncertainty-aware base kernel within the MSM framework.

### 3.1 THE MIXTURE OF SLIDING GP MARGINAL KERNELS

As described in Section 2, we represent each time series  $\mathcal{S}$  in a data set  $\mathcal{D}$  using the posterior Gaussian process it induces under a GP regression model. The proposed mixture of sliding GP marginal kernels  $\mathcal{K}_{\text{MSM}}^{(d)}$  defines a kernel between a pair of time series through a weighted average of a base kernel  $\mathcal{K}_{\text{B}}$  applied to a collection of finite posterior GP marginals. Specifically, let  $u_1, \dots, u_L$  be a uniformly-spaced set of  $L$  time points on  $[0, T]$ , and  $\mathbf{u}^{(s)} = [u_s, \dots, u_{s+d-1}]^\top$  be a window of  $d$  time points starting at  $u_s$ . The MSM kernel compares the posterior GP marginals over the complete collection of valid sliding windows  $\mathbf{u}^{(1)}, \dots, \mathbf{u}^{(L-d+1)}$  as shown below, provided  $w_s \geq 0$  for all  $s$ .

$$\mathcal{K}_{\text{MSM}}^{(d)}(\mathcal{S}_i, \mathcal{S}_j) = \sum_{s=1}^{L-d+1} w_s \mathcal{K}_{\text{B}}\left(\mathcal{GP}(\mathbf{u}^{(s)} | \mathcal{S}_i), \mathcal{GP}(\mathbf{u}^{(s)} | \mathcal{S}_j)\right)$$

<sup>1</sup>See Rasmussen and Williams [2006] for details.

The length of the windows  $d$  is a hyper-parameter of the MSM kernel. In this work, we choose uniform kernel mixture weights  $w_s = 1/k$ . Alternatively, the kernel weights can be learned from data using multiple kernel learning algorithms [Bach et al., 2004].

The base kernel  $\mathcal{K}_B$  can be any valid kernel that takes as input two  $d$ -dimensional Gaussians. Of particular interest are uncertainty-aware base kernels that use the covariance information in the posterior marginals to modulate the similarity between the distributions. We present an uncertainty-aware expected Gaussian kernel in Section 3.3, but first describe a simpler kernel to highlight the trade-offs induced by the window length parameter  $d$ .

### 3.2 GAUSSIAN KERNEL ON MARGINAL MEANS

The Gaussian kernel  $\mathcal{K}_G$  below is one of the most widely used kernels in machine learning.

$$\mathcal{K}_G(\mathbf{x}_i, \mathbf{x}_j) = \exp\left(-\frac{1}{2\gamma^2}\|\mathbf{x}_i - \mathbf{x}_j\|^2\right) \quad (2)$$

The parameter  $\gamma$  controls the bandwidth of the kernel. The Gaussian kernel  $\mathcal{K}_G$  provides a simple kernel  $\mathcal{K}_{G\mu}$  between Gaussian distributions  $\mathcal{N}_i = \mathcal{N}(\boldsymbol{\mu}_i, \boldsymbol{\Sigma}_i)$  and  $\mathcal{N}_j = \mathcal{N}(\boldsymbol{\mu}_j, \boldsymbol{\Sigma}_j)$  when applied to their mean vectors as follows.

$$\mathcal{K}_{G\mu}(\mathcal{N}_i, \mathcal{N}_j) = \mathcal{K}_G(\boldsymbol{\mu}_i, \boldsymbol{\mu}_j) \quad (3)$$

Importantly, this kernel is not uncertainty aware as it discards the covariances from the posterior Gaussians. We use the notation  $\mathcal{K}_{MG}^{(d)}$  to denote the use of  $\mathcal{K}_{G\mu}$  as the base kernel within the MSM framework. In the case where  $d = 1$ , the  $\mathcal{K}_{MG}^{(d)}$  kernel corresponds to taking the average similarity between the means of the two marginal posterior distributions as seen below.

$$\mathcal{K}_{MG}^{(1)}(\mathcal{S}_i, \mathcal{S}_j) = \frac{1}{L} \sum_{s=1}^L \exp\left(-\frac{1}{2\gamma^2}(\mu_{is} - \mu_{js})^2\right)$$

On the other hand, when  $d = L$ , the  $\mathcal{K}_{MG}^{(d)}$  kernel is equivalent to a product of the similarities between the means of the two marginal posterior distributions as seen below.

$$\begin{aligned} \mathcal{K}_{MG}^{(L)}(\mathcal{S}_i, \mathcal{S}_j) &= \exp\left(-\frac{1}{2\gamma^2} \sum_{s=1}^L (\mu_{is} - \mu_{js})^2\right) \\ &= \prod_{s=1}^L \exp\left(-\frac{1}{2\gamma^2} (\mu_{is} - \mu_{js})^2\right) \end{aligned}$$

This comparison shows that  $\mathcal{K}_{MG}^{(1)}$  is much more likely to be robust to the influence of noise and outliers due to the use of averaging, but it ignores the broader structure across time points. On the other hand,  $\mathcal{K}_{MG}^{(L)}$  captures the broader structure across time points, but may be more sensitive to

the presence of noise and outliers due to the product form of the kernel. Importantly, the MSM kernel framework is able to balance these considerations by allowing for the selection of intermediate window lengths  $d$ .

### 3.3 THE EXPECTED GAUSSIAN KERNEL

In this section, we present an uncertainty-aware base kernel  $\mathcal{K}_{EG}$ , which we refer to as the *expected Gaussian kernel*. This kernel is obtained as the expectation of the standard Gaussian kernel shown in (2) under the two independent Gaussians  $\mathcal{N}_i$  and  $\mathcal{N}_j$

$$\mathcal{K}_{EG}(\mathcal{N}_i, \mathcal{N}_j) = \mathbb{E}_{\mathbf{x}_i \sim \mathcal{N}_i, \mathbf{x}_j \sim \mathcal{N}_j} [\mathcal{K}_G(\mathbf{x}_i, \mathbf{x}_j)].$$

Importantly, the value of the expected Gaussian kernel can be computed analytically as shown in (4) where  $\tilde{\boldsymbol{\mu}} = \boldsymbol{\mu}_i - \boldsymbol{\mu}_j$  and  $\tilde{\boldsymbol{\Sigma}} = \boldsymbol{\Sigma}_i + \boldsymbol{\Sigma}_j + \gamma^2 \mathbf{I}$ . (see Appendix A for the derivation).

$$\mathcal{K}_{EG}(\mathcal{N}_i, \mathcal{N}_j) = \sqrt{\frac{|\boldsymbol{\Sigma}|}{|\tilde{\boldsymbol{\Sigma}}|}} \exp\left(-\frac{1}{2} \tilde{\boldsymbol{\mu}}^\top \tilde{\boldsymbol{\Sigma}}^{-1} \tilde{\boldsymbol{\mu}}\right). \quad (4)$$

The positive definiteness of the expected Gaussian kernel follows from the fact that the Gaussian kernel is positive definite and therefore there exists a map  $\phi$  such that the kernel acts as a dot product  $\langle \phi(\mathbf{x}_i), \phi(\mathbf{x}_j) \rangle$ . With the independence assumption, the expected Gaussian kernel also acts as a dot product over the expected map [Smola et al., 2007].

$$\begin{aligned} \mathcal{K}_{EG}(\mathcal{N}_i, \mathcal{N}_j) &= \mathbb{E}_{\mathbf{x}_i \sim \mathcal{N}_i, \mathbf{x}_j \sim \mathcal{N}_j} \langle \phi(\mathbf{x}_i), \phi(\mathbf{x}_j) \rangle \\ &= \langle \mathbb{E}_{\mathbf{x} \sim \mathcal{N}_i} [\phi(\mathbf{x})], \mathbb{E}_{\mathbf{x} \sim \mathcal{N}_j} [\phi(\mathbf{x})] \rangle. \end{aligned}$$

Interestingly, the probability product kernel of Jebara et al. [2004] applied to a pair of Gaussian distributions

$$\mathcal{K}_{PP}(\mathcal{N}_i, \mathcal{N}_j) = \int \mathcal{N}(\mathbf{x}; \boldsymbol{\mu}_i, \boldsymbol{\Sigma}_i)^\rho \mathcal{N}(\mathbf{x}; \boldsymbol{\mu}_j, \boldsymbol{\Sigma}_j)^\rho d\mathbf{x}$$

when  $\rho = 1$  (also known as the expected likelihood kernel) is a limiting case of the expected Gaussian kernel as  $\gamma \rightarrow 0$ . In this case, the  $\mathcal{K}_G$  term inside  $\mathcal{K}_{EG}$  degenerates to the Dirac delta function  $\delta(\mathbf{x}_i - \mathbf{x}_j)$ , and the expected Gaussian kernel collapses to the probability product kernel with  $\rho = 1$  by the sifting property of the delta function.

We refer to the use of the expected Gaussian kernel within the MSM framework as the *mixture of expected Gaussian kernels (MEG)*. Similar to  $\mathcal{K}_{MG}^{(d)}$ , the MEG kernel is able to strike a balance between the use of averaging to mitigate noise and the use of higher-dimensional marginals to capture broader temporal structure under uncertainty through the choice of  $d$ .

In terms of computational complexity, computing the expected Gaussian kernel (4) for  $d$ -dimensional Gaussians takes  $\mathcal{O}(d^3)$  time because of the inversion of  $\tilde{\boldsymbol{\Sigma}}$  and the

computation of its determinant. As a result, for the MEG kernel involving  $k$  GP marginals of  $d$  dimensions, it takes  $\mathcal{O}(kn^2d^3)$  time to compute the  $n \times n$  kernel matrix over  $n$  data cases. In the next section, we discuss scaling learning with MEG kernels to large data sets using random feature approximations.

## 4 RANDOM FOURIER FEATURES

The  $\mathcal{O}(n^2)$  kernel matrix computation time is a significant limitation when working with large data sets. Random Fourier feature approximation [Rahimi and Recht, 2007] is a kernel approximation algorithm based on Bochner’s theorem that maps the input data into a randomized low-dimensional feature space to approximate a shift-invariant kernel. In this section, we show how to extend this idea to scale-up learning with expected Gaussian kernels and apply the result to the MEG kernel.

### 4.1 RANDOM FEATURES FOR EXPECTED GAUSSIAN KERNELS

Following the construction presented by Rahimi and Recht [2007], the Gaussian kernel  $\mathcal{K}_G$  defined in (2) can be approximated by an  $m$ -dimensional random vector

$$\mathbf{z}(\mathbf{x}) = \sqrt{\frac{2}{m}} \left[ \cos(\mathbf{w}_1^\top \mathbf{x} + b_1), \dots, \cos(\mathbf{w}_m^\top \mathbf{x} + b_m) \right]^\top,$$

where  $\mathbf{w}_i \sim \mathcal{N}(\mathbf{0}, \gamma^{-2}\mathbf{I})$ ,<sup>2</sup> and  $b_i \sim \text{uniform}(0, 2\pi)$  so that  $\mathcal{K}_G(\mathbf{x}_i, \mathbf{x}_j) \approx \mathbf{z}(\mathbf{x}_i)^\top \mathbf{z}(\mathbf{x}_j)$ .

The analytic form of the expected Gaussian kernel given in (4) is not shift invariant in terms of the means and covariances of the input Gaussians, and therefore we cannot directly expand the kernel as in Rahimi and Recht [2007]. However, we can derive the random Fourier features for the expected Gaussian kernel by taking the expectation after Gaussian kernel expansion. With the independence of the input Gaussians, we have

$$\begin{aligned} \mathbb{E}_{\mathbf{x}_i, \mathbf{x}_j} [\mathcal{K}_G(\mathbf{x}_i, \mathbf{x}_j)] &\approx \mathbb{E}_{\mathbf{x}_i, \mathbf{x}_j} [\mathbf{z}(\mathbf{x}_i)^\top \mathbf{z}(\mathbf{x}_j)] \\ &= \mathbb{E}_{\mathbf{x}_i} [\mathbf{z}(\mathbf{x}_i)]^\top \mathbb{E}_{\mathbf{x}_j} [\mathbf{z}(\mathbf{x}_j)]. \end{aligned}$$

Next, we note that each entry of  $\mathbb{E}_{\mathbf{x} \sim \mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})} [\mathbf{z}(\mathbf{x})]$  can be obtained analytically as shown below. This result exploits the fact that the expectation of the complex random feature map  $\exp(i\mathbf{w}^\top \mathbf{x})$  derived from the Fourier expansion of the kernel function is the characteristic function of the distribution of  $\mathbf{x}$ . A detailed derivation is given in Appendix B.

$$\begin{aligned} \mathbb{E}[z_i(\mathbf{x})] &= \sqrt{\frac{2}{m}} \mathbb{E}_{\mathbf{x} \sim \mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})} [\cos(\mathbf{w}_i^\top \mathbf{x} + b_i)] \\ &= \sqrt{\frac{2}{m}} \exp\left(-\frac{1}{2} \mathbf{w}_i^\top \boldsymbol{\Sigma} \mathbf{w}_i\right) \cos(\mathbf{w}_i^\top \boldsymbol{\mu} + b_i). \end{aligned}$$

<sup>2</sup>  $\mathbf{w}_i \sim \mathcal{N}(\mathbf{0}, \gamma^{-2}\mathbf{I})$  can be done with each entry drawn independently from  $\mathcal{N}(0, \gamma^{-2})$ .

---

### Algorithm 1: Random Fourier Features for $\mathcal{K}_{EG}$

---

**Input:** A Gaussian  $\mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$  with mean  $\boldsymbol{\mu}$  and covariance  $\boldsymbol{\Sigma}$ . Width parameter  $\gamma^2$  of the Gaussian kernel.

Number of random features  $m$ .

$\mathbf{w}_1, \dots, \mathbf{w}_m \stackrel{\text{iid}}{\sim} \mathcal{N}(\mathbf{0}, \gamma^{-2}\mathbf{I})$

$b_1, \dots, b_m \stackrel{\text{iid}}{\sim} \text{uniform}(0, 2\pi)$

**return**  $\sqrt{\frac{2}{m}} \begin{bmatrix} \exp\left(-\frac{1}{2} \mathbf{w}_1^\top \boldsymbol{\Sigma} \mathbf{w}_1\right) \cos(\mathbf{w}_1^\top \boldsymbol{\mu} + b_1) \\ \vdots \\ \exp\left(-\frac{1}{2} \mathbf{w}_m^\top \boldsymbol{\Sigma} \mathbf{w}_m\right) \cos(\mathbf{w}_m^\top \boldsymbol{\mu} + b_m) \end{bmatrix}$

---

As we can see, each random feature for an expected Gaussian kernel is the product of  $\sqrt{2/m} \cos(\mathbf{w}_i^\top \boldsymbol{\mu} + b_i)$  and  $\exp\left(-\frac{1}{2} \mathbf{w}_i^\top \boldsymbol{\Sigma} \mathbf{w}_i\right)$ . The former is identical to the random Fourier feature with the Gaussian mean as input. The latter is an exponential decay term that decreases as uncertainty in the distribution increases.

The complete procedure for obtaining a random features approximation for the expected Gaussian kernel is given in Algorithm 1.

For the  $d$ -dimensional case, approximating an expected Gaussian kernel with  $m$  random features using Algorithm 1 requires  $\mathcal{O}(md^2)$  time as it takes  $\mathcal{O}(d^2)$  time to compute the quadratic term  $\mathbf{w}^\top \boldsymbol{\Sigma} \mathbf{w}$ . As a result, given a data set of size  $n$ , it takes  $\mathcal{O}(nmd^2)$  to compute the  $n \times m$  feature matrix. This is more efficient compared to the  $\mathcal{O}(n^2d^3)$  time needed to compute the exact kernel, especially when  $n \gg m$ .

### 4.2 ACCELERATION FOR HIGH-DIMENSIONAL GAUSSIANS

The  $\mathcal{O}(d^2)$  time for computing the random features can be computationally prohibitive when working with high-dimensional Gaussians. Le et al. [2013] proposed Fastfood to accelerate the computation of the original random Fourier features of Rahimi and Recht [2007]. Fastfood utilizes the fast Walsh-Hadamard transform to simulate a full Gaussian random matrix using a small portion of i.i.d. Gaussian samples. Essentially, given a vector  $\mathbf{x} \in \mathbb{R}^d$ , Fastfood approximates the matrix-vector product  $\mathbf{V}\mathbf{x}$  in  $\mathcal{O}(m \log d)$  time instead of  $\mathcal{O}(md)$ , where  $\mathbf{V}$  is an  $m \times d$  random matrix with each entry drawn independently from  $\mathcal{N}(0, \gamma^{-2})$ .

With Fastfood, computing the  $\cos(\mathbf{w}_i^\top \boldsymbol{\mu} + b_i)$  term for the expected Gaussian kernel for all  $i = 1, \dots, m$  can be done by first generating the random vector  $\mathbf{V}\boldsymbol{\mu}$  as described above. All  $m$  entries  $\cos([\mathbf{V}\boldsymbol{\mu}]_i + b_i)$  can then be computed in  $\mathcal{O}(m \log d)$  time.

The bottleneck for the expected Gaussian kernel is the computation of the exponential term  $\exp\left(-\frac{1}{2} \mathbf{w}_i^\top \boldsymbol{\Sigma} \mathbf{w}_i\right)$ , which needs  $\mathcal{O}(d^2)$  time if computed naively. This can also be

accelerated by using the Fastfood trick twice:

$$\exp\left(-\frac{1}{2}\mathbf{w}_i^\top \boldsymbol{\Sigma} \mathbf{w}_i\right) = \exp\left(-\frac{1}{2}[\mathbf{V}(\mathbf{V}\boldsymbol{\Sigma})^\top]_{ii}\right). \quad (5)$$

Following the stacking strategy in Le et al. [2013], we choose  $\mathbf{V}$  in (5) to be a  $d \times d$  square matrix<sup>3</sup>, and repeat this step  $\lceil m/d \rceil$  times to produce all  $m$  features. This leads to an overall cost of  $\mathcal{O}(md \log d)$  as opposed to the  $\mathcal{O}(md^2)$  time mentioned before to compute  $m$  random features for the expected Gaussian kernel taking on a single  $d$ -dimensional Gaussian input.

We can further reduce the cost by approximating the covariance matrix with a low rank matrix  $\boldsymbol{\Sigma} \approx \boldsymbol{\Phi}\boldsymbol{\Phi}^\top$  using truncated SVD where  $\boldsymbol{\Phi} \in \mathbb{R}^{d \times r}$ . There exists efficient algorithms to compute top- $r$  SVD such as randomized SVD [Halko et al., 2011] that requires  $\mathcal{O}(d^2 \log r)$  time in contrast with  $\mathcal{O}(d^3)$  for classical algorithms. With Fastfood, the exponential term can be approximated in  $\mathcal{O}(r \log d)$  time:

$$\exp\left(-\frac{1}{2}\mathbf{w}_i^\top \boldsymbol{\Sigma} \mathbf{w}_i\right) \approx \exp\left(-\frac{1}{2}\sum_{j=1}^r [\mathbf{V}\boldsymbol{\Phi}]_{ij}^2\right). \quad (6)$$

This leads to  $\mathcal{O}(mr \log d)$  time for some  $r < d$  to compute  $m$  random features for a single data case.

### 4.3 RANDOM FEATURES FOR THE MIXTURE OF EXPECTED GAUSSIAN KERNELS

Let  $\mathbf{z}(\mathcal{N})$  denote the random features for the expected Gaussian kernel computed by Algorithm 1. As described in Section 3.1, each time series  $\mathcal{S}_i$  is summarized by a collection of  $k$  Gaussian marginals  $\{\mathcal{N}_i^{(1)}, \dots, \mathcal{N}_i^{(k)}\}$  for all  $i$ . The mixture of expected Gaussian kernels can be approximated by the random features of the base kernel applied to each marginal:

$$\begin{aligned} \sum_{s=1}^k w_s \mathcal{K}_{\text{EG}}(\mathcal{N}_i^{(s)}, \mathcal{N}_j^{(s)}) &\approx \sum_s w_s \mathbf{z}_s(\mathcal{N}_i^{(s)})^\top \mathbf{z}_s(\mathcal{N}_j^{(s)}) \\ &= \sum_s \left(\sqrt{w_s} \mathbf{z}_s(\mathcal{N}_i^{(s)})\right)^\top \left(\sqrt{w_s} \mathbf{z}_s(\mathcal{N}_j^{(s)})\right). \end{aligned}$$

Equivalently, each time series can be expressed as the compound random feature map below to approximate the MEG kernel.

$$\widehat{\mathbf{z}}(\mathcal{S}) = \left[\sqrt{w_1} \mathbf{z}_1(\mathcal{N}^{(1)})^\top, \dots, \sqrt{w_k} \mathbf{z}_k(\mathcal{N}^{(k)})^\top\right]^\top. \quad (7)$$

In this work, we set  $w_s = 1/k$  for all  $k$  marginals, that is, the base kernels are weighted equally. Furthermore, each marginal  $\mathcal{N}^{(s)}$  is approximated by the same number of random features  $m$ . Therefore,  $\widehat{\mathbf{z}}(\mathcal{S})$  has  $mk$  random features

<sup>3</sup> Assume  $\boldsymbol{\Sigma}$  is properly padded so that the dimension becomes  $d = 2^\ell$  in order to perform Hadamard transform [Le et al., 2013].

in total. In Section 4.4, we will show that having the same number of random features for each marginal will lead to the lowest error bound under uniform weights.

In general,  $w_s$  can be the coefficients of any non-negative combination, either chosen according to domain knowledge or learned from data. Learning the weights from data with the random features given in (7) can be viewed as an approximation to multiple kernel learning [Bach et al., 2004]. Optimizing  $w_1, \dots, w_k$  is similar to Mahalanobis metric learning [Xing et al., 2002] for the diagonal case except that all random features come from the same base kernel share a scaling factor.

### 4.4 APPROXIMATION GUARANTEES

In this section, we analyze the approximation quality of the expected Gaussian kernel random features computed by Algorithm 1 in terms of the concentration of the approximating kernel matrix. Using the Hermitian matrix Bernstein inequality [Tropp, 2012a,b] and following a derivation similar to [Lopez-Paz et al., 2014], we can bound the spectral norm (denoted  $\|\cdot\|$ ) of the difference between the exact expected Gaussian kernel and its approximation.<sup>4</sup>

**Theorem 1.** *Given a data set with each example represented as a single Gaussian,  $\mathcal{N}_1, \dots, \mathcal{N}_n$ , let  $\mathbf{K} \in \mathbb{R}^{n \times n}$  be the expected Gaussian kernel matrix. Let  $\widehat{\mathbf{K}} \in \mathbb{R}^{n \times n}$ , with each entry  $[\widehat{\mathbf{K}}]_{ij} = \mathbf{z}(\mathcal{N}_i)^\top \mathbf{z}(\mathcal{N}_j)$ , be the approximation matrix constructed using Algorithm 1 with  $m$  random features. Then we have*

$$\mathbb{E}\|\widehat{\mathbf{K}} - \mathbf{K}\| \leq \frac{2n}{m} \sqrt{\frac{2 \log n}{m}} + \frac{2n \log n}{3m^2}.$$

The proof of Theorem 1 is given in Appendix C. It states that the error  $\mathbb{E}\|\widehat{\mathbf{K}} - \mathbf{K}\|$  is bounded by  $\mathcal{O}(n \log n)$  for  $n$  data cases with a fixed number of random features  $m$ . On the other hand, for a fixed number of data cases  $n$ , increasing the number of random features  $m$  induces an  $\mathcal{O}(m^{-3/2})$  reduction in error.

As for the high-dimensional case described in Section 4.2, Le et al. [2013] have shown that the Fastfood feature map is unbiased, and therefore Theorem 1 also holds for the random features computed by Fastfood using (5). However, with the low-rank approximation used in (6),  $\widehat{\mathbf{K}}$  no longer converges to  $\mathbf{K}$  but instead converges to  $\widetilde{\mathbf{K}}$  where

$$[\widetilde{\mathbf{K}}]_{ij} = \mathcal{K}_{\text{EG}}\left(\mathcal{N}(\boldsymbol{\mu}_i, \boldsymbol{\Phi}_i \boldsymbol{\Phi}_i^\top), \mathcal{N}(\boldsymbol{\mu}_j, \boldsymbol{\Phi}_j \boldsymbol{\Phi}_j^\top)\right).$$

Following the construction described in Section 4.3, the mixture of  $k$  expected Gaussian kernels has a total of  $M = |\widehat{\mathbf{z}}(\mathcal{S})| = mk$  features. Since  $w_s = 1/k$  for all  $s$ , each entry of the feature vector is in the form of

<sup>4</sup> This bound can also be applied to the original random Fourier feature approximation [Rahimi and Recht, 2007].

$\sqrt{2/M} \mathbb{E}[\cos(\mathbf{w}^\top \mathbf{x} + b)]$ , whose absolute value is bounded by  $\sqrt{2/M}$ . Following the proof of Theorem 1, we can bound the error of using the proposed random feature approximation to the MEG kernel.

**Corollary 1.** Consider the MEG kernel consisting of  $k$  base kernels. Let  $\mathbf{K} \in \mathbb{R}^{n \times n}$  be the MEG kernel matrix, and  $\widehat{\mathbf{K}}$  be the approximating matrix using  $M = mk$  random features. Then,

$$\mathbb{E} \|\widehat{\mathbf{K}} - \mathbf{K}\| \leq \frac{2n}{M} \sqrt{\frac{2 \log n}{M}} + \frac{2n \log n}{3M^2}. \quad (8)$$

The expected error bound in Corollary 1 has the same form as that in Theorem 1 except the bound is determined by the number of total random features  $M$ . When the number of kernels  $k$  is large, even if each kernel is approximated by only a few random features, a low error bound can still be achieved if  $M = mk$  is sufficiently large.

As a matter of fact, for a *convex combination* of  $k$  expected Gaussian kernels with unequal weights, choosing the number of random features proportional to the corresponding kernel weight will achieve an error bound identical to (8) for a total of  $M$  random features.

## 5 EXPERIMENTS

We evaluate the proposed MEG kernel and the corresponding random feature approximation in terms of time series classification in the presence of sparse and irregular sampling. In the sections below, we describe the experimental methodology and the results.

### 5.1 EXPERIMENTAL METHODOLOGY

**Data.** We conduct experiments on all 43 time series data sets from the UCR time series classification archive [Keogh et al., 2011]. The UCR archive contains a diverse collection of time series data sets that vary significantly in terms of length, number of classes, and number of data cases. However, all the data sets are densely and uniformly sampled. This allows us to perform controlled experiments where we decrease the sampling density and observe the effect on the relative performance of different classification methods. We consider ten different sampling densities from 10% to 100% in steps of 10%.

**Gaussian Process Representation.** Following Section 2, for each data set and each sampling density, we first learn the hyperparameters of the GP regression model by optimizing the log marginal likelihood over the observed data. As described in Section 3.1, we compute the posterior GP marginals over a uniformly-spaced grid of  $L$  points on  $[0, T]$ , where  $T$  is the common length of the fully observed time series of each data set. We select  $L = \min(3T, 500)$ .

**Kernel and Feature Normalization.** We apply standard

Figure 1: Comparing MSM kernel framework with different base kernels.

kernel normalization to all kernel matrices before averaging. We also normalize each random feature vector to have unit length. Empirically, we found that normalization improves the classification performance.

**Base Classifiers and Hyperparameters.** We use support vector machines (SVMs) for classification. For kernel-based methods we use libsvm [Chang and Lin, 2011] with precomputed kernels. For random feature approximation, we use liblinear [Fan et al., 2008], which is tailored for linear models. We use five-fold stratified cross validation to jointly select the SVM regularization parameter and the parameter  $\gamma$  for the expected Gaussian kernels.

**Accuracy Measures.** We assess the performance of each method in terms of classification accuracy using the benchmark train/test splits in the UCR archive. We report results in terms of average *accuracy ratios* over all 43 data sets to emphasize the relative differences between methods across different sampling densities. For a given data set and sampling density, the accuracy ratio for a method is the accuracy of the method divided by the accuracy of the best performing method on that data set and sampling density. We also report one-standard-error error bars.

### 5.2 EXPERIMENTS AND RESULTS

**Comparing Base Kernels for MSM Framework.** We evaluate several instances of the MSM framework using different base kernels. The linear MSM kernel  $\mathcal{K}_{\text{MLIN}}$  uses the linear kernel on the univariate marginal means  $\mathcal{K}_{\text{LIN}}(\mathcal{N}_i, \mathcal{N}_j) = \mu_i \mu_j$  as the base kernel. The Gaussian MSM kernel  $\mathcal{K}_{\text{MG}}$  uses  $\mathcal{K}_{G\mu}$  defined in (3) also on the univariate marginal means. We compare these baseline methods to two expected Gaussian kernel based MSM kernels: the MEG kernel  $\mathcal{K}_{\text{MEG}}^{(1)}$  on the univariate marginals, and the MEG kernel  $\mathcal{K}_{\text{MEG}}^{(10)}$  with a sliding window size of 10.

Figure 1 shows the classification performance of these methods on each sampling density. The Gaussian MSM kernel  $\mathcal{K}_{\text{MG}}$  significantly outperforms the linear MSM kernel  $\mathcal{K}_{\text{MLIN}}$ . However,  $\mathcal{K}_{\text{MEG}}^{(1)}$  and  $\mathcal{K}_{\text{MEG}}^{(10)}$  both outperform  $\mathcal{K}_{\text{MG}}$ , particularly under high sparsity. This is expected since  $\mathcal{K}_{\text{MEG}}^{(1)}$  and  $\mathcal{K}_{\text{MEG}}^{(10)}$  both capture posterior uncertainty while  $\mathcal{K}_{\text{MG}}$  does not.

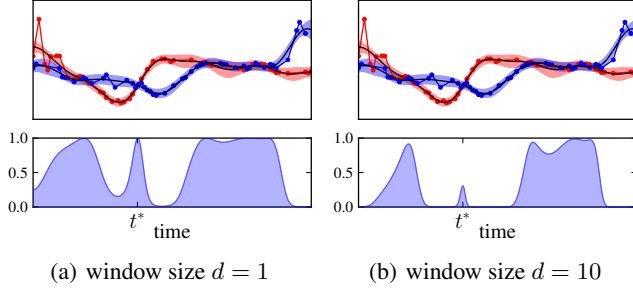

Figure 2: Comparison of different window size  $d$ . The plot on the top of each panel shows two time series from the ECG200 data set at 50% sampling density with visualization of their posterior Gaussian process. The plot on the bottom shows the value of the corresponding expected Gaussian kernel at each time slice.

Figure 3: Comparison of classification accuracy under different window sizes on ECG200 at 50% sampling density.

**Effect of Sliding Window Size for MEG Kernel.** Figure 2 illustrates how different window sizes affect the similarity output by the expected Gaussian kernel on the ECG200 data set from the UCR archive at 50% sampling density. The two time series intersect at around  $t^*$ ; however, they have opposite trends at this time point. Since  $\mathcal{K}_{\text{MEG}}^{(1)}$  does not take local correlation structure into account at all, it achieves the highest possible value at  $t^*$ . On the other hand,  $\mathcal{K}_{\text{MEG}}^{(10)}$  outputs a low value at  $t^*$  since a larger window captures the fact that the two processes are anti-correlated in the neighborhood of  $t^*$ .

Figure 3 shows the classification performance across various window sizes ranging from 1 to  $L$  on the ECG200 data set at 50% sampling density. For this experiment, we fixed the SVM regularization parameter to  $C = 2000$ , and the covariance parameter of the expected Gaussian kernel to  $\gamma = 0.01d$ , which grows linearly as the window size  $d$  increases. Empirically, such choice of  $\gamma$  makes the values of the expected Gaussian kernels numerically stable.

The results show that the classification accuracy on ECG200 improves as the window size increases and peaks at around  $0.75L$ . We note that using larger window size is computationally more expensive, and that not all data sets show a benefit with increasing window size.

**Comparing MEG to Existing Methods.** We compare the MEG kernel with two existing methods for time series classification. The reproducing kernel Hilbert space (RKHS)

Figure 4: Comparison with other time series classification methods. The plot on the top corresponds to the 20 data sets whose optimal warping window size is at most 12; the plot on the bottom corresponds to the rest of 23 data sets with optimal warping window size greater than 12.

kernel  $\mathcal{K}_{\mathcal{H}}$  proposed by Lu et al. [2008] is a time series kernel also designed for irregularly sampled time series. The RKHS kernel is defined as the squared norm between two posterior GP mean functions in the RKHS induced by a common prior covariance function. The kernel can be computed in closed form, but also discards posterior uncertainty since it only depends on the posterior GP means. It is also not possible to focus the kernel on assessing similarity over a specific time interval.

Dynamic time warping [Berndt and Clifford, 1994; Sakoe and Chiba, 1971] (DTW) is a widely used distance function for misaligned and warped time series. We compare to the 1-nearest neighbor algorithm using DTW distance subject to the Sakoe-Chiba warping constraint using the optimal window size published along with the UCR time series archive. Since classic DTW is not designed for irregularly sampled time series data, we also use GP regression to interpolate each time series on the same set of reference time points as the MSM kernels, and use the posterior means as the input to DTW.

In this experiment, we split the data sets into two groups according to their published optimal warping window sizes. Smaller warping window size implies the corresponding time series are almost aligned and have minimal warping. The 23 data sets with optimal window size greater than 12 are selected as the *warped* group, which implies that the corresponding time series require significant alignment or warping before direct comparison. The need for alignment and warping violates the assumptions of the MSM kernel as well as the RKHS kernel, which does not explicitly take warping or alignment into account. The rest of the 20 data sets are regarded as the *aligned* group.

Figure 4 shows that the RKHS kernel  $\mathcal{K}_{\mathcal{H}}$  consistently performs the worst on both groups, because it fails to focus on a finite time interval of interest where data points are observed and does not account for uncertainty. For

Figure 5: Comparison of the classification accuracy ratio of the exact time series expected Gaussian kernel against the random Fourier feature approximation. The baseline method  $\mathcal{K}_{MG}$  is included as a reference.

the aligned group, our method always outperforms DTW. When the time series is more sparsely sampled, the advantage of our uncertainty-aware framework becomes more significant. For the warped group, DTW achieves better classification accuracy under low sparsity, but our approach achieves comparable or better accuracy under high sparsity while the RKHS kernel does not.

**Random Features for MEG Kernels.** To evaluate the random feature approximation to the MEG kernel in terms of classification accuracy, we use  $m = \lceil 10,000/k \rceil$  random features to approximate the expected Gaussian kernel on each of  $k$  marginals, so that the total number of random features  $M = mk$  is at most 10,000. In the experiment,  $\mathcal{R}_{MEG}^{(1)}$  and  $\mathcal{R}_{MEG}^{(10)}$  denote the random feature approximation for  $\mathcal{K}_{MEG}^{(1)}$  and  $\mathcal{K}_{MEG}^{(10)}$  with window size 1 and 10.

Figure 5 shows that the random feature approximation produces similar classification results compared to the exact kernels for both marginal window sizes. The baseline method  $\mathcal{K}_{MG}$  is included to show that even when the accuracy declines due to approximation, it still outperforms the baseline method.

Table 1 shows the classification training and prediction time on the four largest data sets in the UCR archive. We divide the training and prediction task using either  $\mathcal{K}_{MEG}^{(1)}$  or  $\mathcal{R}_{MEG}^{(1)}$  into two steps: first, computing the kernel matrix for  $\mathcal{K}_{MEG}^{(1)}$  or the random feature matrix for  $\mathcal{R}_{MEG}^{(1)}$ , which are shown as the 3rd and 5th column (denoted prep.) in Table 1; second, training and prediction time spent solely in the classifier, denoted train and test in the table.

The results in Table 1 show that computing the feature/kernel matrix dominates the entire training/prediction task. It is consistent with the time and space complexity analysis given in Table 2. In terms of the data size, computing the exact kernel takes  $\mathcal{O}(n^2)$  time, while computing the random feature matrix takes  $\mathcal{O}(n)$  time. As the window size  $d$  increases, computing the exact kernel takes  $\mathcal{O}(d^3)$  time as oppose to  $\mathcal{O}(d^2)$  for random feature approximation.

As for the actual classifier learning and prediction time, we can see that  $\mathcal{R}_{MEG}^{(1)}$  takes longer than  $\mathcal{K}_{MEG}^{(1)}$ . This is because

Table 1: Comparison of classification time (in seconds) on the four largest data sets using exact expected Gaussian kernels as opposed to random feature approximation under window sizes 1 and 10. In the table, the MEG kernel subscripts are dropped from the notation for brevity. The two numbers  $(n, L)$  for each data set denote the number of examples and the number of reference time points. Note that a MEG kernel with window size  $d$  consists of  $k = L - d + 1$  base kernels (see Section 3).

the final kernel matrix for  $\mathcal{K}_{MEG}^{(1)}$  can be stored in  $\mathcal{O}(n^2)$  space, as oppose to  $\mathcal{O}(nmk)$  for  $\mathcal{R}_{MEG}^{(1)}$ , which is notably larger for our choice of  $m$  ( $mk \approx 10,000$ ). By adjusting  $m$ , the total time using  $\mathcal{R}_{MEG}^{(1)}$  can be further reduced, but it is already significantly faster overall with the value of  $m$  used here.

**Comparing Random Features to Nyström Method.** The Nyström method [Williams and Seeger, 2001] is a commonly used kernel approximation algorithm based on low-rank approximation to the full kernel matrix computed using a subset of the training data. We compare the time versus kernel approximation error trade-off when approximating the MEG kernel by the Nyström method and random features using window sizes 1 and 10. The experiment is conducted on the largest data set in the UCR archive, StarLightCurves, at 10% sampling density. For Nyström method, we plot the results using  $s = 10, 20, \dots, 500$  samples. For the random feature approximation, we plot the results using  $m = 1, 2, \dots, 100$  random features for each expected Gaussian kernel (at most 50,000 total features for the largest  $m$ ). Note that the number of training cases used for the Nyström method is at most the size of the training data; however, the number of random features can exceed the size of the training data.

The results show that the Nyström approximation can achieve higher approximation accuracy than random features when sufficient training data samples are used [Yang

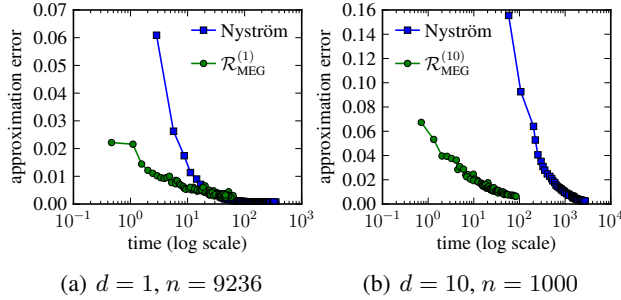

Figure 6: Comparing time versus approximation error (in terms of the relative error  $\mathbb{E}\|\tilde{\mathbf{K}} - \mathbf{K}\|/\|\mathbf{K}\|$ ) of Nyström method under various sizes of the subset of training data and random feature approximation with various numbers of random features.

Table 2: Comparing time and space complexity of the classification using the MEG kernel with window size  $d$  constructed from  $k$  expected Gaussian kernels, where  $n$  is the training data size,  $n'$  is the test data size. Nyström method uses a subset of the training data of size  $s$ , and  $\mathcal{R}_{\text{MEG}}^{(d)}$  uses a total of  $M = mk$  random features.

|             | $\mathcal{K}_{\text{MEG}}^{(d)}$ | Nyström                            | $\mathcal{R}_{\text{MEG}}^{(d)}$ |
|-------------|----------------------------------|------------------------------------|----------------------------------|
| train time  | $\mathcal{O}(d^3 n^2 k)$         | $\mathcal{O}(d^3 n s k + s^3)$     | $\mathcal{O}(d^2 n M)$           |
| test time   | $\mathcal{O}(d^3 n' n k)$        | $\mathcal{O}(d^3 n' s k + n' s^2)$ | $\mathcal{O}(d^2 n' M)$          |
| train space | $\mathcal{O}(n^2)$               | $\mathcal{O}(n s)$                 | $\mathcal{O}(n M)$               |
| test space  | $\mathcal{O}(n' n)$              | $\mathcal{O}(n' s)$                | $\mathcal{O}(n' M)$              |

et al., 2012]. However, for  $d$ -dimensional Gaussians (for the MEG kernel with window size  $d$ ), computing a single entry of the expected Gaussian kernel takes  $\mathcal{O}(d^3)$  comparing to  $\mathcal{O}(d^2)$  to compute a single random feature, as in the case of comparing to exact kernel computation. The detailed complexity analysis is given in Table 2. Figure 6(b) shows that for window size 10, the random feature approximation needs significantly less time to achieve an acceptable error rate.

**Fastfood Method for High-Dimensional Marginals.** We compare the straightforward random feature computation to two acceleration methods using Fastfood as described in Section 4.2. This experiment is conducted on the data set StarLightCurves from the UCR archive at 10% sampling density with the full window size  $L = 500$ . That is, there is a single expected Gaussian kernel with  $d = 500$  in the MEG kernel. We use randomized truncated SVD [Halko et al., 2011] for the low-rank approximation of covariance matrices with rank  $r = 10$ .

Figure 7 shows the time-versus-error relationship using three different methods with  $2^\ell$  random features for  $\ell = 9, \dots, 13$  (from top to bottom). It shows that all three methods achieve similar errors (relative error in terms of spectral norms) when using the same feature size. However, the Fastfood method using (5), denoted Fastfood in the figure, is at least 14 times faster among five feature sizes than the

Figure 7: Comparing time versus approximation error (relative error) of the standard feature computation and the two Fastfood methods under  $d = 500$  and  $n = 1000$ . The five points for each method correspond to using 512, 1024, 2048, 4096, and 8192 features from top to bottom.

standard method, due to the  $\mathcal{O}(n M d \log d)$  time for Fastfood as opposed to  $\mathcal{O}(n M d^2)$ . With low-rank covariance approximation, the running time can be improved significantly again, even if an extra truncated SVD is required. The SVD overhead is roughly a constant of 2.7 seconds, which accounts for 86% time in the smallest case (512 features) and 42% in the largest case (8192 features).

## 6 CONCLUSIONS AND FUTURE WORK

We have proposed a kernel-based framework for classification of sparse and irregularly sampled time series that re-represents time series using Gaussian process and then assesses the similarity between the GPs based on the similarity between their finite marginals defined over sliding time windows. Our results show that the proposed approach achieves better average accuracy on a large time series classification benchmark compared to all other methods considered when the time series are aligned or under high sparsity. Further, our extension to random Fourier features achieves significant speedups relative to exact kernel computations as well as Nyström approximation on large time series data sets. Our application of Fastfood and low-rank covariance approximations yields further speedups in the case where large-dimensional marginals are required.

Possible directions for future work include learning kernel combination weights, extending the MSM framework to multi-output Gaussian processes for multivariate time series, and the extension of this framework to distributions other than Gaussians or different base kernels. Moreover, instead of performing classification on the random features using linear SVMs, we can use the random feature vector as an uncertainty-aware embedding of the data in various deep learning architectures, as well as unsupervised learning models for problems like clustering.

## Abstract

Consider a doctor choosing a treatment for an uncertain disorder for which there are  $n$  costly tests available. Based on the test results observed so far, the doctor can either order another test or proceed to the treatment decision. Although test sequencing is a problem that arises frequently in many decision situations, finding an exact solution is NP-hard with respect to  $n$ . In this paper, we analyze the time complexity of classic symmetric and asymmetric formulations, using influence diagrams and decision trees, to the general test sequencing problem, making no assumptions of conditional independence among the test results. We develop an alternative influence diagram formulation that scales better, and show how a decision circuit formulation improves even more on the decision tree solution through recursive coalescence. We prove that this decision circuit formulation achieves the lower bound complexity for any method for the general test sequencing problem that examines the entire policy space. As a result, the problem is tractable for much larger  $n$  than has been possible to date.

## 1 INTRODUCTION

Consider a doctor who must choose a treatment for an uncertain disorder for which there are  $n$  costly tests available. After each test is performed, the doctor can order another test or proceed to the treatment decision. Therefore, the doctor would like an optimal strategy for sequencing the tests, taking into account the costs of the tests and all of the test results observed so far. In this paper we examine the computational time complexity of exact solution methods for this problem.

The test sequencing problem is an asymmetric decision problem, where many combinations of uncertain variable states given decision variables have zero probability

(Bielza and Shenoy, 1999). The problem arises frequently in many practical decision situations and is of theoretical interest in operations research, machine learning, and the design of experiments. Although finding an exact solution is NP-hard with respect to the number of tests  $n$  (Papadimitriou and Tsitsiklis, 1987), the complexity of standard algorithms for this problem has not been analyzed or compared explicitly in the literature. Traditional graphical models used to solve such problems include decision trees (von Neumann and Morgenstern, 1944) and influence diagrams (Howard and Matheson, 1981; Shachter, 1986). Decision trees with limited coalescence (Howard, 1977; Olmsted, 1983) reuse some of the calculations to improve efficiency. There are many other asymmetric decision model representations, primarily designed to improve model formulation, including asymmetric influence diagrams (Smith et al., 1993), valuation networks (Shenoy, 2000), sequential decision diagrams (Covaliu and Oliver, 1995), sequential valuation networks (Demirer and Shenoy, 2006), and unconstrained influence diagrams (Jensen and Vomlelová, 2002). See Bielza et al. (2011) for a review and comparison of such models.

The test sequencing problem involves a decision maker with one key high-stakes decision and a set of information gathering activities. There has been rich and varied research on this problem dating back to the initial work on dynamic programming (Bellman, 1956), but due to the complexity of the problem much subsequent work in this area has focused on designing heuristic and approximate solution methods. Some exact methods feature state variables representing the belief of the decision maker, instead of maintaining all of the observations in the state, such as in Ulu and Smith (2009). Bickel and Smith (2006) consider a test sequencing problem in the context of oil exploration, and advocate “recombining” decision tree models for efficient computation, an example of the recursive coalescence that we focus on in this paper. Despite all of the research in this area, however, there had been no significant improvements in computational complexity for exact solutions to the general test sequencing problem.

Decision circuits, a generalization of decision trees, were developed by Bhattacharjya and Shachter (2007) and Bhattacharjya (2009) to efficiently evaluate influence diagrams with methods similar to arithmetic circuits for Bayesian networks (Darwiche, 2003). Although decision circuits share similar “tree-like” structures with decision trees, especially decision trees with coalescence, they are also as capable of exploiting conditional independence as influence diagrams, and as able to decompose problems as junction trees (Shachter and Peot, 1992; Jensen et al., 1994).

In the next section we formally define the general test sequencing problem, and in the following sections we formulate and analyze the complexity of exact solutions using the symmetric approach of influence diagrams and the asymmetric approaches of decision trees and decision circuits. We show that the decision circuit achieves the lower bound complexity of any algorithm for the problem that examines the entire policy space. We conclude with a comparison of the results and their implications.

## 2 NOTATION AND FRAMEWORK

In the *general test sequencing problem*, a doctor is treating a patient who has an uncertain disorder  $D$  with  $b$  possible states and probability distribution  $\Pr\{D\}$ . The doctor will choose a treatment  $T_x$  from among  $a$  alternatives in order to maximize the expected dollar value  $V$  from the treatment. Before making the treatment choice, there are  $n$  possible tests available, each with at most  $c$  possible results. Although we will evaluate the costs of the tests in dollars, the costs could also arise in practice from the delay in treatment or the side effects from performing the tests. At any point in time the doctor can make the treatment decision or order another test, knowing the results of all of the tests that have been previously ordered. Because the choice the doctor makes can depend on the results of those tests, the policy space of the test sequencing problem is exponential in the number of tests  $n$ ,  $(c + 1)^n$ , the number of possible sets of observations available in the decision making process.

Each test  $T_m$  has an associated cost  $C_m > 0$ ,  $m = 1, \dots, n$ , and we assume that the time horizon is short enough that its cost does not depend on when that particular test was performed. Therefore, the expected value of the prospect of any scenario is the difference between the dollar value of the treatment,  $E[V|T_x, T_1, \dots, T_n]$ , and the costs of the tests ordered,  $C_1 + \dots + C_n$ . Such a value model is said to be *separable*, and we exploit that in our formulations. We assume, without loss of generality, that the same test will produce the same result if performed more than once, so it would never be optimal to order the same test twice. (A test that might be worth repeating could be included as multiple available tests.) The test sequencing

problem is *general* as we impose no (conditional) independence assumptions on the  $n$ -vector of observable test results  $\mathbf{R}$  conditioned on the disorder  $D$ , with probability distribution  $\Pr\{\mathbf{R}|D\}$ .

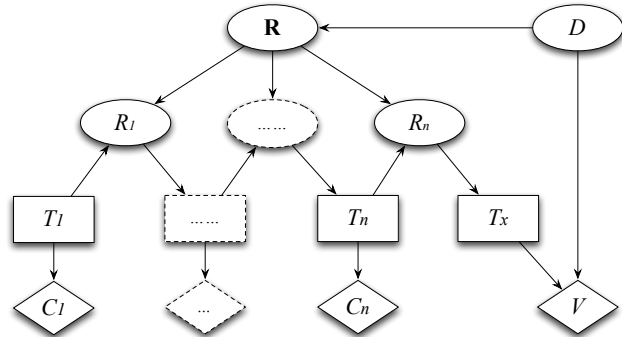

Figure 1: Influence diagram for the general test sequencing problem with  $n$  tests

An influence diagram for the general test sequencing problem is shown in Figure 1. There are  $n$  testing decisions,  $T_1, \dots, T_n$ , each with  $n + 1$  alternatives (including not to test), and the treatment decision,  $T_x$ . Corresponding to each of the testing decisions  $T_m$  there is a dollar cost  $C_m$  of testing, depending on the test chosen, and an expected dollar value  $V$  that depends on both the disorder  $D$  and the treatment decision  $T_x$ ,  $E[V|D, T_x]$ . The potentially observable test results,  $\mathbf{R}$ , depends on  $D$ , and the actual test result  $R_m$  observed after testing decision  $T_m$  is therefore a deterministic function of  $T_m$  and  $\mathbf{R}$ ,

$$R_m = \begin{cases} \mathbf{R}_{T_m} & \text{if } T_m \neq 0 \\ 1 & \text{if } T_m = 0 \end{cases} \quad \text{for } m = 1, \dots, n. \quad (1)$$

Earlier observations and decisions are known at the time of later decisions (Howard, 1977). Therefore, at the time of decision  $T_m$  the doctor will know which tests were ordered,  $T_1, \dots, T_{m-1}$ , and their corresponding results,  $R_1, \dots, R_{m-1}$ . At the time of the treatment decision  $T_x$  the doctor will know all tests that were ordered,  $T_1, \dots, T_n$ , and their results,  $R_1, \dots, R_n$ . These definitions are summarized in Table 1. In the following sections we will consider different approaches to the exact solution of this problem.

## 3 INFLUENCE DIAGRAM SOLUTIONS

In this section we formulate an influence diagram solution to the general test sequencing problem and a more efficient formulation based on a Markov Decision Process (MDP) model. This method is symmetric in the sense that the probability distributions are full arrays and all variables are included in the formulations of every scenario.

| Symbol         | Definition  |
|----------------|---|
| $T_x$          | treatment decision  |
| $a$            | number of treatment alternatives                                  |
| $D$            | uncertain disorder  |
| $b$            | number of disorder states   |
| $V$            | expected dollar value of the treatment $T_x$ for the disorder $D$ |
| $n$            | number of tests available   |
| $\mathbf{R}$   | $n$ -vector of potentially observable test results                |
| $c$            | maximum number of possible results for each test                  |
| $T_m$          | decision which test to order $m$ th, $m = 1, \dots, n$            |
| $R_m$          | results of the $m$ th test ordered                                |
| $C_m$          | cost of the $m$ th test ordered                                   |
| $\mathbf{S}_m$ | $n$ -vector of test results observed after $m$ decisions          |

Table 1: Symbol Definitions

We can solve the influence diagram shown in Figure 1 by constructing a rooted cluster tree, as shown in Figure 2 (Shachter and Peot, 1992), similar for our purposes to a strong junction tree (Jensen et al., 1994), and minimal because these cliques are necessary to represent the problem (Shachter, 1999). The computational time complexity of the solution is determined by the total of the sizes of cluster tables,  $abc^n + ac^{2n}(n+1)^n$ , recognizing that the number of possible states for  $T_x$ ,  $D$ ,  $\mathbf{R}$ ,  $T_m$ , and  $R_m$  are  $a$ ,  $b$ ,  $c^n$ ,  $n+1$ , and  $c$ , respectively.

Figure 2: Rooted cluster tree for the influence diagram in Figure 1

**Theorem 1.** *The computational complexity of the standard influence diagram formulation of the general test sequencing problem is  $O(c^{2n}(n+1)^n)$ .*

An influence diagram formulation based on an MDP model, however, is more efficient than the standard influence diagram model for large  $n$ . The key is to introduce a *Markov state variable*,  $\mathbf{S}_m$ , the observed test results after  $m$  testing decisions, which renders past observations and decisions independent of future decisions.  $\mathbf{S}_m$  is an  $n$ -vector, with components corresponding to the different possible test results, but with  $c+1$  possible values for

each component, including a new state “0” corresponding to the “test results not yet observed”. Therefore, letting  $\mathbf{S}_0 = \mathbf{0}$  indicate that no tests have been performed before the first testing decision, we can define  $\mathbf{S}_m$  for each possible  $j, m = 1, \dots, n$  as a deterministic function of  $\mathbf{S}_{m-1}$ ,  $T_m$ , and  $\mathbf{R}$  by

$$(\mathbf{S}_m)_j = \begin{cases} \mathbf{R}_{T_m} & \text{if } T_m = j \neq 0 \\ (\mathbf{S}_{m-1})_j & \text{otherwise} \end{cases} \quad (2)$$

With this definition of  $\mathbf{S}_m$  we can formulate the influence diagram shown in Figure 3. Because of the Markov state, the decisions  $T_2, \dots, T_n$  and  $T_x$  depend only on the corresponding state variables  $\mathbf{S}_1, \dots, \mathbf{S}_n$ , respectively, rather than any of the past decisions and observations. However, this is not yet an MDP and would not be efficient to solve because of the role played by the uncertain potentially observable test results  $\mathbf{R}$ . Nevertheless, the definition of  $\mathbf{S}_m$  allows us to reformulate this influence diagram into an MDP influence diagram without  $\mathbf{R}$ , as shown in Figure 4, that is efficient to solve.

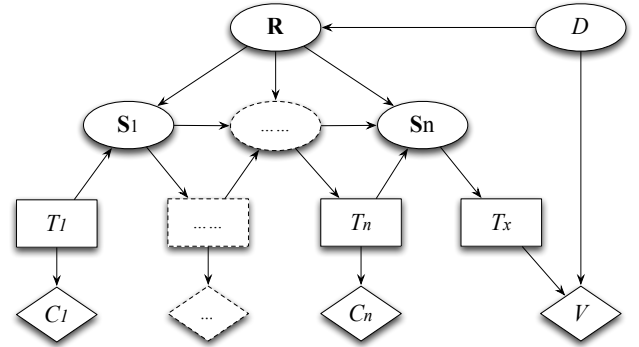

Figure 3: The influence diagram of the general test sequencing problem with Markov states

**Theorem 2.** *The influence diagram shown in Figure 4 is a valid representation of the general test sequencing problem.*

*Proof.* Given the relationships represented by the influence diagram shown in Figure 3,  $D$  is conditionally independent of  $T_1, \dots, T_n, \mathbf{S}_1, \dots, \mathbf{S}_n$  given  $\mathbf{R}$ . By the definition of  $\mathbf{S}_m$ ,  $\mathbf{R}$  is conditionally independent of  $T_1, \dots, T_n, \mathbf{S}_1, \dots, \mathbf{S}_{n-1}$  given  $\mathbf{S}_n$ . Therefore, it follows that  $D$  must be conditionally independent of  $T_1, \dots, T_n, \mathbf{S}_1, \dots, \mathbf{S}_{n-1}$  given  $\mathbf{S}_n$ . Likewise, by the definition of  $\mathbf{S}_m$ ,  $\mathbf{S}_{m+1}$  is conditionally independent of  $T_1, \dots, T_m, \mathbf{S}_1, \dots, \mathbf{S}_{m-1}$  given  $\mathbf{S}_m$  and  $T_{m+1}$  for  $m = 1, \dots, n-1$ , as shown in Figure 4.  $\square$

Even though the earlier testing decisions and their results will be known at the time of later decisions, it is sufficient to observe the Markov state  $\mathbf{S}_m$  as shown in the MDP

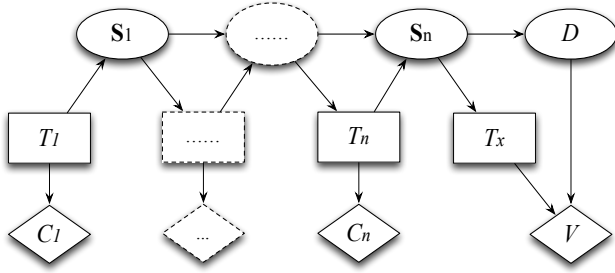

Figure 4: The MDP influence diagram for the general test sequencing problem

influence diagram (Figure 4). Therefore, we can solve it using the rooted cluster tree shown in Figure 5. As before, the computational time complexity of the solution is determined by the total of the sizes of cluster tables,  $(n + 1)(c + 1)^n + (n - 1)(n + 1)(c + 1)^{2n} + ab(c + 1)^n$ , recognizing that the number of possible states for  $T_x$ ,  $D$ ,  $T_m$ , and  $S_m$  are  $a, b, n + 1$ , and  $(c + 1)^n$ , respectively. We must also account for the cost of preprocessing to reformulate the diagram to the MDP at a complexity of  $bc^n(c + 1)^n + (n + 1)(c + 1)^{2n}$ . Although this is dominated by the expression above, we include it in our final comparisons.

Figure 5: The rooted cluster tree for the MDP influence diagram

**Theorem 3.** *The computational complexity of the MDP influence diagram formulation of the general test sequencing problem is  $O(n^2(c + 1)^{2n})$ .*

#### 4 PURE DECISION TREE SOLUTION

In this section we formulate and analyze the computational complexity of the exact solution to the general test sequencing problem using an asymmetric pure decision analysis decision tree without *coalescence*, the reuse of sub-tree calculations. Such decision trees maintain the strict tree structure in which each node has at most one parent. Despite the prevalence and usefulness of decision tree models, there has been limited evaluation of their complexity when applied to asymmetric decision problems.

A decision tree is a natural representation for the asymmetry in the general test sequencing problem, recognizing that after we have observed  $m$  test results, there are only  $n - m$  remaining tests to consider and the choice of which test to order, if any, can depend on the test results that we have already observed. To build a decision tree we will

need to preprocess the probability distributions for  $D$ ,  $\mathbf{R}$ , and  $R_1, \dots, R_n$  from the assessed distributions as shown in the influence diagram in Figure 1 to the inferential order they need to appear in the decision tree, where  $D$  and  $\mathbf{R}$  are not observed before any of the decisions. The computational effort to perform this pre-processing is substantial,  $O(bc(c + 1)^n)$ , but dominated by the work needed to evaluate the decision tree. Hence, we can ignore it in our analysis but include it in our final comparisons.

For each possible sequence of  $m$  tests and their observed test results,  $m = 0, \dots, n$ , there is a decision node in the decision tree corresponding to the choice of treatment or of another test. There are  $\binom{n}{m}m!c^m$  such possible sequences in the tree.

**Proposition 1.** *The total number of decision nodes in a pure decision tree without coalescence is*

$$\sum_{m=0}^n \binom{n}{m} m! c^m.$$

Figure 6: A generic decision node in the pure decision tree without coalescence, with  $m$  observed test results

The computational time complexity of the decision tree solution is determined by the number of arcs (or nodes) in the tree. Figure 6 shows a generic decision node within the decision tree whose ancestors include exactly  $m$  tests and their corresponding test results. There are  $a + n - m$  alternatives, corresponding to choosing from one of the remaining  $n - m$  tests or choosing to stop testing and make the treatment decision. For each of the test alternatives there are  $c$  possible test results, each leading to a different decision node in the tree, and for each of the  $a$  treatment alternatives there are  $b$  possible disorder states. Therefore, for each of the decision nodes in the tree there are

$a + ab + (n - m)c$  arcs in the tree, and the total number of arcs is given by

$$\begin{aligned}
& \sum_{m=0}^n \binom{n}{m} m! c^m [(a + ab) + (n - m)c] \\
= & (a + ab) \sum_{m=0}^n \frac{n!}{(n - m)!} c^m + \sum_{m=0}^n \frac{n!}{(n - m - 1)!} c^{m+1} \\
= & (a + ab) c^n n! \sum_{m=0}^n \frac{c^{-m}}{m!} + c^n n! \sum_{m=0}^{n-1} \frac{c^{-m}}{m!} \\
\approx & (a + ab) c^n n! e^{1/c} + c^n n! e^{1/c} \\
= & (a + ab + 1) c^n n! e^{1/c} = O(c^n n!)
\end{aligned}$$

**Theorem 4.** *The computational complexity of the decision tree formulation with no coalescence of the general test sequencing problem is  $O(c^n n!)$ .*

We will see in the next section that we can improve on the efficiency of the influence diagram and decision tree by allowing recursive coalescence, reusing subtree calculations as much as possible. Coalescence has traditionally been applied with decision trees in a limited fashion, at most once for any path in the tree (Howard, 1977; Olmsted, 1983), but we will apply it much more extensively in a generalization of decision trees called decision circuits.

## 5 DECISION CIRCUIT SOLUTION

In this section we formulate a decision circuit solution to the general test sequencing problem and show that it achieves the lower bound complexity of any algorithm for the problem that examines the entire policy space. Although this solution can be viewed as an extension of the pure decision tree solution with recursive coalescence, the decision circuit naturally integrates such coalescence and, unlike decision trees, does not need the distributions to be preprocessed.

### 5.1 INTRODUCTION TO DECISION CIRCUITS

Decision circuits are generalized decision trees that maintain their asymmetry while exploiting any conditional independence. They were developed by Bhattacharjya and Shachter (2007) and Bhattacharjya (2009) to efficiently evaluate influence diagrams with methods similar to arithmetic circuits for Bayesian networks (Darwiche, 2003). A decision problem represented by an influence diagram, or an intermediate structure, a decision circuit backbone, can be transformed into a decision circuit for efficient evaluation and sensitivity analysis (Shachter and Bhattacharjya, 2010; Bhattacharjya and Shachter, 2008, 2010). Although decision circuits were not developed as a repre-

sentation for communication, Bhattacharjya and Shachter (2012) showed how formulating asymmetric decision circuits directly, instead of formulating an influence diagram and transforming it into a decision circuit, could be desirable in many applications. They also showed how to build decision circuits in assessed form, avoiding the probability distribution preprocessing effort (Bayes Theorem “tree flipping”) needed for decision trees.

Decision circuits generalize decision trees in several key ways. Both decision circuits and decision trees are natural representations for asymmetric problems. Extensive, even recursive, coalescence is encouraged in the decision circuit, by allowing nodes to have multiple parents. Because the expectation operation for an uncertain variable in decision trees is represented as separate *sum* and *product* operations in the decision circuit, the probability distribution corresponding to the variable can appear further downstream (Shenoy, 1998). As a result, probability distributions can be incorporated into the decision circuit as assessed and there is no need for preprocessing the assessed distributions. Decision circuits are also able to exploit separable problem structure as found in influence diagrams and junction trees (Tatman and Shachter, 1990; Shachter and Peot, 1992; Jensen et al., 1994). Finally, once the probability and value distributions are specified the decision circuit can be compiled for even greater efficiency.

### 5.2 DECISION CIRCUIT FORMULATION

An example of our decision circuit formulation is shown in Figure 7 for the general test sequencing problem with  $a = b = c = n = 2$ , that is, there are two treatment alternatives, two disorder states, and two tests available with two test results each. Decision circuits can have “indicator variables”  $\lambda$  to control and manage evidence and sensitivity analysis, but we have omitted them to simplify the diagram. Including the indicators would not significantly affect the computational complexity for the test sequencing problem.

At the leaves of the decision circuit shown in Figure 7 are the expected dollar values for each prospect  $E[V|D, T_x]$ , the costs  $C$  for each type of test, the probabilities  $\Pr\{D\}$ , and the likelihoods  $\Pr\{\mathbf{R}|D\}$ . The separable costs are incorporated using *branching sum* (“B+”) nodes (Shachter and Bhattacharjya, 2010). The quantities at the leaves are combined and reused throughout the circuit both as probabilities and as unnormalized probability-value hybrids for decision making. For example, we can marginalize for the case where some of the tests are not performed. The decision circuit is evaluated by sweeping up from the leaves to the root and, in the process, making all of the decisions at *max* nodes and determining the optimal expected value (Darwiche, 2003; Bhattacharjya and Shachter, 2007). A sweep down through the circuit computes derivatives of the optimal value with respect to any

Figure 7: The decision circuit for general test sequencing involving two treatment alternatives, two disorder states, and two tests with two test results each

of the nodes and assessed parameters for use in sensitivity analysis (Bhattacharjya and Shachter, 2008, 2010). Therefore, we can compute the computational time complexity of a decision circuit by counting the number of arcs.

The coalescence in the decision circuit allows us to exploit essential properties of the general test sequencing problem. For example, when the results from  $m$  tests have been observed, the order those tests were performed does not matter (Jaynes, 2003; Bickel and Smith, 2006). In our decision circuit those  $m!$  different test sequences (corresponding to  $m$  equivalent observed test results) all lead to the same decision ( $max$ ) node for the selection of an  $(m+1)$ st test or to make the treatment decision. The structure of our circuit relies on the fact that the same choice will be optimal regardless what order the observed tests were performed, similar to the Markov state in our MDP formulation or an “information set” in game theory (Shenoy, 1998).

### 5.3 THE COMPLEXITY OF THE DECISION CIRCUIT FORMULATION

In our decision circuit formulation, for each possible set of  $m$  tests and their observed test results,  $m = 0, \dots, n$ , there is a decision node in the decision tree corresponding to the choice of treatment or another test. There are  $\binom{n}{m} c^m$  such possible sets in the circuit. Note that, by contrast, in the decision tree there was a distinction about the order of the tests, increasing the number of decision nodes by a factor of  $m!$ . The binomial theorem provides a closed-form expression for the number of decision nodes in the decision circuit.

**Proposition 2.** *The total number of decision nodes in the decision circuit is*

$$\sum_{m=0}^n \binom{n}{m} c^m = (c+1)^n.$$

The number of arcs in the decision circuit determines the computational time complexity for the circuit. Figure 8 shows a generic decision node within the decision circuit whose ancestors include exactly  $m$  tests and their cor-

responding test results. There are  $m$  arcs into the node, corresponding to the  $m$  different tests that could have been observed last. There are  $a+n-m$  alternatives, corresponding to choosing from one of the remaining  $n-m$  tests or choosing to stop testing and make the treatment decision. For each of the  $a$  treatment alternatives and  $b$  possible disorder states we marginalize over  $c$  possible test results (except when  $m$  is either 0 or  $n$ ) to compute the probabilities and probability-value hybrids of the disease and observed test results from those used by decisions with  $m+1$  test results. For each of the  $n-m$  test alternatives there are three arcs into or out of the branching sum node used to register the separable cost of the test, followed by  $c$  test results, each leading to a different decision node in the circuit, and counted as incoming arcs for those nodes. Therefore, for each of the decision nodes in the circuit there are less than  $m+(a+ab+abc)+3(n-m)$  arcs in the decision circuit. We will compute the complexity from each of these three terms separately.

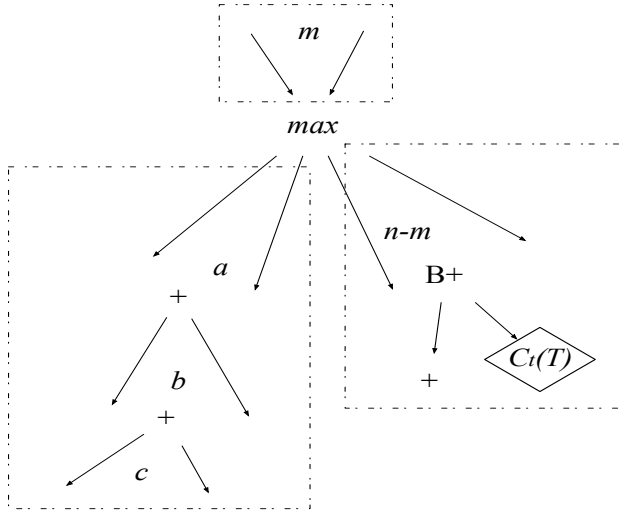

Figure 8: A generic decision node in the decision circuit with  $m$  observed test results

The first term corresponds to the  $m$  arcs directed into the decision node. The total for all decision nodes is

$$\begin{aligned}
 \sum_{m=0}^n \binom{n}{m} m c^m &= \sum_{m=1}^n \binom{n}{m} m c^m \\
 &= \sum_{m=1}^n \frac{n!}{(m-1)!(n-m)!} c^m \\
 &= n c \sum_{m=1}^n \frac{(n-1)!}{(m-1)!(n-m)!} c^{m-1} \\
 &= n c (c+1)^{n-1}.
 \end{aligned} \tag{3}$$

The second term is the less than  $abc$  arcs corresponding to the treatment alternatives. The total for all decision

nodes is less than

$$(a+ab+abc) \sum_{m=0}^n \binom{n}{m} c^m = (a+ab+abc)(c+1)^n. \tag{4}$$

The third term is the  $3(n-m)$  arcs corresponding to the next tests and the arcs needed to register the cost of the test. The total for all decision nodes is

$$\begin{aligned}
 3 \sum_{m=0}^{n-1} \binom{n}{m} (n-m) c^m &= 3 \sum_{m=0}^{n-1} \frac{n!}{m!(n-m)!} (n-m) c^m \\
 &= 3n \sum_{m=0}^{n-1} \frac{(n-1)!}{m!(n-1-m)!} c^m \\
 &= 3n(c+1)^{n-1}.
 \end{aligned} \tag{5}$$

Finally, including the  $2ab(c^n+1)$  arcs at the bottom of the decision circuit that incorporate the  $E[V|D, T_x]$ ,  $\Pr\{D\}$ , and  $\Pr\{\mathbf{R}|D\}$  tables, the total number of arcs is less than

$$2ab(c^n+1) + n(c+3)(c+1)^{n-1} + (a+ab+abc)(c+1)^n,$$

and we have shown the following result.

**Theorem 5.** *The computational complexity of the decision circuit formulation of the general test sequencing problem is  $O(n(c+1)^{n-1})$ .*

In general the test sequencing problem can have an arbitrary optimal policy for any of the  $(c+1)^n$  possible sets of observations. Given  $m$  tests have been performed and any of the  $c^m$  possible test results, the corresponding policy is determined by comparing the net expected values among the remaining  $n-m$  tests that could be performed. The number of such comparisons is  $\sum_{m=0}^{n-1} \binom{n}{m} (n-m) c^m$ , similar to Equation 5, and this provides a lower bound on the complexity of any algorithm for the general problem that examines the entire policy space,  $O(n(c+1)^{n-1})$ . Because the decision circuit formulation achieves this bound, the bound must be tight.

**Theorem 6.** *Any algorithm for the general test sequencing problem that examines the entire policy space of test results must have time complexity with lower bound  $\Omega(n(c+1)^{n-1})$ , as achieved by the decision circuit formulation.*

We compare the computational complexity of the four models with the parameters  $a=b=c$  set to 2 and 3. The results as a function of the number of tests available,  $n$ , are displayed in Table 2, and the logs of the complexities are shown in Figure 9 for  $a=b=c=2$ . The plots would appear similar, but with greater slopes, if we increased the values of the parameters  $a$ ,  $b$ , and/or  $c$ .

Figure 9: Log of the computational complexity of different formulations with model parameters  $a = b = c = 2$

## 6 CONCLUSIONS

The general test sequencing problem has been known to be NP-hard with respect to the number of tests available, so most past research efforts have searched for approximate solution methods, heuristics, simulations, and simplifying assumptions.

In this paper, we develop a decision circuit formulation for the general test sequencing problem that solves the problem exactly without imposing any additional assumptions. We analyze its computational complexity and compare it with other frequently used sequential decision making models, pure decision trees and influence diagrams, and we develop a more efficient influence diagram model based on an MDP. In our comparison, the decision circuit model significantly outperforms the others. In fact, it achieves

the lower bound on the computational complexity for any method for the general test sequencing problem that examines the entire policy space.

We could have obtained this same order of computational complexity by implementing decision trees with recursive coalescence. To construct such decision trees would have required explicit preprocessing of the assessed distributions, which is more efficiently done implicitly within our decision circuit formulation. It would also have used coalescence in a recursive manner natural in decision circuits but not common for decision trees.

In a similar fashion, we could have obtained a more efficient MDP formulation by recognizing the structural asymmetry in the problem. Because we observe at most one test result in each time period we could prune from

the state space those paths with more observations. This would improve the run-time computational complexity of the MDP and lead to a problem structure quite similar to the decision circuit.

Another advantage of using decision circuits is the efficient sensitivity analysis available on the assessed problem parameters, the probabilities and costs. The decision circuit formulation developed here allows us to solve the general test sequencing problem exactly for much larger values of  $n$  than has been possible before.

Information gathering decisions are strategic components in many decision problems in medicine, engineering, and other domains where they can significantly improve performance (Bickel and Smith, 2006). This paper has focused on the general test sequencing problem, with no assumptions, such as probabilistic independence. We realize that this is a specific class of problems, but we have used its structure to analyze and compare different exact techniques, and to demonstrate that a relatively new approach, decision circuits, allows us to achieve the complexity lower bound. This suggests that well-crafted decision circuits might perform relatively well on more general problems, such as troubleshooting, where observations and actions are interspersed and actions affect both the state of the system and future observations (Breese and Heckerman, 1996).

## Abstract

In this paper, we show for the first time how gradient TD (GTD) reinforcement learning methods can be formally derived as true stochastic gradient algorithms, not with respect to their original objective functions as previously attempted, but rather using derived primal-dual saddle-point objective functions. We then conduct a saddle-point error analysis to obtain finite-sample bounds on their performance. Previous analyses of this class of algorithms use stochastic approximation techniques to prove asymptotic convergence, and no finite-sample analysis had been attempted. Two novel GTD algorithms are also proposed, namely projected GTD2 and GTD2-MP, which use proximal “mirror maps” to yield improved convergence guarantees and acceleration, respectively. The results of our theoretical analysis imply that the GTD family of algorithms are comparable and may indeed be preferred over existing least squares TD methods for off-policy learning, due to their linear complexity. We provide experimental results showing the improved performance of our accelerated gradient TD methods.

## 1 INTRODUCTION

Obtaining a true stochastic gradient temporal difference method has been a longstanding goal of reinforcement learning (RL) [Bertsekas and Tsitsiklis, 1996; Sutton and Barto, 1998], ever since it was discovered that the original TD method was unstable in many off-policy scenarios where the target behavior being learned and the exploratory behavior producing samples differ. Sutton *et al.* [2008, 2009] proposed the family of gradient-based temporal difference (GTD) algorithms which offer several interesting properties. A key property of this class of GTD algorithms is that they are asymptotically off-policy convergent, which was shown using stochastic approximation

[Borkar, 2008]. This is quite important when we notice that many RL algorithms, especially those that are based on stochastic approximation, such as  $TD(\lambda)$ , do not have convergence guarantees in the off-policy setting. Unfortunately, this class of GTD algorithms are *not true stochastic gradient methods with respect to their original objective functions*, as pointed out in Szepesvári [2010]. The reason is not surprising: the gradient of the objective functions used involve products of terms, which cannot be sampled directly, and was decomposed by a rather ad-hoc splitting of terms. In this paper, we take a major step forward in resolving this problem by showing a principled way of designing true stochastic gradient TD algorithms by using a primal-dual saddle point objective function, derived from the original objective functions, coupled with the principled use of *operator splitting* [Bauschke and Combettes, 2011].

Since in real-world applications of RL, we have access to only a finite amount of data, finite-sample analysis of gradient TD algorithms is essential as it clearly shows the effect of the number of samples (and the parameters that play a role in the sampling budget of the algorithm) in their final performance. However, most of the work on finite-sample analysis in RL has been focused on batch RL (or approximate dynamic programming) algorithms (e.g., Kakade and Langford 2002; Munos and Szepesvári 2008; Antos *et al.* 2008; Lazaric *et al.* 2010a), especially those that are least squares TD (LSTD)-based (e.g., Lazaric *et al.* 2010b; Ghavamzadeh *et al.* 2010, 2011; Lazaric *et al.* 2012), and more importantly restricted to the on-policy setting. In this paper, we provide the finite-sample analysis of the GTD family of algorithms, a relatively novel class of gradient-based TD methods that are guaranteed to converge even in the off-policy setting, and for which, to the best of our knowledge, no finite-sample analysis has been reported. This analysis is challenging because **1**) the stochastic approximation methods that have been used to prove the asymptotic convergence of these algorithms do not address convergence rate analysis; **2**) as we explain in detail in Section 2.1, the techniques used for the analysis of the stochastic gradient methods cannot be applied here;

3) finally, the difficulty of finite-sample analysis in the off-policy setting.

The major contributions of this paper include the first finite-sample analysis of the class of gradient TD algorithms, as well as the design and analysis of several improved GTD methods that result from our novel approach of formulating gradient TD methods as true stochastic gradient algorithms w.r.t. a saddle-point objective function. We then use the techniques applied in the analysis of the stochastic gradient methods to propose a unified finite-sample analysis for the previously proposed as well as our novel gradient TD algorithms. Finally, given the results of our analysis, we study the GTD class of algorithms from several different perspectives, including acceleration in convergence, learning with biased importance sampling factors, etc.

## 2 PRELIMINARIES

Reinforcement Learning (RL) [Bertsekas and Tsitsiklis, 1996; Sutton and Barto, 1998] is a class of learning problems in which an agent interacts with an unfamiliar, dynamic and stochastic environment, where the agent’s goal is to optimize some measure of its long-term performance. This interaction is conventionally modeled as a Markov decision process (MDP). A MDP is defined as the tuple  $(\mathcal{S}, \mathcal{A}, P_{ss'}^a, R, \gamma)$ , where  $\mathcal{S}$  and  $\mathcal{A}$  are the sets of states and actions, the transition kernel  $P_{ss'}^a$  specifying the probability of transition from state  $s \in \mathcal{S}$  to state  $s' \in \mathcal{S}$  by taking action  $a \in \mathcal{A}$ ,  $R(s, a) : \mathcal{S} \times \mathcal{A} \rightarrow \mathbb{R}$  is the reward function bounded by  $R_{\max}$ , and  $0 \leq \gamma < 1$  is a discount factor. A stationary policy  $\pi : \mathcal{S} \times \mathcal{A} \rightarrow [0, 1]$  is a probabilistic mapping from states to actions. The main objective of a RL algorithm is to find an optimal policy. In order to achieve this goal, a key step in many algorithms is to calculate the value function of a given policy  $\pi$ , i.e.,  $V^\pi : \mathcal{S} \rightarrow \mathbb{R}$ , a process known as *policy evaluation*. It is known that  $V^\pi$  is the unique fixed-point of the *Bellman operator*  $T^\pi$ , i.e.,

$$V^\pi = T^\pi V^\pi = R^\pi + \gamma P^\pi V^\pi, \quad (1)$$

where  $R^\pi$  and  $P^\pi$  are the reward function and transition kernel of the Markov chain induced by policy  $\pi$ . In Eq. 1, we may imagine  $V^\pi$  as a  $|\mathcal{S}|$ -dimensional vector and write everything in vector/matrix form. In the following, to simplify the notation, we often drop the dependence of  $T^\pi$ ,  $V^\pi$ ,  $R^\pi$ , and  $P^\pi$  to  $\pi$ .

We denote by  $\pi_b$ , the behavior policy that generates the data, and by  $\pi$ , the target policy that we would like to evaluate. They are the same in the on-policy setting and different in the off-policy scenario. For each state-action pair  $(s_i, a_i)$ , such that  $\pi_b(a_i|s_i) > 0$ , we define the importance-weighting factor  $\rho_i = \pi(a_i|s_i)/\pi_b(a_i|s_i)$  with  $\rho_{\max} \geq 0$  being its maximum value over the state-action pairs.

When  $\mathcal{S}$  is large or infinite, we often use a linear approximation architecture for  $V^\pi$  with parameters  $\theta \in$

$\mathbb{R}^d$  and  $L$ -bounded basis functions  $\{\varphi_i\}_{i=1}^d$ , i.e.,  $\varphi_i : \mathcal{S} \rightarrow \mathbb{R}$  and  $\max_i \|\varphi_i\|_\infty \leq L$ . We denote by  $\phi(\cdot) = (\varphi_1(\cdot), \dots, \varphi_d(\cdot))^\top$  the feature vector and by  $\mathcal{F}$  the linear function space spanned by the basis functions  $\{\varphi_i\}_{i=1}^d$ , i.e.,  $\mathcal{F} = \{f_\theta \mid \theta \in \mathbb{R}^d \text{ and } f_\theta(\cdot) = \phi(\cdot)^\top \theta\}$ . We may write the approximation of  $V$  in  $\mathcal{F}$  in the vector form as  $\hat{v} = \Phi\theta$ , where  $\Phi$  is the  $|\mathcal{S}| \times d$  feature matrix. When only  $n$  training samples of the form  $\mathcal{D} = \{(s_i, a_i, r_i = r(s_i, a_i), s'_i)\}_{i=1}^n$ ,  $s_i \sim \xi$ ,  $a_i \sim \pi_b(\cdot|s_i)$ ,  $s'_i \sim P(\cdot|s_i, a_i)$ , are available ( $\xi$  is a distribution over the state space  $\mathcal{S}$ ), we may write the *empirical Bellman operator*  $\hat{T}$  for a function in  $\mathcal{F}$  as

$$\hat{T}(\hat{\Phi}\theta) = \hat{R} + \gamma \hat{\Phi}'\theta, \quad (2)$$

where  $\hat{\Phi}$  (resp.  $\hat{\Phi}'$ ) is the empirical feature matrix of size  $n \times d$ , whose  $i$ -th row is the feature vector  $\phi(s_i)^\top$  (resp.  $\phi(s'_i)^\top$ ), and  $\hat{R} \in \mathbb{R}^n$  is the reward vector, whose  $i$ -th element is  $r_i$ . We denote by  $\delta_i(\theta) = r_i + \gamma \phi'_i{}^\top \theta - \phi_i^\top \theta$ , the TD error for the  $i$ -th sample  $(s_i, r_i, s'_i)$  and define  $\Delta\phi_i = \phi_i - \gamma \phi'_i$ . Finally, we define the matrices  $A$  and  $C$ , and the vector  $b$  as

$$A := \mathbb{E}[\rho_i \phi_i (\Delta\phi_i)^\top], \quad b := \mathbb{E}[\rho_i \phi_i r_i], \quad C := \mathbb{E}[\phi_i \phi_i^\top], \quad (3)$$

where the expectations are w.r.t.  $\xi$  and  $P^{\pi_b}$ . We also denote by  $\Xi$ , the diagonal matrix whose elements are  $\xi(s)$ , and  $\xi_{\max} := \max_s \xi(s)$ . For each sample  $i$  in the training set  $\mathcal{D}$ , we can calculate an unbiased estimate of  $A$ ,  $b$ , and  $C$  as follows:

$$\hat{A}_i := \rho_i \phi_i \Delta\phi_i^\top, \quad \hat{b}_i := \rho_i r_i \phi_i, \quad \hat{C}_i := \phi_i \phi_i^\top. \quad (4)$$

### 2.1 GRADIENT-BASED TD ALGORITHMS

The class of gradient-based TD (GTD) algorithms were proposed by Sutton *et al.* [2008, 2009]. These algorithms target two objective functions: the *norm of the expected TD update* (NEU) and the *mean-square projected Bellman error* (MSPBE), defined as (see e.g., Maei 2011)<sup>1</sup>

$$\text{NEU}(\theta) = \|\Phi^\top \Xi (T\hat{v} - \hat{v})\|^2, \quad (5)$$

$$\text{MSPBE}(\theta) = \|\hat{v} - \Pi T\hat{v}\|_\xi^2 = \|\Phi^\top \Xi (T\hat{v} - \hat{v})\|_{C^{-1}}^2, \quad (6)$$

where  $C = \mathbb{E}[\phi_i \phi_i^\top] = \Phi^\top \Xi \Phi$  is the covariance matrix defined in Eq. 3 and is assumed to be non-singular, and  $\Pi = \Phi(\Phi^\top \Xi \Phi)^{-1} \Phi^\top \Xi$  is the orthogonal projection operator into the function space  $\mathcal{F}$ , i.e., for any bounded function  $g$ ,  $\Pi g = \arg \min_{f \in \mathcal{F}} \|g - f\|_\xi$ . From (5) and (6), it is clear that NEU and MSPBE are square unweighted and weighted by  $C^{-1}$ ,  $\ell_2$ -norms of the quantity  $\Phi^\top \Xi (T\hat{v} - \hat{v})$ , respectively, and thus, the two objective functions can be unified as

$$J(\theta) = \|\Phi^\top \Xi (T\hat{v} - \hat{v})\|_{M^{-1}}^2 = \|\mathbb{E}[\rho_i \delta_i(\theta) \phi_i]\|_{M^{-1}}^2, \quad (7)$$

<sup>1</sup> It is important to note that  $T$  in (5) and (6) is  $T^\pi$ , the Bellman operator of the target policy  $\pi$ .

with  $M$  equals to the identity matrix  $I$  for NEU and to the covariance matrix  $C$  for MSPBE. The second equality in (7) holds because of the following lemma from Section 4.2 in Maei [2011].

**Lemma 1.** *Let  $\mathcal{D} = \{(s_i, a_i, r_i, s'_i)\}_{i=1}^n$ ,  $s_i \sim \xi$ ,  $a_i \sim \pi_b(\cdot|s_i)$ ,  $s'_i \sim P(\cdot|s_i, a_i)$  be a training set generated by the behavior policy  $\pi_b$  and  $T$  be the Bellman operator of the target policy  $\pi$ . Then, we have*

$$\Phi^\top \Xi(T\hat{v} - \hat{v}) = \mathbb{E}[\rho_i \delta_i(\theta) \phi_i] = b - A\theta.$$

Motivated by minimizing the NEU and MSPBE objective functions using the stochastic gradient methods, the GTD and GTD2 algorithms were proposed with the following update rules:

$$\begin{aligned} \text{GTD:} \quad y_{t+1} &= y_t + \alpha_t (\rho_t \delta_t(\theta_t) \phi_t - y_t), \\ \theta_{t+1} &= \theta_t + \alpha_t \rho_t \Delta \phi_t (y_t^\top \phi_t), \end{aligned} \quad (8)$$

$$\begin{aligned} \text{GTD2:} \quad y_{t+1} &= y_t + \alpha_t (\rho_t \delta_t(\theta_t) - \phi_t^\top y_t) \phi_t, \\ \theta_{t+1} &= \theta_t + \alpha_t \rho_t \Delta \phi_t (y_t^\top \phi_t). \end{aligned} \quad (9)$$

However, it has been shown that the above update rules do not update the value function parameter  $\theta$  in the gradient direction of NEU and MSPBE, and thus, NEU and MSPBE are not the true objective functions of the GTD and GTD2 algorithms [Szepesvári, 2010]. Consider the NEU objective function in (5). Taking its gradient w.r.t.  $\theta$ , we obtain

$$\begin{aligned} -\frac{1}{2} \nabla \text{NEU}(\theta) &= -(\nabla \mathbb{E}[\rho_i \delta_i(\theta) \phi_i^\top]) \mathbb{E}[\rho_i \delta_i(\theta) \phi_i] \\ &= -(\mathbb{E}[\rho_i \nabla \delta_i(\theta) \phi_i^\top]) \mathbb{E}[\rho_i \delta_i(\theta) \phi_i] \\ &= \mathbb{E}[\rho_i \Delta \phi_i \phi_i^\top] \mathbb{E}[\rho_i \delta_i(\theta) \phi_i]. \end{aligned} \quad (10)$$

If the gradient can be written as a single expectation, then it is straightforward to use a stochastic gradient method. However, we have a product of two expectations in (10), and unfortunately, due to the correlation between them, the sample product (with a single sample) won't be an unbiased estimate of the gradient. To tackle this, the GTD algorithm uses an auxiliary variable  $y_t$  to estimate  $\mathbb{E}[\rho_i \delta_i(\theta) \phi_i]$ , and thus, the overall algorithm is no longer a true stochastic gradient method w.r.t. NEU. It can be easily shown that the same problem exists for GTD2 w.r.t. the MSPBE objective function. This prevents us from using the standard convergence analysis techniques of stochastic gradient descent methods to obtain a finite-sample performance bound for the GTD and GTD2 algorithms.

It should be also noted that in the original publications of GTD/GTD2 algorithms [Sutton *et al.*, 2008, 2009], the authors discussed handling the off-policy scenario using both importance and rejected sampling. In rejected sampling that was mainly used in Sutton *et al.* [2008, 2009], a sample  $(s_i, a_i, r_i, s'_i)$  is rejected and the parameter  $\theta$  does not update for this sample, if  $\pi(a_i|s_i) = 0$ . This sampling strategy is not efficient since a lot of samples will be discarded if  $\pi_b$  and  $\pi$  are very different.

## 2.2 RELATED WORK

Before we present a finite-sample performance bound for GTD and GTD2, it would be helpful to give a brief overview of the existing literature on finite-sample analysis of the TD algorithms. The convergence rate of the TD algorithms mainly depends on  $(d, n, \nu)$ , where  $d$  is the size of the approximation space (the dimension of the feature vector),  $n$  is the number of samples, and  $\nu$  is the smallest eigenvalue of the sample-based covariance matrix  $\hat{C} = \hat{\Phi}^\top \hat{\Phi}$ , i.e.,  $\nu = \lambda_{\min}(\hat{C})$ .

Antos *et al.* [2008] proved an error bound of  $O(\frac{d \log d}{n^{1/4}})$  for LSTD in bounded spaces. Lazaric *et al.* [2010b] proposed a LSTD analysis in leaner spaces and obtained a tighter bound of  $O(\sqrt{\frac{d \log d}{n\nu}})$  and later used it to derive a bound for the least-squares policy iteration (LSPI) algorithm [Lazaric *et al.*, 2012]. Tagorti and Scherrer [2014] recently proposed the first convergence analysis for LSTD( $\lambda$ ) and derived a bound of  $\tilde{O}(d/\nu\sqrt{n})$ . The analysis is a bit different than the one in Lazaric *et al.* [2010b] and the bound is weaker in terms of  $d$  and  $\nu$ . Another recent result is by Prashanth *et al.* [2014] that use stochastic approximation to solve LSTD(0), where the resulting algorithm is exactly TD(0) with random sampling (samples are drawn i.i.d. and not from a trajectory), and report a Markov design bound (the bound is computed only at the states used by the algorithm) of  $O(\sqrt{\frac{d}{n\nu}})$  for LSTD(0). All these results are for the on-policy setting, except the one by Antos *et al.* [2008] that also holds for the off-policy formulation. Another work in the off-policy setting is by Ávila Pires and Szepesvári [2012] that uses a bounding trick and improves the result of Antos *et al.* [2008] by a  $\log d$  factor.

The line of research reported here has much in common with work on proximal reinforcement learning [Mahadevan *et al.*, 2014], which explores first-order reinforcement learning algorithms using *mirror maps* [Bubeck, 2014; Juditsky *et al.*, 2008] to construct primal-dual spaces. This work began originally with a dual space formulation of first-order sparse TD learning [Mahadevan and Liu, 2012]. A saddle point formulation for off-policy TD learning was initially explored in Liu *et al.* [2012], where the objective function is the norm of the approximation residual of a linear inverse problem [Ávila Pires and Szepesvári, 2012]. A sparse off-policy GTD2 algorithm with regularized dual averaging is introduced by Qin and Li [2014]. These studies provide different approaches to formulating the problem, first as a variational inequality problem [Juditsky *et al.*, 2008; Mahadevan *et al.*, 2014] or as a linear inverse problem [Liu *et al.*, 2012], or as a quadratic objective function (MSPBE) using two-time-scale solvers [Qin and Li, 2014]. In this paper, we are going to explore the true nature of the GTD algorithms as stochastic gradient algorithm w.r.t the convex-concave saddle-point formulations of NEU and MSPBE.

### 3 SADDLE-POINT FORMULATION OF GTD ALGORITHMS

In this section, we show how the GTD and GTD2 algorithms can be formulated as true stochastic gradient (SG) algorithms by writing their respective objective functions, NEU and MSPBE, in the form of a convex-concave saddle-point. As discussed earlier, this new formulation of GTD and GTD2 as true SG methods allows us to use the convergence analysis techniques for SGs in order to derive finite-sample performance bounds for these RL algorithms. Moreover, it allows us to use more efficient algorithms that have been recently developed to solve SG problems, such as *stochastic Mirror-Prox* (SMP) [Juditsky *et al.*, 2008], to derive more efficient versions of GTD and GTD2.

A particular type of convex-concave saddle-point formulation is formally defined as

$$\min_{\theta} \max_y (L(\theta, y) = \langle b - A\theta, y \rangle + F(\theta) - K(y)), \quad (11)$$

where  $F(\theta)$  is a convex function and  $K(y)$  is a smooth convex function such that

$$K(y) - K(x) - \langle \nabla K(x), y - x \rangle \leq \frac{L_K}{2} \|x - y\|^2. \quad (12)$$

Next we follow Juditsky *et al.* [2008]; Nemirovski *et al.* [2009]; Chen *et al.* [2013] and define the following error function for the saddle-point problem (11).

**Definition 1.** *The error function of the saddle-point problem (11) at each point  $(\theta', y')$  is defined as*

$$\text{Err}(\theta', y') = \max_y L(\theta', y) - \min_{\theta} L(\theta, y'). \quad (13)$$

In this paper, we consider the saddle-point problem (11) with  $F(\theta) = 0$  and  $K(y) = \frac{1}{2} \|y\|_M^2$ , i.e.,

$$\min_{\theta} \max_y \left( L(\theta, y) = \langle b - A\theta, y \rangle - \frac{1}{2} \|y\|_M^2 \right), \quad (14)$$

where  $A$  and  $b$  were defined by Eq. 3, and  $M$  is a positive definite matrix. It is easy to show that  $K(y) = \frac{1}{2} \|y\|_M^2$  satisfies the condition in Eq. 12.

We first show in Proposition 1 that if  $(\theta^*, y^*)$  is the saddle-point of problem (14), then  $\theta^*$  will be the optimum of NEU and MSPBE defined in Eq. 7. We then prove in Proposition 2 that GTD and GTD2 in fact find this saddle-point.

**Proposition 1.** *For any fixed  $\theta$ , we have  $\frac{1}{2} J(\theta) = \max_y L(\theta, y)$ , where  $J(\theta)$  is defined by Eq. 7.*

*Proof.* Since  $L(\theta, y)$  is an unconstrained quadratic program w.r.t.  $y$ , the optimal  $y^*(\theta) = \arg \max_y L(\theta, y)$  can be analytically computed as

$$y^*(\theta) = M^{-1}(b - A\theta). \quad (15)$$

The result follows by plugging  $y^*$  into (14) and using the definition of  $J(\theta)$  in Eq. 7 and Lemma 1.  $\square$

**Proposition 2.** *GTD and GTD2 are true stochastic gradient algorithms w.r.t. the objective function  $L(\theta, y)$  of the saddle-point problem (14) with  $M = I$  and  $M = C = \Phi^\top \Xi \Phi$  (the covariance matrix), respectively.*

*Proof.* It is easy to see that the gradient updates of the saddle-point problem (14) (ascending in  $y$  and descending in  $\theta$ ) may be written as

$$\begin{aligned} y_{t+1} &= y_t + \alpha_t (b - A\theta_t - My_t), \\ \theta_{t+1} &= \theta_t + \alpha_t A^\top y_t. \end{aligned} \quad (16)$$

We denote  $\hat{M} := I$  (resp.  $\hat{M} := \hat{C}$ ) for GTD (resp. GTD2). We may obtain the update rules of GTD and GTD2 by replacing  $A$ ,  $b$ , and  $C$  in (16) with their unbiased estimates  $\hat{A}$ ,  $\hat{b}$ , and  $\hat{C}$  from Eq. 4, which completes the proof.  $\square$

### 4 FINITE-SAMPLE ANALYSIS

In this section, we provide a finite-sample analysis for a revised version of the GTD/GTD2 algorithms. We first describe the revised GTD algorithms in Section 4.1 and then dedicate the rest of Section 4 to their sample analysis. Note that from now on we use the  $M$  matrix (and its unbiased estimate  $\hat{M}_t$ ) to have a unified analysis for GTD and GTD2 algorithms. As described earlier,  $M$  is replaced by the identity matrix  $I$  in GTD and by the covariance matrix  $C$  (and its unbiased estimate  $\hat{C}_t$ ) in GTD2.

#### 4.1 THE REVISED GTD ALGORITHMS

The revised GTD algorithms that we analyze in this paper (see Algorithm 1) have three differences with the standard GTD algorithms of Eqs. 8 and 9 (and Eq. 16). **1)** We guarantee that the parameters  $\theta$  and  $y$  remain bounded by projecting them onto bounded convex feasible sets  $\Theta$  and  $Y$  defined in Assumption 2. In Algorithm 1, we denote by  $\Pi_\Theta$  and  $\Pi_Y$ , the projection into sets  $\Theta$  and  $Y$ , respectively. This is standard in stochastic approximation algorithms and has been used in off-policy TD( $\lambda$ ) [Yu, 2012] and actor-critic algorithms (e.g., Bhatnagar *et al.* 2009). **2)** after  $n$  iterations ( $n$  is the number of training samples in  $\mathcal{D}$ ), the algorithms return the weighted (by the step size) average of the parameters at all the  $n$  iterations (see Eq. 18). **3)** The step-size  $\alpha_t$  is selected as described in the proof of Proposition 3 in the supplementary material. Note that this fixed step size of  $O(1/\sqrt{n})$  is required for the high-probability bound in Proposition 3 (see Nemirovski *et al.* 2009 for more details).

#### 4.2 ASSUMPTIONS

In this section, we make several assumptions on the MDP and basis functions that are used in our finite-sample analysis of the revised GTD algorithms. These assumptions are

---

**Algorithm 1** Revised GTD Algorithms
 

---

 1: **for**  $t = 1, \dots, n$  **do**

2: Update parameters

$$\begin{aligned} y_{t+1} &= \Pi_Y \left( y_t + \alpha_t (\hat{b}_t - \hat{A}_t \theta_t - \hat{M}_t y_t) \right) \\ \theta_{t+1} &= \Pi_\Theta \left( \theta_t + \alpha_t \hat{A}_t^\top y_t \right) \end{aligned} \quad (17)$$

 3: **end for**

4: OUTPUT

$$\bar{\theta}_n := \frac{\sum_{t=1}^n \alpha_t \theta_t}{\sum_{t=1}^n \alpha_t}, \quad \bar{y}_n := \frac{\sum_{t=1}^n \alpha_t y_t}{\sum_{t=1}^n \alpha_t} \quad (18)$$

---

quite standard and are similar to those made in the prior work on GTD algorithms [Sutton *et al.*, 2008, 2009; Maei, 2011] and those made in the analysis of SG algorithms [Nemirovski *et al.*, 2009].

**Assumption 2. (Feasibility Sets)** We define the bounded closed convex sets  $\Theta \subset \mathbb{R}^d$  and  $Y \subset \mathbb{R}^d$  as the feasible sets in Algorithm 1. We further assume that the saddle-point  $(\theta^*, y^*)$  of the optimization problem (14) belongs to  $\Theta \times Y$ .

We also define  $D_\theta := [\max_{\theta \in \Theta} \|\theta\|_2^2 - \min_{\theta \in \Theta} \|\theta\|_2^2]^{1/2}$ ,  $D_y := [\max_{y \in Y} \|y\|_2^2 - \min_{y \in Y} \|y\|_2^2]^{1/2}$ , and  $R = \max \{ \max_{\theta \in \Theta} \|\theta\|_2, \max_{y \in Y} \|y\|_2 \}$ .

**Assumption 3. (Non-singularity)** We assume that the covariance matrix  $C = \mathbb{E}[\phi_i \phi_i^\top]$  and matrix  $A = \mathbb{E}[\rho_i \phi_i (\Delta \phi_i)^\top]$  are non-singular.

**Assumption 4. (Boundedness)** Assume the features  $(\phi_i, \phi'_i)$  have uniformly bounded second moments. This together with the boundedness of features (by  $L$ ) and importance weights (by  $\rho_{\max}$ ) guarantees that the matrices  $A$  and  $C$ , and vector  $b$  are uniformly bounded.

This assumption guarantees that for any  $(\theta, y) \in \Theta \times Y$ , the unbiased estimators of  $b - A\theta - My$  and  $A^\top y$ , i.e.,

$$\begin{aligned} \mathbb{E}[\hat{b}_t - \hat{A}_t \theta - \hat{M}_t y] &= b - A\theta - My, \\ \mathbb{E}[\hat{A}_t^\top y] &= A^\top y, \end{aligned} \quad (19)$$

all have bounded variance, i.e.,

$$\begin{aligned} \mathbb{E}[|\hat{b}_t - \hat{A}_t \theta - \hat{M}_t y - (b - A\theta - My)|^2] &\leq \sigma_1^2, \\ \mathbb{E}[|\hat{A}_t^\top y - A^\top y|^2] &\leq \sigma_2^2, \end{aligned} \quad (20)$$

where  $\sigma_1$  and  $\sigma_2$  are non-negative constants. We further define

$$\sigma^2 = \sigma_1^2 + \sigma_2^2. \quad (21)$$

Assumption 4 also gives us the following ‘‘light-tail’’ assumption. There exist constants  $M_{*,\theta}$  and  $M_{*,y}$  such that

$$\begin{aligned} \mathbb{E}[\exp\{\frac{|\hat{b}_t - \hat{A}_t \theta - \hat{M}_t y|^2}{M_{*,\theta}^2}\}] &\leq \exp\{1\}, \\ \mathbb{E}[\exp\{\frac{|\hat{A}_t^\top y|^2}{M_{*,y}^2}\}] &\leq \exp\{1\}. \end{aligned} \quad (22)$$

This ‘‘light-tail’’ assumption is equivalent to the assumption in Eq. 3.16 in Nemirovski *et al.* [2009] and is necessary for the high-probability bound of Proposition 3. We will show how to compute  $M_{*,\theta}$ ,  $M_{*,y}$  in the Appendix.

### 4.3 FINITE-SAMPLE PERFORMANCE BOUNDS

The finite-sample performance bounds that we derive for the GTD algorithms in this section are for the case that the training set  $\mathcal{D}$  has been generated as discussed in Section 2. We further discriminate between the on-policy ( $\pi = \pi_b$ ) and off-policy ( $\pi \neq \pi_b$ ) scenarios. The sampling scheme used to generate  $\mathcal{D}$ , in which the first state of each tuple,  $s_i$ , is an i.i.d. sample from a distribution  $\xi$ , also considered in the original GTD and GTD2 papers, for the analysis of these algorithms, and not in the experiments [Sutton *et al.*, 2008, 2009]. Another scenario that can motivate this sampling scheme is when we are given a set of high-dimensional data generated either in an on-policy or off-policy manner, and  $d$  is so large that the value function of the target policy cannot be computed using a least-squares method (that involves matrix inversion), and iterative techniques similar to GTD/GTD2 are required.

We first derive a high-probability bound on the error function of the saddle-point problem (14) at the GTD solution  $(\bar{\theta}_n, \bar{y}_n)$ . Before stating this result in Proposition 3, we report the following lemma that is used in its proof.

**Lemma 2.** *The induced  $\ell_2$ -norm of matrix  $A$  and the  $\ell_2$ -norm of vector  $b$  are bounded by*

$$\|A\|_2 \leq (1 + \gamma)\rho_{\max}L^2d, \quad \|b\|_2 \leq \rho_{\max}LR_{\max}. \quad (23)$$

*Proof.* See the supplementary material.  $\square$

**Proposition 3.** *Let  $(\bar{\theta}_n, \bar{y}_n)$  be the output of the GTD algorithm after  $n$  iterations (see Eq. 18). Then, with probability at least  $1 - \delta$ , we have*

$$\begin{aligned} \text{Err}(\bar{\theta}_n, \bar{y}_n) &\leq \sqrt{\frac{5}{n}}(8 + 2 \log \frac{2}{\delta})R^2 \\ &\times \left( \rho_{\max}L \left( 2(1 + \gamma)Ld + \frac{R_{\max}}{R} \right) + \tau + \frac{\sigma}{R} \right), \end{aligned} \quad (24)$$

where  $\text{Err}(\bar{\theta}_n, \bar{y}_n)$  is the error function of the saddle-point problem (14) defined by Eq. 13,  $R$  defined in Assumption 2,  $\sigma$  is from Eq. 21, and  $\tau = \sigma_{\max}(M)$  is the largest singular value of  $M$ , which means  $\tau = 1$  for GTD and  $\tau = \sigma_{\max}(C)$  for GTD2.

*Proof.* See the supplementary material.  $\square$

**Theorem 1.** *Let  $\bar{\theta}_n$  be the output of the GTD algorithm after  $n$  iterations (see Eq. 18). Then, with probability at least  $1 - \delta$ , we have*

$$\frac{1}{2} \|A\bar{\theta}_n - b\|_\xi^2 \leq \tau \xi_{\max} \text{Err}(\bar{\theta}_n, \bar{y}_n). \quad (25)$$

*Proof.* From Proposition 1, for any  $\theta$ , we have

$$\max_y L(\theta, y) = \frac{1}{2} \|A\theta - b\|_{M^{-1}}^2.$$

Given Assumption 3, the system of linear equations  $A\theta = b$  has a solution  $\theta^*$ , i.e., the (off-policy) fixed-point  $\theta^*$  exists, and thus, we may write

$$\begin{aligned} \min_{\theta} \max_y L(\theta, y) &= \min_{\theta} \frac{1}{2} \|A\theta - b\|_{M^{-1}}^2 \\ &= \frac{1}{2} \|A\theta^* - b\|_{M^{-1}}^2 = 0. \end{aligned}$$

In this case, we also have<sup>2</sup>

$$\begin{aligned} \min_{\theta} L(\theta, y) &\leq \max_y \min_{\theta} L(\theta, y) \leq \min_{\theta} \max_y L(\theta, y) \\ &= \frac{1}{2} \|A\theta^* - b\|_{M^{-1}}^2 = 0. \end{aligned} \quad (26)$$

From Eq. 26, for any  $(\theta, y) \in \Theta \times Y$  including  $(\bar{\theta}_n, \bar{y}_n)$ , we may write

$$\begin{aligned} \text{Err}(\bar{\theta}_n, \bar{y}_n) &= \max_y L(\bar{\theta}_n, y) - \min_{\theta} L(\theta, \bar{y}_n) \\ &\geq \max_y L(\bar{\theta}_n, y) = \frac{1}{2} \|A\bar{\theta}_n - b\|_{M^{-1}}^2. \end{aligned} \quad (27)$$

Since  $\|A\bar{\theta}_n - b\|_{\xi}^2 \leq \tau \xi_{\max} \|A\bar{\theta}_n - b\|_{M^{-1}}^2$ , where  $\tau$  is the largest singular value of  $M$ , we have

$$\frac{1}{2} \|A\bar{\theta}_n - b\|_{\xi}^2 \leq \frac{\tau \xi_{\max}}{2} \|A\bar{\theta}_n - b\|_{M^{-1}}^2 \leq \tau \xi_{\max} \text{Err}(\bar{\theta}_n, \bar{y}_n). \quad (28)$$

The proof follows by combining Eqs. 28 and Proposition 3. It completes the proof.  $\square$

With the results of Proposition 3 and Theorem 1, we are now ready to derive finite-sample bounds on the performance of GTD/GTD2 in both on-policy and off-policy settings.

### 4.3.1 On-Policy Performance Bound

In this section, we consider the on-policy setting in which the behavior and target policies are equal, i.e.,  $\pi_b = \pi$ , and the sampling distribution  $\xi$  is the stationary distribution of the target policy  $\pi$  (and the behavior policy  $\pi_b$ ). We use Lemma 3 to derive our on-policy bound. The proof of this lemma can be found in Geist *et al.* [2012].

**Lemma 3.** *For any parameter vector  $\theta$  and corresponding  $\hat{v} = \Phi\theta$ , the following equality holds*

$$V - \hat{v} = (I - \gamma \Pi P)^{-1} [(V - \Pi V) + \Phi C^{-1}(b - A\theta)]. \quad (29)$$

Using Lemma 3, we derive the following performance bound for GTD/GTD2 in the on-policy setting.

<sup>2</sup>We may write the second inequality as an equality for our saddle-point problem defined by Eq. 14.

**Proposition 4.** *Let  $V$  be the value of the target policy and  $\bar{v}_n = \Phi\bar{\theta}_n$ , where  $\bar{\theta}_n$  defined by (18), be the value function returned by on-policy GTD/GTD2. Then, with probability at least  $1 - \delta$ , we have*

$$\|V - \bar{v}_n\|_{\xi} \leq \frac{1}{1 - \gamma} \left( \|V - \Pi V\|_{\xi} + \frac{L}{\nu} \sqrt{2d\tau \xi_{\max} \text{Err}(\bar{\theta}_n, \bar{y}_n)} \right) \quad (30)$$

where  $\text{Err}(\bar{\theta}_n, \bar{y}_n)$  is upper-bounded by Eq. 24 in Proposition 3, with  $\rho_{\max} = 1$  (on-policy setting).

*Proof.* See the supplementary material.  $\square$

**Remark:** It is important to note that Proposition 4 shows that the error in the performance of the GTD/GTD2 algorithm in the on-policy setting is of  $O\left(\frac{L^2 d \sqrt{\tau \xi_{\max} \log \frac{1}{\delta}}}{n^{1/4} \nu}\right)$ . Also note that the term  $\frac{\tau}{\nu}$  in the GTD2 bound is the conditioning number of the covariance matrix  $C$ .

### 4.3.2 Off-Policy Performance Bound

In this section, we consider the off-policy setting in which the behavior and target policies are different, i.e.,  $\pi_b \neq \pi$ , and the sampling distribution  $\xi$  is the stationary distribution of the behavior policy  $\pi_b$ . We assume that off-policy fixed-point solution exists, i.e., there exists a  $\theta^*$  satisfying  $A\theta^* = b$ . Note that this is a direct consequence of Assumption 3 in which we assumed that the matrix  $A$  in the off-policy setting is non-singular. We use Lemma 4 to derive our off-policy bound. The proof of this lemma can be found in Kolter [2011]. Note that  $\kappa(\bar{D})$  in his proof is equal to  $\sqrt{\rho_{\max}}$  in our paper.

**Lemma 4.** *If  $\Xi$  satisfies the following linear matrix inequality*

$$\begin{bmatrix} \Phi^{\top} \Xi \Phi & \Phi^{\top} \Xi P \Phi \\ \Phi^{\top} P^{\top} \Xi \Phi & \Phi^{\top} \Xi \Phi \end{bmatrix} \succeq 0 \quad (31)$$

and let  $\theta^*$  be the solution to  $A\theta^* = b$ , then we have

$$\|V - \Phi\theta^*\|_{\xi} \leq \frac{1 + \gamma \sqrt{\rho_{\max}}}{1 - \gamma} \|V - \Pi V\|_{\xi}. \quad (32)$$

Note that the condition on  $\Xi$  in Eq. 31 guarantees that the behavior and target policies are not too far away from each other. Using Lemma 4, we derive the following performance bound for GTD/GTD2 in the off-policy setting.

**Proposition 5.** *Let  $V$  be the value of the target policy and  $\bar{v}_n = \Phi\bar{\theta}_n$ , where  $\bar{\theta}_n$  is defined by (18), be the value function returned by off-policy GTD/GTD2. Also let the sampling distribution  $\Xi$  satisfies the condition in Eq. 31. Then,*

with probability at least  $1 - \delta$ , we have

$$\|V - \bar{v}_n\|_\xi \leq \frac{1 + \gamma\sqrt{\rho_{\max}}}{1 - \gamma} \|V - \Pi V\|_\xi \quad (33)$$

$$+ \sqrt{\frac{2\tau_C\tau\xi_{\max}}{\sigma_{\min}(A^\top M^{-1}A)} \text{Err}(\bar{\theta}_n, \bar{y}_n)},$$

where  $\tau_C = \sigma_{\max}(C)$ .

*Proof.* See the supplementary material.  $\square$

## 5 ACCELERATED ALGORITHM

As discussed at the beginning of Section 3, this saddle-point formulation not only gives us the opportunity to use the techniques for the analysis of SG methods to derive finite-sample performance bounds for the GTD algorithms, as we will show in Section 4, but also it allows us to use the powerful algorithms that have been recently developed to solve the SG problems and derive more efficient versions of GTD and GTD2. Stochastic Mirror-Prox (SMP) [Juditsky *et al.*, 2008] is an ‘‘almost dimension-free’’ non-Euclidean extra-gradient method that deals with both smooth and non-smooth stochastic optimization problems (see Juditsky and Nemirovski 2011 and Bubeck 2014 for more details). Using SMP, we propose a new version of GTD/GTD2, called GTD-MP/GTD2-MP, with the following update formula.<sup>3</sup>

$$y_t^m = y_t + \alpha_t(\hat{b}_t - \hat{A}_t\theta_t - \hat{M}_ty_t), \quad \theta_t^m = \theta_t + \alpha_t\hat{A}_t^\top y_t,$$

$$y_{t+1} = y_t + \alpha_t(\hat{b}_t - \hat{A}_t\theta_t^m - \hat{M}_ty_t^m), \quad \theta_{t+1} = \theta_t + \alpha_t\hat{A}_t^\top y_t^m.$$

After  $T$  iterations, these algorithms return  $\bar{\theta}_T := \frac{\sum_{t=1}^T \alpha_t \theta_t}{\sum_{t=1}^T \alpha_t}$  and  $\bar{y}_T := \frac{\sum_{t=1}^T \alpha_t y_t}{\sum_{t=1}^T \alpha_t}$ . The details of the algorithm is shown in Algorithm 2, and the experimental comparison study between GTD2 and GTD2-MP is reported in Section 7.

## 6 FURTHER ANALYSIS

### 6.1 ACCELERATION ANALYSIS

In this section, we are going to discuss the convergence rate of the accelerated algorithms using off-the-shelf accelerated solvers for saddle-point problems. For simplicity, we will discuss the error bound of  $\frac{1}{2}\|A\theta - b\|_{M^{-1}}^2$ , and the corresponding error bound of  $\frac{1}{2}\|A\theta - b\|_\xi^2$  and  $\|V - \bar{v}_n\|_\xi$  can be likewise derived as in above analysis. As can be seen from the above analysis, the convergence rate of the GTD algorithms family is

$$\text{(GTD/GTD2)} : \quad O\left(\frac{\tau + \|A\|_2 + \sigma}{\sqrt{n}}\right) \quad (35)$$

<sup>3</sup>For simplicity, we only describe mirror-prox GTD methods where the mirror map is identity, which can also be viewed as extragradient (EG) GTD methods. Mahadevan *et al.* [2014] gives a more detailed discussion of a broad range of mirror maps in RL.

---

### Algorithm 2 GTD2-MP

---

1: **for**  $t = 1, \dots, n$  **do**

2: Update parameters

$$\delta_t = r_t - \theta_t^\top \Delta \phi_t$$

$$y_t^m = y_t + \alpha_t(\rho_t \delta_t - \phi_t^\top y_t) \phi_t$$

$$\theta_t^m = \theta_t + \alpha_t \rho_t \Delta \phi_t (\phi_t^\top y_t)$$

$$\delta_t^m = r_t - (\theta_t^m)^\top \Delta \phi_t$$

$$y_{t+1} = y_t + \alpha_t(\rho_t \delta_t^m - \phi_t^\top y_t^m) \phi_t$$

$$\theta_{t+1} = \theta_t + \alpha_t \rho_t \Delta \phi_t (\phi_t^\top y_t^m)$$

3: **end for**

4: OUTPUT

$$\bar{\theta}_n := \frac{\sum_{t=1}^n \alpha_t \theta_t}{\sum_{t=1}^n \alpha_t}, \quad \bar{y}_n := \frac{\sum_{t=1}^n \alpha_t y_t}{\sum_{t=1}^n \alpha_t} \quad (34)$$

---

In this section, we raise an interesting question: what is the ‘‘optimal’’ GTD algorithm? To answer this question, we review the convex-concave formulation of GTD2. According to convex programming complexity theory [Juditsky *et al.*, 2008], the un-improvable convergence rate of stochastic saddle-point problem (14) is

$$\text{(Optimal)} : \quad O\left(\frac{\tau}{n^2} + \frac{\|A\|_2}{n} + \frac{\sigma}{\sqrt{n}}\right) \quad (36)$$

There are many readily available stochastic saddle-point solvers, such as stochastic Mirror-Prox (SMP) [Juditsky *et al.*, 2008] algorithm, which leads to our proposed GTD2-MP algorithm. SMP is able to accelerate the convergence rate of our gradient TD method to:

$$\text{(SMP)} : \quad O\left(\frac{\tau + \|A\|_2}{n} + \frac{\sigma}{\sqrt{n}}\right), \quad (37)$$

and stochastic accelerated primal-dual (SAPD) method [Chen *et al.*, 2013] which can reach the optimal convergence rate in (36). Due to space limitations, we are unable to present a more complete description, and refer interested readers to Juditsky *et al.* [2008]; Chen *et al.* [2013] for more details.

### 6.2 LEARNING WITH BIASED $\rho_t$

The importance weight factor  $\rho_t$  is lower bounded by 0, but yet may have an arbitrarily large upper bound. In real applications, the importance weight factor  $\rho_t$  may not be estimated exactly, i.e., the estimation  $\hat{\rho}_t$  is a biased estimation of the true  $\rho_t$ . To this end, the stochastic gradient we obtained is not unbiased gradient of  $L(\theta, y)$  anymore. This falls into a broad category of learning with inexact stochastic gradient, or termed as stochastic gradient methods with an inexact oracle [Devolder, 2011]. Given the inexact stochastic gradient, the convergence rate and performance bound become much worse than the results with

exact stochastic gradient. Based on the analysis by Juditsky *et al.* [2008], we have the error bound for inexact estimation of  $\rho_t$ .

**Proposition 6.** *Let  $\bar{\theta}_n$  be defined as above. Assume at the  $t$ -th iteration,  $\hat{\rho}_t$  is the estimation of the importance weight factor  $\rho_t$  with bounded bias such that  $\mathbb{E}[\hat{\rho}_t - \rho_t] \leq \epsilon$ . The convergence rates of GTD/GTD2 algorithms with iterative averaging is as follows, i.e.,*

$$\|A\bar{\theta}_n - b\|_{M^{-1}}^2 \leq O\left(\frac{\tau + \|A\|_2 + \sigma}{\sqrt{n}}\right) + O(\epsilon) \quad (38)$$

This implies that the inexact estimation of  $\rho_t$  may cause disastrous estimation error, which implies that an exact estimation of  $\rho_t$  is very important.

### 6.3 FINITE-SAMPLE ANALYSIS OF ONLINE LEARNING

Another more challenging scenario is online learning scenario, where the samples are interactively generated by the environment, or by an interactive agent. The difficulty lies in that the sample distribution does not follow i.i.d sampling condition anymore, but follows an underlying Markov chain  $\mathcal{M}$ . If the Markov chain  $\mathcal{M}$ 's mixing time is small enough, i.e., the sample distribution reduces to the stationary distribution of  $\pi_b$  very fast, our analysis still applies. However, it is usually the case that the underlying Markov chain's mixing time  $\tau_{\text{mix}}$  is not small enough. The analysis result can be obtained by extending the result of recent work [Duchi *et al.*, 2012] from strongly convex loss functions to saddle-point problems, which is non-trivial and is thus left for future work.

### 6.4 DISCUSSION OF TDC ALGORITHM

Now we discuss the limitation of our analysis with regard to the temporal difference with correction (TDC) algorithm [Sutton *et al.*, 2009]. Interestingly, the TDC algorithm seems not to have an explicit saddle-point representation, since it incorporates the information of the optimal  $y_t^*(\theta_t)$  into the update of  $\theta_t$ , a quasi-stationary condition which is commonly used in two-time-scale stochastic approximation approaches. An intuitive answer to the advantage of TDC over GTD2 is that the TDC update of  $\theta_t$  can be considered as incorporating the prior knowledge into the update rule: for a stationary  $\theta_t$ , if the optimal  $y_t^*(\theta_t)$  has a closed-form solution or is easy to compute, then incorporating this  $y_t^*(\theta_t)$  into the update law tends to accelerate the algorithm's convergence performance. For the GTD2 update, note that there is a sum of two terms where  $y_t$  appears, which are  $\rho_t(\phi_t - \gamma\phi_t)(y_t^T \phi_t) = \rho_t\phi_t(y_t^T \phi_t) - \gamma\rho_t\phi_t'(y_t^T \phi_t)$ . Replacing  $y_t$  in the first term with  $y_t^*(\theta_t) = \mathbb{E}[\phi_t\phi_t^T]^{-1}\mathbb{E}[\rho_t\delta_t(\theta_t)\phi_t]$ , we have the TDC update rule. Note that in contrast to GTD/GTD2, TDC is a two-time scale algorithm; Also, note that TDC does not minimize

any objective functions and the convergence of TDC requires more restrictions than GTD2 as shown by Sutton *et al.* [2009].

## 7 EMPIRICAL EVALUATION

In this section, we compare the previous GTD2 method with our proposed GTD2-MP method using various domains with regard to their value function approximation performance capability. It should be mentioned that since the major focus of this paper is on policy evaluation, the comparative study focuses on value function approximation and thus comparisons on control learning performance is not reported in this paper.

### 7.1 BAIRD DOMAIN

The Baird example [Baird, 1995] is a well-known example to test the performance of off-policy convergent algorithms. Constant stepsize  $\alpha = 0.005$  for GTD2 and  $\alpha = 0.004$  for GTD2-MP, which are chosen via comparison studies as in [Dann *et al.*, 2014]. Figure 1 shows the MSPBE curve of GTD2, GTD2-MP of 8000 steps averaged over 200 runs. We can see that GTD2-MP has a significant improvement over the GTD2 algorithm wherein both the MSPBE and the variance are substantially reduced.

Figure 1: Off-Policy Convergence Comparison

### 7.2 50-STATE CHAIN DOMAIN

The 50 state chain [Lagoudakis and Parr, 2003] is a standard MDP domain. There are 50 discrete states  $\{s_i\}_{i=1}^{50}$  and two actions moving the agent left  $s_i \rightarrow s_{\max(i-1,1)}$  and right  $s_i \rightarrow s_{\min(i+1,50)}$ . The actions succeed with probability 0.9; failed actions move the agent in the opposite direction. The discount factor is  $\gamma = 0.9$ . The agent receives a reward of +1 when in states  $s_{10}$  and  $s_{41}$ . All other states have a reward of 0. In this experiment, we compare the performance of the value approximation w.r.t different set of stepsizes  $\alpha = 0.0001, 0.001, 0.01, 0.1, 0.2, \dots, 0.9$  using the BEBF basis [Parr *et al.*, 2007], and Figure 2 shows the value function approximation result, where the cyan curve

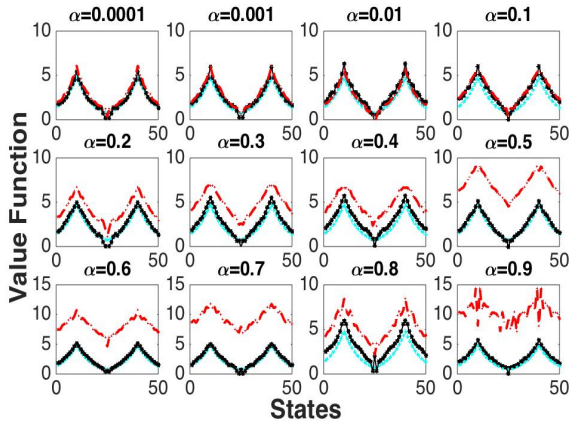

Figure 2: Chain Domain

is the true value function, the red dashed curve is the GTD result, and the black curve is the GTD2-MP result. From the figure, one can see that GTD2-MP is much more robust with stepsize choice than the GTD2 algorithm.

### 7.3 ENERGY MANAGEMENT DOMAIN

In this experiment we compare the performance of the algorithms on an energy management domain. The decision maker must decide how much energy to purchase or sell subject to stochastic prices. This problem is relevant in the context of utilities as well as in settings such as hybrid vehicles. The prices are generated from a Markov chain process. The amount of available storage is limited and it also degrades with use. The degradation process is based on the physical properties of lithium-ion batteries and discourages fully charging or discharging the battery. The energy arbitrage problem is closely related to the broad class of inventory management problems, with the storage level corresponding to the inventory. However, there are no known results describing the structure of optimal threshold policies in energy storage.

Note that since for this off-policy evaluation problem, the formulated  $A\theta = b$  does not have a solution, and thus the optimal  $MSPBE(\theta^*)$  (resp.  $MSBE(\theta^*)$ ) do not reduce to 0. The result is averaged over 200 runs, and  $\alpha = 0.001$  for both GTD2 and GTD2-MP is chosen via comparison studies for each algorithm. As can be seen from Figure 3, in the initial transit state, GTD2-MP performs much better than GTD2 at the transient state. Then after reaching the steady state, as can be seen from Table 1, we can see that GTD2-MP reaches better steady state solution than the GTD algorithm. Based on the above empirical results and many other experiments we have conducted in other domains, we can conclude that GTD2-MP usually performs much better than the “vanilla” GTD2 algorithm.

Figure 3: Energy Management Example

| Algorithm | MSPBE | MSBE  |
|-----------|-------|-------|
| GTD2      | 176.4 | 228.7 |
| GTD2-MP   | 138.6 | 191.4 |

Table 1: Steady State Performance Comparison

## 8 SUMMARY

In this paper, we showed how gradient TD methods can be shown to be true stochastic gradient methods with respect to a saddle-point primal-dual objective function, which paved the way for the finite-sample analysis of off-policy convergent gradient-based temporal difference learning algorithms such as GTD and GTD2. Both error bound and performance bound are provided, which shows that the value function approximation bound of the GTD algorithms family is  $O\left(\frac{d}{n^{1/4}}\right)$ . Further, two revised algorithms, namely the projected GTD2 algorithm and the accelerated GTD2-MP algorithm, are proposed. There are many interesting directions for future research. Our framework can be easily used to design regularized sparse gradient off-policy TD methods. One interesting direction is to investigate the convergence rate and performance bound for the TDC algorithm, which lacks a saddle-point formulation. The other is to explore tighter value function approximation bounds for off-policy learning.

## Abstract

Importance sampling (IS) and its variant, annealed IS (AIS) have been widely used for estimating the partition function in graphical models, such as Markov random fields and deep generative models. However, IS tends to underestimate the partition function and is subject to high variance when the proposal distribution is more peaked than the target distribution. On the other hand, “reverse” versions of IS and AIS tend to overestimate the partition function, and degenerate when the target distribution is more peaked than the proposal distribution. In this work, we present a simple, general method that gives much more reliable and robust estimates than either IS (AIS) or reverse IS (AIS). Our method works by converting the estimation problem into a simple classification problem that discriminates between the samples drawn from the target and the proposal. We give extensive theoretical and empirical justification; in particular, we show that an annealed version of our method significantly outperforms both AIS and reverse AIS as proposed by Burda et al. (2015), which has been the state-of-the-art for likelihood evaluation in deep generative models.

## 1 INTRODUCTION

Probabilistic graphical models, such as Markov random fields, Bayesian networks, and deep generative models provide a powerful set of tools for machine learning (e.g., Lauritzen, 1996, Salakhutdinov and Hinton, 2009). Bayesian analysis utilizing graphical models often involves calculating the partition function, *i.e.* the normalizing constant of the distribution. Unfortunately, such computations are prohibitive (often intractable) for general loopy graphical

models. As such, efficient approximations via variational inference and Monte Carlo methods are of great interest.

Importance sampling (IS) and its variants, such as annealed importance sampling (AIS) (Neal, 2001), are probably the most widely used Monte Carlo methods for estimating the partition function. IS works by drawing samples from a tractable proposal (or reference) distribution  $p_0(x)$ , and estimates the target partition function  $Z = \int f(x)$  by averaging the importance weights  $f(x)/p_0(x)$  across the samples. Unfortunately, the IS estimate often has very high variance if the choice of proposal distribution is very different from the target, especially when the proposal is more peaked or has thinner tails than the target. In addition, in practice IS often underestimates the partition function due to the heavy-tailed nature of the importance weights, leading to overly optimistic likelihood estimates when used for model evaluation (e.g., Burda et al., 2015).

On the other hand, the weighted harmonic mean method (Gelfand and Dey, 1994), which we refer to as a *reverse importance sampling* (RIS), works in an opposite way from IS. It draws samples from the *target distribution*  $p(x) = f(x)/Z$ , and estimates  $Z$  by taking the harmonic mean of the importance weights  $f(x)/p_0(x)$  across these samples. In contrast to IS, reverse IS tends to overestimate the partition function, and gives a high variance when the target distribution is more peaked than the proposal. A reverse version of annealed importance sampling was recently proposed by Burda et al. (2015) to give conservative estimates of test likelihood, in contrast to standard AIS that (like IS) tends to overestimate the likelihood.

Given the opposing properties of IS and RIS, a natural way to improve both is to take the average, or weighted average, of their estimates, in the hope of canceling their individual biases. Unfortunately, the magnitude of bias in IS and RIS can be extremely imbalanced, and it is difficult to decide how much weight each should be given. What is worse, the average would inherit the largest variance between IS and RIS, making even more stringent requirements on the proposal, which should then be neither more peaked nor more flat than the target.

---

\*Both authors contributed equally.

In this work, we study a more efficient and straightforward method for estimating the partition function based on samples from *both* the target distribution and the proposal distribution. The idea is to re-frame estimation of  $Z$  as a simple classification problem that discriminates between the two samples from the target  $p(x)$  and proposal  $p_0(x)$ , respectively. Our method does not have the inherent biases observed in IS and RIS, and is much more robust in that it always has finite variance whenever the proposal and target distributions overlap, a far more mild condition that is easy to satisfy in practice. We provide extensive theoretical and empirical justification for our method. In addition, we show that an annealed importance sampling (AIS) counterpart of our method significantly outperforms AIS, reverse AIS, and their average, which are currently state-of-the-art for model evaluation in deep generative models (Salakhutdinov and Murray, 2008, Burda et al., 2015).

**Outline** The remainder of the paper is organized as follows. We discuss related work in Section 2 and introduce background on IS and RIS in Section 3. Section 4 discusses the proposed method followed by an annealed extension in Section 5. We give experiments in Section 6. The conclusion is provided in Section 7.

## 2 RELATED WORK

The same idea of estimating normalization constants by discriminating between different samples was first proposed independently by Geyer (1991, 1994), although it seems not to be well known in the machine learning community;<sup>1</sup> our work appears to be the first to apply the idea in graphical models, and importantly, propose the annealed version that we show is effective on challenging deep generative models. Another interesting connection can be drawn with a recent noise-matching algorithm (Gutmann and Hyvärinen, 2010) for learning graphical models with intractable partition functions, which is based on a similar idea of discriminating between the observed data (from a *unknown* target distribution) and some artificially generated noise (from the proposal distribution). In fact, our algorithm can be treated as a special noise matching algorithm on a graphical model with only a single unknown parameter  $Z$ . This connection is surprising in part because a naïve likelihood-based or Bayesian inference procedure treating  $Z$  as an unknown parameter fails to work, as discussed in Wasserman (Example 11.10, page 188, 2011) and a thread of related internet discussion (e.g., Wasserman, 2012, and links therein). An intriguing open question is to understand if there exists a principled procedure that turns any *partition function free* learning algorithm, such as Hinton (2002), Lyu (2011), Asuncion et al. (2010), Sohl-Dickstein et al. (2011), into a corresponding *partition function inference* method.

<sup>1</sup> This connection was found by the authors after acceptance.

Related to importance sampling, its use in graphical models almost always require certain variance reduction techniques. Variants of annealed importance sampling based approaches (e.g., Salakhutdinov and Murray, 2008, Theis et al., 2011, Burda et al., 2015, Ma et al., 2013) have been proposed, and are widely used for likelihood evaluation of deep generative models. Other examples of variance reduction methods include adaptive improvement of the proposal (e.g., Cheng and Druzdzal, 2000), and combining with search based methods (e.g., Gogate, 2009, Gogate and Dechter, 2012, 2011) or variational methods (e.g., Wexler and Geiger, 2007). Note that our approach is orthogonal to these developments, and can be combined with them to achieve even better results. In fact, many of our experiments are set up to demonstrate the advantages of combining our method with variational and annealing techniques.

There are also other algorithms that leverage samples from the target distribution. For example, Chib (1995), Chib and Jeliazkov (2001) calculate the marginal likelihood from the output of Gibbs sampling or Metropolis-Hastings. Also related are other generalizations of importance sampling, such as bridge sampling and path sampling (Meng and Wong, 1996, Gelman and Meng, 1998).

## 3 BACKGROUND

Assume we have a distribution  $p(x) = f(x)/Z$ , where  $Z = \int f(x)d\mu(x)$  is the partition function that we are interested in calculating; here the base measure  $\mu(x)$  can be the counting measure for discrete variables, or Lebesgue for continuous variables. We consider Monte Carlo methods for estimating  $Z$ . Two basic methods are the following:

**Importance Sampling (IS)** Assume we have a tractable distribution  $p_0(x)$  which has been properly normalized, that is,  $\int p_0(x)d\mu(x) = 1$ . We draw samples  $\{x_0^1, \dots, x_0^n\}$  from  $p_0(x)$ , and estimate  $Z$  by

$$\hat{Z}_{\text{is}} = \frac{1}{n} \sum_{i=1}^n \frac{f(x_0^i)}{p_0(x_0^i)}.$$

This is an unbiased estimator of  $Z$ , that is,  $\mathbb{E}(\hat{Z}_{\text{is}}) = Z$ , and its mean squared error is known to be

$$n\mathbb{E}\left[\frac{(\hat{Z}_{\text{is}} - Z)^2}{Z^2}\right] = \chi^2(p||p_0) = \int \frac{p^2}{p_0} d\mu(x) - 1, \quad (1)$$

where  $\chi^2(\cdot||\cdot)$  represents the chi-square divergence.

Unfortunately,  $\chi^2(p||p_0)$  is often impractically large, or even infinite, especially when  $p_0(x)$  is more peaked than  $p(x)$ . Additionally, despite the theoretical unbiasedness of  $\hat{Z}$ , it often underestimates  $Z$ . This is due to the distribution of the weights  $f(x)/p_0(x)$  being heavy-tailed with a resulting propensity for outliers. Consequently, the results

using IS may be more properly viewed as a probabilistic lower bound rather than an unbiased estimate (e.g., Burda et al., 2015).

**Reverse Importance Sampling (RIS)** The *weighted harmonic mean method* (Gelfand and Dey, 1994), which we refer to as a reverse importance sampling method, works in an opposite way to importance sampling. It draws samples  $\{x_1^1, \dots, x_1^n\}$  from the *target distribution*  $p(x)$  (e.g., via MCMC when exact sampling is difficult for  $p(x)$ ), and estimates  $Z$  by

$$\hat{Z}_{\text{ris}} = \left[ \frac{1}{n} \sum_{i=1}^n \frac{p_0(x_1^i)}{f(x_1^i)} \right]^{-1}.$$

Note that  $1/\hat{Z}_{\text{ris}}$  can be viewed as a regular importance sampling estimate for  $1/Z$ , justifying  $\hat{Z}_{\text{ris}}$  as a reasonable estimate of  $Z$ . Under regularity conditions (Gelfand and Dey, 1994), the asymptotic MSE of  $\hat{Z}_{\text{ris}}$  (assuming it exists) is

$$n\mathbb{E} \left[ \frac{(\hat{Z}_{\text{ris}} - Z)^2}{Z^2} \right] = \chi^2(p_0||p) = \int \frac{p_0^2}{p} d\mu(x) - 1.$$

The  $\chi^2$ -divergence here has the opposite order as that in (1) for IS, and tends to be large or infinite when  $p(x)$  is more peaked than  $p_0(x)$ . In addition,  $\hat{Z}_{\text{ris}}$  often gives upper bounds on  $Z$  (in contrast to lower bounds by IS), which can be easily seen by viewing  $1/\hat{Z}$  is a regular IS estimate for  $1/Z$ . The special case when  $p_0(x)$  is a uniform distribution is called the *harmonic mean method* (Newton and Raftery, 1994), and sometimes the *Ogata-Tanemura method* (Ogata and Tanemura, 1985).

The fact that IS and RIS give under- and over-estimates respectively suggests the use of their average  $\log \hat{Z}_{\text{avg}} = (\log \hat{Z}_{\text{is}} + \log \hat{Z}_{\text{ris}})/2$  with asymptotic MSE of

$$n\mathbb{E} \left[ \frac{(\hat{Z}_{\text{avg}} - Z)^2}{Z^2} \right] = \frac{1}{4} (\chi^2(p||p_0) + \chi^2(p_0||p)). \quad (2)$$

Unfortunately, this is large whenever one of  $\chi^2(p||p_0)$  or  $\chi^2(p_0||p)$  is large and thus imposes more stringent constraints on  $p_0$  such that (2) is finite, *i.e.* it can neither be too peaked nor too flat compared to the target distribution. This can be significant even for simple distributions as in the following example.

**Example 1.** Consider normal distributions  $p(x) = \mathcal{N}(x; 0, \sigma^2)$  and  $p_0(x) = \mathcal{N}(x; 0, \sigma_0^2)$ . One can show that  $\text{var}(\hat{Z}_{\text{is}}) = +\infty$  if  $\sigma_0 \leq \sigma/\sqrt{2}$  ( $p_0$  is much more peaked than  $p$ ). Conversely,  $\text{var}(\hat{Z}_{\text{ris}}) = +\infty$  if  $\sigma \leq \sigma_0/\sqrt{2}$  ( $p$  is much more peaked than  $p_0$ ). Therefore, their average  $Z_{\text{avg}}$  has finite variance only when  $\sigma/\sqrt{2} \leq \sigma_0 \leq \sqrt{2}\sigma$ .

More advanced combinations of IS and RIS can be obtained by estimating their variances, and taking weighted

averages, or selecting the better one according to their variance. Unfortunately, the variance estimates themselves are unreliable, often over- or under-estimated, making these methods ineffective. We explore and compare several of these options in our experiments; see Section 6 for details.

## 4 DISCRIMINANCE SAMPLING

Here we propose a new estimator of  $Z$ , termed *discriminance sampling* (evoking *importance* and *discriminative*), based on both  $\{x_1^i\} \sim p(x)$  and  $\{x_0^i\} \sim p_0(x)$  jointly. The idea is to reframe estimation of  $Z$  as a classification problem between  $\{x_1^i\}$  and  $\{x_0^i\}$ . To start, we assign a binary label  $y_1^i = 1$  for each  $x_1^i \sim p(x)$ , and correspondingly  $y_0^i = 0$  for each  $x_0^i \sim p_0(x)$ . Putting these samples together we get  $\{x^i\} = \{x_1^i\} \cup \{x_0^i\}$  and  $\{y^i\} = \{y_1^i\} \cup \{y_0^i\}$ . In this way, the conditional distribution of  $y^i$  given  $x^i$  is

$$p(y^i = 0 | x^i) = \frac{p_0(x^i)}{f(x^i)/Z + p_0(x^i)},$$

where  $Z$  can be treated as an unknown parameter. This motivates a parameter estimation procedure where we consider a family of conditional probabilities  $p(y = 1|x; c) = \frac{p_0(x)}{f(x)/c + p_0(x)}$ , indexed by a parameter  $c$ , and estimate  $c$  by maximizing the conditional likelihood:

$$\hat{Z}_{\text{dis}} = \arg \max_{c: c \geq 0} \sum_{i=1}^{2n} \log \frac{y^i f(x^i)/c + (1 - y^i) p_0(x^i)}{f(x^i)/c + p_0(x^i)}.$$

Calculating the zero-gradient equation of the objective function, we see that the optimal  $c$  should satisfy the following ratio matching condition:

$$\frac{1}{2n} \sum_{i=1}^{2n} \frac{p_0(x^i)}{f(x^i)/c + p_0(x^i)} = \frac{1}{2}, \quad (3)$$

that is, the proportion of  $y = 0$  (and  $y = 1$ ) predicted by the model should equal  $1/2$ , matching the label proportions in the data. Because the LHS of (3) is an increasing function on  $c$ , Eq. (3) yields a unique solution unless  $p(x^i)p_0(x^i) = 0$  for all  $i$ , that is, when  $p(x)$  and  $p_0(x)$  do not overlap. In practice, we can solve (3) efficiently using root finding algorithms such as the `fzero` function in MATLAB.

**Proposition 1.** Assume  $\{x_1^i\}_{i=1}^n$  and  $\{x_0^i\}_{i=1}^n$  are i.i.d. samples from  $p(x)$  and  $p_0(x)$ , respectively. Let  $e_1 = \sqrt{2n}(\hat{Z}_{\text{dis}}/Z - 1)$  and  $e_2 = \sqrt{2n}(\log \hat{Z}_{\text{dis}} - \log Z)$ . Define

$$\gamma = \mathbb{E}[\text{var}(y|x)] = \frac{1}{2} \int \frac{p(x)p_0(x)}{p(x) + p_0(x)} d\mu(x), \quad (4)$$

then if  $\gamma \neq 0$ , we have  $\hat{Z}_{\text{dis}} \xrightarrow{a.s.} Z$  as  $n \rightarrow \infty$ , and  $e_1$  and  $e_2$  have a normal distribution  $\mathcal{N}(0, (\frac{1}{4} - \gamma)/\gamma^2)$ .

*Proof.* Apply the standard asymptotic result in DasGupta (Theorem 17.2, Page 264, 2008); the condition  $\gamma \neq 0$  guarantees (3) has a unique solution as  $n \rightarrow \infty$ . Note that  $e_1$  and  $e_2$  are asymptotically equivalent because  $\log \epsilon \approx \epsilon - 1$  for  $\epsilon \approx 1$ .  $\square$

*Remarks.* (i) Eq (4) above relates the accuracy of  $\hat{Z}_{\text{dis}}$  with the variance of the label  $y$  given  $x$ , which is a measure of distinguishability between the two samples  $\{x_1^i\}$  and  $\{x_0^i\}$ . Ideally, we want to choose  $p_0$  so that it is hard to distinguish between  $\{x_1^i\}$  and  $\{x_0^i\}$ ; when  $p_0 = p$ ,  $\hat{Z}_{\text{dis}}$  equals  $Z$  exactly.

(ii) The variance of  $\hat{Z}_{\text{dis}}$  is infinite only if  $\gamma = 0$ , that is,  $\int \frac{pp_0}{p+p_0} = 0$ ; this is possible only if  $p(x)$  and  $p_0(x)$  do not overlap, that is,  $p(x)p_0(x) = 0$  almost everywhere. Note that this is a much milder condition compared to that for IS, RIS and their average, since in practice it is usually easy to choose a  $p_0(x)$  that shares some support with  $p(x)$ .

**Example 2.** To continue with Example 1, the MSE of  $\hat{Z}_{\text{dis}}$  is finite for any  $\sigma_0 > 0$  and  $\sigma > 0$ , making it far more robust than IS or reverse IS, which have finite MSE only when  $\sigma_0 > \sigma/\sqrt{2}$  and  $\sigma_0 < \sqrt{2}\sigma$ , respectively.

## 5 ANNEALED DISCRIMINANCE SAMPLING

One advantage of our method is that it can be naturally extended to cases when we have more than two distributions, in which case it is straightforward to frame a corresponding multinomial classification problem. In this section, we consider an improvement to our method by introducing a set of auxiliary distributions that serve as intermediate points between the target and reference distributions. This extension is analogous to annealed importance sampling (AIS) (Neal, 2001, Salakhutdinov and Murray, 2008) and reverse AIS (Burda et al., 2015), but with significantly better performance.

Both AIS and reverse AIS are based on a set of distributions  $\{p_k = f_k(x)/Z_k : k = 0, \dots, m\}$  where  $p_0$  is the normalized reference distribution ( $Z_0 = 1$ ) and  $p_m(x) = f(x)/Z$  is the target distribution; the other distributions serve as “intermediate points” between  $p_0$  and  $p$ . A typical choice of the distributions is  $f_k(x) = f(x)^{k/m} f_0(x)^{1-k/m}$ , where  $k$  can be interpreted as a temperature parameter that anneals between  $p$  and  $p_0$ .

Now assume we draw  $m$  sets of samples  $\{x_k^i\}_{i=1}^n \sim p_k(x)$ ,  $k = 0, \dots, m$ . Similar to Section 4, we assign each  $x_k^i$  with a label  $y_k^i = k$ , resulting a conditional likelihood of

$$p(y^i = k | x^i) = \frac{f_k(x^i)/Z_k}{\sum_{k=0}^m f_k(x^i)/Z_k}.$$

We then treat  $\{Z_k : k = 1, \dots, m\}$  as a set of unknown parameters, and estimate them by performing maximum con-

---

### Algorithm 1 Annealed Discriminace Sampling (Sequential Binary Version)

---

Draw  $x_0^i \sim p_0(x)$ . Set  $w_0^i = 1$  and  $Z_0 = 1$ .

**for**  $k = 1$  to  $m$  **do**

    Generate weighted sample  $\{x_k^i, w_k^i\}_{i=1}^n$  by the AIS update in (8).

    update  $\hat{Z}_k = Z_{k-1} \hat{r}_k$ , where  $\hat{r}_k$  maximizes the weighted conditional likelihood (9).

**end for**

**Return:**  $\hat{Z}_m$  is an estimate of the partition function  $Z$ .

---

ditional likelihood:

$$\{\hat{Z}_k\}_{k=0}^m = \arg \max_{c_0: c_0=Z_0} \sum_{k=0}^m \sum_{i=1}^n \log \frac{f_k(x_k^i)/c_k}{\sum_{k=0}^m f_k(x_k^i)/c_k}, \quad (5)$$

where  $c_0$  is fixed to its known value ( $Z_0 = 1$ ). Similar to the binary case, it is easy to show that  $\{\hat{Z}_k\}$  forms a consistent estimation of  $\{Z_k\}$  (although we are only interested in  $\hat{Z}_m$ ).

Note that (5) is a convex optimization w.r.t.  $\{\log c_k\}$ , and can be solved efficiently. A further simplification of (5) is to construct and combine a sequence of binary classifications between the  $(p_k, p_{k+1})$  pairs, instead of the joint multinomial classification. To be specific, we sequentially estimate the ratio  $r_{k+1} = Z_{k+1}/Z_k$  between  $p_k$  and  $p_{k+1}$  by discriminating between  $\{x_k^i\}$  and  $\{x_{k+1}^i\}$ :

$$\hat{r}_{k+1} = \arg \max_{\substack{c_{k+1} > 0 \\ c_k = 1}} \sum_{k'=k}^{k+1} \sum_{i=1}^n \log \frac{f_{k'}(x_{k'}^i)/c_{k'}}{\sum_{\ell=k}^{k+1} f_{\ell}(x_{k'}^i)/c_{\ell}} \quad (6)$$

and estimate  $Z = Z_m$  by chaining the ratios together:

$$\log \hat{Z} = \sum_{k=1}^m \log \hat{r}_k \approx \sum_{k=1}^m \log r_k = \log Z. \quad (7)$$

Interestingly, we find that such sequential binary classification works as well as the joint multinomial classification in our experiments, possibly because the neighboring  $\{p_k, p_{k+1}\}$  are close to each other and provide more accurate estimates of their ratios.

**Practical Implementation** In practice, it is expensive to sample from all  $p_k(x) = f_k(x)/Z_k$  at each temperature independently, especially when the number of temperatures is large. Instead, we use AIS (Neal, 2001) to sequentially generate *importance weighted samples* for each  $p_k(x)$ : we start with  $x_0^i \sim p_0(x)$  and set  $w_0^i = 1$ , and sequentially update the samples using Markov chain transitions and adjust the weights accordingly:

$$x_k^i \sim T_k(\cdot | x_{k-1}^i), \quad w_k^i = w_{k-1}^i \frac{f_k(x_{k-1}^i)}{f_{k-1}(x_{k-1}^i)}, \quad (8)$$

---

**Algorithm 2** Annealed Discriminace Sampling (Multinomial Version)

---

1. Use AIS to generate  $\{x_k^i, w_k^i\}_{i=1}^n$  for  $\forall 0 \leq k \leq m$ .
2. Estimate  $\hat{Z}_k$  by maximizing

$$\{\hat{Z}_k\}_{k=0}^m = \arg \max_{c>0: c_0=Z_0} \sum_{k=0}^m \sum_{i=1}^n \tilde{w}_k^i \log \frac{f_k(x_k^i)/c_k}{\sum_{k=0}^m f_k(x_k^i)/c_k},$$

where  $\tilde{w}_k^i = w_k^i / \sum_i w_k^i$  are the normalized weights.

**Return:**  $\hat{Z}_m$  is an estimate of the partition function  $Z$ .

---

for  $\forall 1 \leq k \leq m$ , where  $T_k(\cdot)$  is a Gibbs or Metropolis-Hastings transition kernel of  $p_k$ . By the augmented variable space argument of Neal (2001), we can show the weighted sample  $(x_k^i, w_k^i)_{i=1}^n$  follows  $p_k(x)$  in the sense that

$$\mathbb{E}(w_k^i h(x_k^i)) = \text{const} \cdot \mathbb{E}_{x \sim q_k}(h(x))$$

for any  $0 \leq k \leq m$  and integrable function  $h(x)$ ; this allows us to estimate the partition functions  $Z_k$  using weighted versions of the multinomial (5) or sequential binary (6) classifications based on the weighted samples  $(x_k^i, w_k^i)$ . For example, we can estimate the ratio  $r_{k+1} = Z_{k+1}/Z_k$  between  $p_{k+1}$  and  $p_k$  by maximizing a weighted version of the conditional likelihood in (6),

$$\hat{r}_{k+1} = \arg \max_{\substack{c_{k+1}>0 \\ c_k=1}} \sum_{k'=k}^{k+1} \sum_{i=1}^n \tilde{w}_{k'}^i \log \frac{f_{k'}(x_{k'}^i)/c_{k'}}{\sum_{\ell=k}^{k+1} f_{\ell}(x_{k'}^i)/c_{\ell}}, \quad (9)$$

where  $\tilde{w}_k^i = w_k^i / \sum_{i=1}^n w_k^i$  are the normalized weights under each temperature  $k$ . See Algorithm 1 for the full algorithm of the sequential binary version of our method; the corresponding multinomial version is shown in Algorithm 2. Note that both Algorithm 1 and 2 can recycle the samples and weights generated by AIS and can be implemented conveniently based on AIS. Alternatively, we can also base our estimator on other methods that draw samples jointly from different temperatures, such as simulated tempering and parallel tempering (see Liu, 2008, and references therein).

## 6 EXPERIMENTS

We present experimental results on a toy Gaussian example, pairwise Markov random fields ( $10 \times 10$  grids), and deep generative models trained on real world data. Our contributions are threefold: (1) We demonstrate the advantage of our method compared to IS, reverse IS and their combinations, and show that our method yields significantly smaller bias and variance across all our experiments. (2) We illustrate the benefits of combining deterministic variational methods and the Monte Carlo based methods discussed in this paper; we show that Monte Carlo methods can provide tighter (but “probabilistic”) bounds than

deterministic variational methods, and can be further improved by using variational methods to provide better reference distributions  $p_0$ . (3) We test the annealed version of our algorithm in real-world deep learning models, including restricted Boltzmann machines (RBM) and deep Boltzmann machines (DBM), and show that it significantly outperforms the state-of-the-art AIS and reverse AIS methods (Burda et al., 2015).

**Setting** We compare our algorithm with IS, RIS and three different methods that combine IS and RIS in hopes of off-setting their relative biases:

(1) *Naive Averaging*:

$$\log \hat{Z}_{\text{avg}} = (\log \hat{Z}_{\text{is}} + \log \hat{Z}_{\text{ris}})/2.$$

Here the average is taken on the log domain; note that averaging in the  $Z$  domain, i.e.,  $(\hat{Z}_{\text{is}} + \hat{Z}_{\text{ris}})/2$  does not make sense since we almost always have  $\hat{Z}_{\text{is}} \ll \hat{Z}_{\text{ris}}$ , and the result will be dominated by  $\hat{Z}_{\text{ris}}$ .

(2) *Weighted Averaging*:

$$\log \hat{Z}_{\text{w}} = (\hat{v}_{\text{is}}^{-1} \log \hat{Z}_{\text{is}} + \hat{v}_{\text{ris}}^{-1} \log \hat{Z}_{\text{ris}}) / (\hat{v}_{\text{is}}^{-1} + \hat{v}_{\text{ris}}^{-1}),$$

where  $\hat{v}_{\text{is}}, \hat{v}_{\text{ris}}$  are empirical estimates of  $\text{var}(\log \hat{Z}_{\text{is}})$  and  $\text{var}(\log \hat{Z}_{\text{ris}})$ ,

$$\hat{v}_{\text{is}} = \widehat{\text{var}}\left(\left\{\frac{f(x_0^i)}{p_0(x_0^i)}\right\}\right) / \hat{Z}_{\text{is}}^2,$$

$$\hat{v}_{\text{ris}} = \widehat{\text{var}}\left(\left\{\frac{p_0(x_1^i)}{f(x_1^i)}\right\}\right) \hat{Z}_{\text{ris}}^2,$$

where  $\widehat{\text{var}}(\cdot)$  represents the empirical variance estimate. Note that the weights defined above should minimize the variance of the combination if the variance estimates are accurate. Unfortunately, variance estimates for the weighted averaging approach are typically unreliable and have the same under- / over-estimation problem as IS and RIS, causing the weighted average to perform poorly.

(3) *Weighted Selection*:

$$\log \hat{Z}_{\text{s}} = [\hat{v}_{\text{is}} < \hat{v}_{\text{ris}}] \log \hat{Z}_{\text{is}} + [\hat{v}_{\text{ris}} < \hat{v}_{\text{is}}] \log \hat{Z}_{\text{ris}},$$

where we select the estimator with smaller estimated variance; here  $[\cdot]$  is the indicator function.

Note that IS (resp. RIS) uses only  $\{x_0^i\}_{i=1}^n \sim p_0(x)$  (resp.  $\{x_1^i\}_{i=1}^n \sim p(x)$ ), while our method uses both  $\{x_0^i\}$  and  $\{x_1^i\}$ . To make a conservative comparison, we use *only the first half of the samples*  $\{x_1^i\}_{i=1}^{n/2}$  and  $\{x_0^i\}_{i=1}^{n/2}$  in our method. However, we do not halve the samples when calculating the averages  $\hat{Z}_{\text{avg}}, \hat{Z}_{\text{w}}$  and  $\hat{Z}_{\text{s}}$ , allowing them to use *exactly twice the information* as our method. Despite these unfavorable conditions, our method still consistently outperforms IS, RIS and all the averaging based methods.

Figure 1: Gaussian toy example. The estimated values (a) and mean square errors (b) on  $\log Z$  by different methods (the true value is  $\log Z = 0$ ). IS performs poorly when  $\sigma_0$  is small ( $p_0$  is too peaked), while reverse IS is poor when  $\sigma_0$  is large ( $p$  is too peaked). Our method performs much better and is robust for all values of  $\sigma_0$ . The result is averaged over 1000 random trials.

**Gaussian Toy Example** As in Example 1, we consider  $p(x) = \mathcal{N}(x; 0, \sigma^2)$  with fixed  $\sigma = 1$  and  $p_0(x) = \mathcal{N}(x; 0, \sigma_0^2)$  with different values of  $\sigma_0$ . We are interested in calculating the normalization constant of  $p(x)$ , which is trivially  $Z = 1$  in this case. We use  $n = 1000$  samples from both the target  $p(x)$  and reference  $p_0(x)$ .

Figure 1 reports the bias and MSE on  $\log Z$  as returned by our methods, IS, reverse IS, and the weighted selection  $\log \hat{Z}_s$  (the naïve average  $\log \hat{Z}_{\text{avg}}$  and weighted average  $\log \hat{Z}_w$  are worse than  $\log \hat{Z}_s$  and not shown in the figure for clarity). We find that our method significantly outperforms all the other algorithms, despite using fewer samples than the averaging based methods.

The performance of IS and reverse IS in Figure 1(a) is consistent with the theoretical analysis: IS tends to give a lower bound, and degenerates quickly when  $\sigma_0$  is small ( $p_0$  is more peaked than  $p$ ), while reverse IS gives an upper bound, and degenerates when  $\sigma_0$  is large ( $p$  is more peaked than  $p_0$ ). In this case, it is interesting to see that the performances of IS and reverse IS are extremely imbalanced and anti-correlated (whenever IS performs well, RIS performs poorly, and vice versa), which explains why weighted selection is better than naïve averaging in this case.

**MRF on  $10 \times 10$  Grid** We consider Markov random fields (MRFs) on a  $10 \times 10$  grid

$$p(x) = \frac{1}{Z} \exp \left( \sum_{ij} \theta_{ij}(x_i, x_j) + \sum_i \theta_i(x_i) \right),$$

where  $x_i \in \{0, 1\}$ . We generate each  $\theta_i(k)$  randomly by  $\mathcal{N}(0, \sigma_s^2)$ , with fixed  $\sigma_s = 0.1$  and each  $\theta_{ij}(k, l)$  from  $\mathcal{N}(0, \sigma_p^2)$ , where  $\sigma_p$  characterizes the interaction strength in the MRF. We also explore different choices of reference distribution  $p_0$  for the MRF, including

(1) *Uniform distribution* as shown in Figure 2(a).

(2) *Mean field* approximation as shown in Figure 2(b).

(3) *Mixture of trees* constructed from the reparameterization obtained from tree reweighted belief propagation (TRBP) (Wainwright et al., 2005) (Figure 2(c)). The edge appearance probabilities in TRBP are set by assigning uniform weights to a random set of spanning trees.

The samples from  $p_0$  are drawn exactly, while those from  $p$  are drawn using Gibbs sampling with 500 burn-in steps. We use  $n = 1000$  samples from each distribution in all cases, and average the results over 500 random trials.

From Figure 2, we find our method significantly outperforms IS and reverse IS, and all the versions of their combinations under all three choices of  $p_0$ . The deterministic bounds returned by TRBP and MF are shown in Figure 2(a), and are significantly looser than the sampling based bounds in these cases (which, however, provides probabilistic, instead of deterministic bound guarantees as the variational methods). We note that the proposal produced by MF is only as good as the uniform proposal. On the other hand, the  $p_0$  produced by a mixture of TRBP trees gives significantly better results (note that the y-axes are not on the same scale). This result demonstrates the potential of combining variational methods and sampling methods, with carefully designed choices for  $p_0$  and estimation methods (such as our method).

Interestingly, we find the performance of IS and reverse IS are relatively balanced in the MRF examples, making the naïve average of IS and reverse IS outperform both the weighted average and weighted selection. This is in contrast to the Gaussian toy example, where IS and reverse IS are extremely imbalanced. Unfortunately, there is no general method to tell whether IS and reverse IS will be balanced or not beforehand.

**Deep Generative Models** We compare our annealed discriminant sampling (ADS) with the AIS and reverse AIS estimator (RAISE) as introduced in Burda et al. (2015) for partition function estimation in deep generative models, including a restricted Boltzmann machine (RBM) and a deep Boltzmann machine (DBM). We implement AIS and RAISE following Algorithm 1 and Algorithm 3<sup>2</sup> in Burda et al. (2015), respectively. We then take the samples and weights generated by AIS and run our sequential binary ADS in Algorithm 1 and multinomial ADS in Algorithm 2. In principle, we can also reuse the same samples generated by AIS to construct a version of a reverse AIS estimator. Unfortunately, we find this works poorly in practice, and it seems to be important to follow Algorithm 3 in Burda et al. (2015) to generate new samples specifically for the

<sup>2</sup> Algorithm 3 of Burda et al. (2015) was designed for calculating the testing likelihood; we adopt it for calculating the partition function by replacing its conditional kernel  $\tilde{T}_k^{(\text{v}_{\text{test}})}(\cdot | h_{k-1})$  in the forward step with the unconditional kernel  $\tilde{T}_k(\cdot | x'_{k-1})$ .

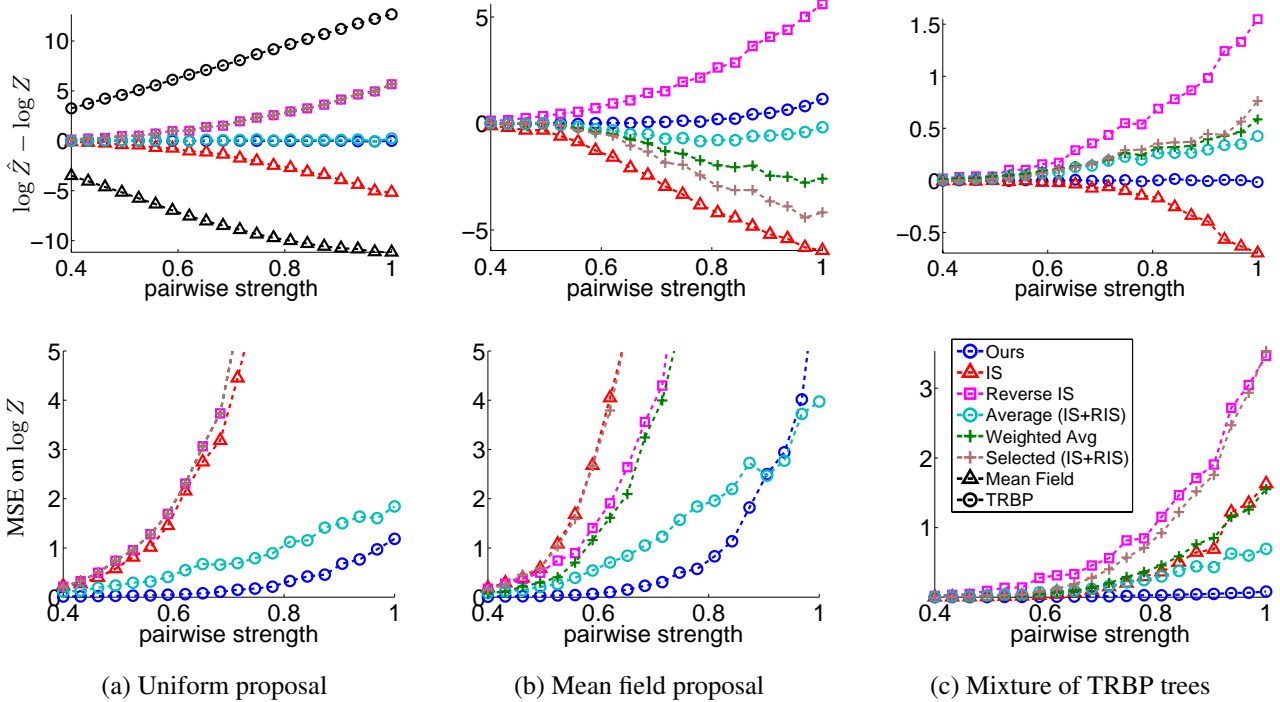

Figure 2: MRFs on a  $10 \times 10$  grid. The three columns represent the results when using different reference distributions  $p_0$ , including the uniform distribution (a), mean field approximation (b) and a mixture of trees constructed from TRBP (c). Our algorithm consistently performs best. Note that the comparison is again in favor of the averaging methods since they use twice as many samples as our method.

reverse AIS estimates. Note that implemented in this way, the average of AIS and RAISE uses twice the number of samples as our method. In addition, we emphasize that the RAISE as proposed in Algorithm 3 in Burda et al. (2015) includes both a forward and backward sampling step, requiring twice the computational cost of AIS. In contrast, our method has roughly the same time complexity as AIS, because the cost of the discriminance analysis step in our method, especially the sequential binary version, is negligible compared to the sample generation steps of AIS as used in Algorithm 1 in Burda et al. (2015).

In both our experiments for RBM and DBM and for all the annealing-based algorithms, we use  $2^1 \sim 2^{10}$  linearly spaced intermediate temperatures (or distributions) and  $n = 1000$  samples (corresponding to 1000 separate MCMC chains in AIS). The reference distribution  $p_0$  is taken to be the *data base rate* (DBR) distribution as suggested by Salakhutdinov and Hinton (2009), which is constructed based the marginal statistics of the image dataset. In all cases, we repeat the estimates 10 times and report the average bias and MSE results.

To obtain the true partition function of both RBM and DBM, we calculate the average of AIS and RAISE with an extremely large number (in our case, 100,000) of temperatures, until their estimates coincide to within 0.1 nats, i.e.,

Figure 3: Estimates of log-partition function of a restricted Boltzmann machine trained on MNIST with different numbers of intermediate temperatures. While all methods converge to the same value, our method significantly outperforms other methods when the intermediate temperatures are few.

$|\log \hat{Z}_{\text{is}} - \log \hat{Z}_{\text{ris}}| \leq 0.1$ . This gives a high confidence estimate of the true partition function, since AIS and RAISE are probabilistic lower and upper bounds, respectively.

We first consider a restricted Boltzmann machine (RBM) with 500 hidden nodes trained on MNIST using contrastive divergence with 25 steps. Figure 3 shows the results of different algorithms. When there are many intermediate

Figure 4: Estimates of log-partition function of a 784-500-1000 deep Boltzmann machine trained on MNIST with different numbers of intermediate temperatures. While all methods converge to the same value, our method outperforms both AIS and RAISE when the intermediate temperatures are few. Our multinomial ADS performs the same as our binary version, and is omitted in the figure for clarity.

temperatures, all algorithms give accurate estimates. When there are fewer intermediate temperatures, our ADS is able to compute significantly more accurate estimates than AIS and RAISE, or even their average. In addition, we find that the binary and multinomial versions of our ADS algorithm work similarly (almost identically) in all our experiments.

We then experiment on a more complex deep Boltzmann machine, trained with a 784-500-1000 structure on MNIST closely following the procedure in Salakhutdinov and Hinton (2009): we initially train the first layer RBM for 100 epochs, then the second layer with 200 epochs and then fine-tune the two layers jointly for 300 epochs. The results of the different algorithms are shown in Figure 4. Similarly to the results in the RBM experiment, ADS significantly outperforms both AIS and RAISE when the number of temperatures is small. In this case, we find that the average of AIS and RAISE is quite accurate for this DBM model, almost as good as ADS. However, our algorithm still gives significant advantages in practice: again, we use only half the number of samples that are used by the average of AIS and RAISE and have only 1/3 of the total computational cost (because RAISE is twice as expensive as AIS or our ADS method, as discussed previously).

## 7 CONCLUSION

In this paper, we introduced *discriminance* sampling, a novel and efficient method for estimating log-partition functions of probabilistic distributions. Using samples drawn from both the target and proposal distributions, we formulated the estimation problem into a discriminant analysis problem that classifies samples into their corresponding distributions. Our approach does not under- / overestimate the true values like IS and reverse IS, and places much less stringent requirements on the proposal distribu-

tions. In addition, we also extend our method to define annealed discriminance sampling (ADS) and demonstrate that ADS significantly outperform AIS, reverse AIS, and performs as well or better than their average, which are currently state-of-the-art methods for model evaluation in deep generative models.

## Abstract

In a randomized experiment with noncompliance, scientific interest is often in testing whether the treatment exposure  $X$  has an effect on the final outcome  $Y$ . We propose a finite-population significance test of the sharp null hypothesis that  $X$  has no effect on  $Y$ , within the principal stratum of Compliers, using a generalized likelihood ratio test. We present a new algorithm that solves the corresponding integer programs.

## 1 INTRODUCTION

Randomized experiments are often employed in order to determine whether a treatment  $X$  has a causal effect on an outcome  $Y$ . For example, individuals may be randomly assigned to either an active treatment group ( $X = 1$ ) or to the placebo or control group ( $X = 0$ ).

This problem may be formulated in terms of potential outcomes. Denote  $Y(x = 1)$  as the outcome that the patient would have if assigned to the treatment arm, while  $Y(x = 0)$  is the outcome that would arise under placebo. The absence of an effect of  $X$  on  $Y$  when the sharp causal null holds is formalized by  $Y(x = 1) = Y(x = 0)$ , such that every individual in the finite population has the same outcome regardless of the treatment group  $X$  to which they were assigned [19].

Randomization of treatment implies that  $X \perp\!\!\!\perp \{Y(x = 1), Y(x = 0)\}$ . Under the sharp causal null, this then implies  $X \perp\!\!\!\perp Y$ . Hence testing this latter independence may thus be seen as a test of the sharp causal null. For the case of binary outcomes  $Y$ , we may use Fisher's exact test [5], see for example [16, pg. 308].

A key feature of the potential outcome framework is that the set of individuals in the population and the values of their potential outcomes are regarded as fixed. Differences between results over hypothetical replications arise *only*

due to different random assignments of this fixed set of individuals to treatment or control.

However, often we are interested in the effect of a treatment  $X$  that was not randomized. In this paper we consider the circumstance where, although  $X$  is not randomized, there is another variable  $Z$ , called an 'instrument' that is randomized, and influences  $X$ , but does not influence  $Y$  directly; see Figure 1.

Figure 1: Graphical Representation of the Instrumental Variable Model, where  $H$  are unobserved confounding variables.

A common example of this circumstance is a randomized study with 'noncompliance'. In this context  $Z$  represents the assigned treatment, while  $X$  is the treatment that the patient actually receives.  $X$  and  $Z$  may differ owing to noncompliance.

Randomized experiments with treatment 'noncompliance' arise in many situations. For example, in a randomized psychology experiment, whether or not participants adhere to their assigned treatment depends on their personalities and the type of manipulation (treatment). Patients in a randomized clinical trial may choose not to take their prescribed treatment, possibly due to side-effects. In studies where a randomly selected subset of subjects are offered an incentive to avail themselves of a treatment, or 'encouragement' studies, the inducement may be sufficient for some but not for others.

For each of these randomized experiments, every unit now has a treatment actually received ( $X$ ) that was *not* randomized, following an *assigned* treatment ( $Z$ ) that was randomized. We will make the assumption that  $Z$  has no (direct) effect on  $Y$  except through  $X$ , sometimes termed an 'exclusion restriction'.

In such studies with noncompliance with a binary treatment, Angrist et al. [1] and Imbens and Rubin [8] among others, propose to find the effect of treatment on the subset of individuals who would conform with the assigned treatment regardless of the arm to which they are assigned. Sommer and Zeger [18] describe this subgroup of individuals as ‘Compliers’: individuals who would take the treatment only if assigned to do so and would not if assigned not to do so. Balke and Pearl [2] used a symbolic linear program to derive the bounds for counterfactual probabilities, and the average causal effect of  $X$  on  $Y$ . Rubin [17] uses randomization-based posterior-predictive p-values to test a null treatment effect; Imbens and Rosenbaum [7] use randomization-based inference to obtain valid confidence intervals for the treatment effect under an additive structural model even when the instrument is ‘weak’.

In this paper we address the problem of testing the sharp null hypothesis of no effect of  $X$  on  $Y$  for ‘Compliers’, the subpopulation or principal stratum where  $X(z=0)=0$  and  $X(z=1)=1$ , where here  $X(z)$  indicates the treatment a patient would receive if (counter to fact) assigned to  $Z=z$ . Under the exclusion restriction, the null hypothesis within this sub-population that  $X$  has no effect on  $Y$  is equivalent to the null hypothesis that  $Z$  has no effect of  $Y$ . Under random assignment for the whole population, each individual in the Complier subpopulation has the same probability of being *assigned* to treatment. Thus we could use the randomization distribution of the outcomes for Compliers under the null hypothesis to carry out a significance test.

However, we face the obvious difficulty that membership in the Complier subpopulation generally cannot be determined from the observed data alone. Although we know that Compliers will have  $Z=X$ , this condition is necessary but not sufficient. For example, in the  $Z=1$  arm individuals with  $X=1$  may be either Compliers or ‘Always Takers’, where the latter subgroup are individuals who would always take the active treatment even if (counter to fact) they had been assigned to the placebo group ( $Z=0$ ). Conversely, an individual with  $Z=X=0$  may be either a Complier or someone who refuses to take treatment regardless of their assigned group, in other words a ‘Never Taker’.

If somehow we were told which individuals in the population were Compliers, then we could simply test the sharp null hypothesis by performing a significance test, such as Fisher’s exact test, on the  $(X, Y)$  sub-table, or equivalently the  $(Z, Y)$  subtable, for Compliers. One may circumvent the problem of not knowing who the Compliers are by just considering all *logically* possible values for the number of Compliers in any given  $(Z, X, Y)$  stratum that may contain them (in which  $Z=X$ ), and then carrying out the significance test for the corresponding  $(X, Y)$  subtable for the Compliers. Taking the maximum over all the resulting p-values would then give a valid p-value for the null hypothesis.

There are, however, two concerns with such an approach. The first is that such a procedure will have no or very low statistical power to reject the null hypothesis, since it is logically possible (though extremely unlikely) that there are no Compliers in a given stratum (in which  $Z=X$ ). The second is that such an approach ignores the information provided by strata that do not contain Compliers, in which  $Z \neq X$ .

We will assume that there are no patients who consistently do the opposite of their assignment, sometimes called ‘Defiers’ [3], so for all individuals:

$$X(z=0) \leq X(z=1). \quad (1)$$

It follows from this assumption that all individuals in the  $(Z=1, X=0)$  stratum are Never Takers. Under random assignment of treatment ( $Z$ ), the proportion of Never Takers in the  $Z=1$  arm should be approximately the same as in the  $Z=0$  arm. This information then reduces the range of probable values (under the randomization distribution) for the number of Compliers in the  $(Z=X=0)$  stratum.

Loh and Richardson [10], following [11], use a pre-specified significance level  $\gamma$  to construct a confidence set of values for the number of Compliers in a given  $(Z, X)$  stratum. Only values of the number of Compliers that do not indicate large imbalance between the  $Z=1$  and  $Z=0$  arms, under the randomization distribution, are used to carry out Fisher’s exact test in the implied  $(X, Y)$  table for Compliers. Taking the maximum over these p-values and adding  $\gamma$  then provides a valid but conservative p-value.

However, the procedure in [10] requires a pre-determined (non-zero) value of  $\gamma$  to eliminate ‘unlikely’ values for the number of Compliers from consideration when controlling the Type I error rate in a *hypothesis* test. The resulting p-value will hence always be greater than or equal to  $\gamma$ . This is problematic if, as in a *significance* test, we wish to interpret the p-value as measuring the strength of evidence against the null hypothesis.

In this paper we consider an alternative approach whereby we compare the ratio of the largest probability for the observed data assuming that the sharp null hypothesis holds among Compliers, with the largest probability in the case where we allow a causal effect among Compliers. Such a generalized likelihood ratio (GLR) criterion (see for example [15]) lets us evaluate whether the alternative hypothesis is a significantly better explanation for the observed dataset than the null hypothesis, even when the number of Compliers is unknown.

For a given number of Compliers, the relative frequency with which, over hypothetical replications under the null hypothesis, we would obtain a value of the GLR that is as small or smaller than that which we observed, would then be a p-value. Since this relative frequency will depend on the number of Compliers, we maximize the p-value over

the number of Compliers. This results in a valid p-value that is suitable to be used in a significance test since it can be arbitrarily close to zero (it does not require specification of some  $\gamma$ ). Furthermore, the resulting test has power against some alternatives in which there is a non-zero average causal effect among Compliers.

The remainder of the paper is organized as follows. Section 2 formalizes the potential outcome framework and sets up the motivating examples. The steps to find the maximum likelihood when the null hypothesis holds, and in general, are detailed in Section 3. Section 4 presents the generalized likelihood ratio (GLR) and describes how to find a valid frequentist p-value. The results from applying the procedure to the motivating examples are shown in Section 5. Finally, in Section 6 we briefly describe the extension to include Always Takers.

## 2 POTENTIAL OUTCOME FRAMEWORK

We now formalize the foregoing development. Recall the following:

- $Z$  is the randomized treatment assignment, where 1 indicates assignment to drug;
- $X$  is the treatment exposure subsequent to assignment, where 1 indicates drug received;
- $Y$  is the final response, where 1 indicates a desirable outcome, such as survival.

The potential outcome  $X_{z_i}$  is the treatment  $X$  a patient *would* be exposed to if assigned  $z = i$ . Using these potential outcomes we may define four generic compliance ‘types’  $t_X$  listed in Table 1. We denote the set of such types by  $\mathbb{D}_X$ .

The potential outcomes are linked to the observed outcomes by the consistency axiom [14], which requires that  $Z = z$  implies  $X = X_z$ .

Table 1: Compliance Types ( $t_X$ ) based on Potential Outcomes  $X_z$ , [8].

| $X_{z_0}$ | $X_{z_1}$ | Compliance Type $t_X$ |              |
|-----------|-----------|-----------------------|--------------|
| 0         | 0         | NT                    | Never Taker  |
| 1         | 0         | DE                    | Defier       |
| 0         | 1         | CO                    | Complier     |
| 1         | 1         | AT                    | Always Taker |

As stated above in (1) we will assume that there are no Defiers. We will also focus on the case where there are no Always Takers, so:

$$Z = 0 \Rightarrow X = 0. \tag{2}$$

This assumption will hold in studies where individuals not assigned to treatment are unable to obtain the active treat-

ment outside of the trial.

### 2.1 EXCLUSION RESTRICTION

The potential outcome for a given individual  $Y_{x_j z_i}$  is the subject’s response  $Y$  under exposure to treatment  $x = j$ , and treatment assignment  $z = i$ . Without further assumptions there are  $16 = 2^{2^2}$  possible sets of values for the variables  $(Y_{x_0 z_0}, Y_{x_1 z_0}, Y_{x_0 z_1}, Y_{x_1 z_1})$ . However, we will assume that there is no (individual-level) direct effect of  $Z$  on  $Y$  relative  $X$ , so that for  $j, i, i' \in \{0, 1\}$ , we have:

$$Y_{x_j z_i} = Y_{x_j z_{i'}} \equiv Y_{x_j}. \tag{3}$$

Assumption (3) is guaranteed to hold under double-blind placebo-controlled trials in which the active treatment is without side-effects and unavailable to patients in the control arm. The response type  $t_Y$  then simplifies to just four types, with  $\mathbb{D}_Y$  as the set of such types, shown in Table 2.

The potential outcomes for  $Y$  are again linked to the observed outcomes via the consistency axiom, so that if  $X = x$  then  $Y = Y_x$ .

Table 2: Response Types ( $t_Y$ ) under Exclusion Restriction (3), [6].

| $Y_{x_0}$ | $Y_{x_1}$ | Response Type $t_Y$ |                |
|-----------|-----------|---------------------|----------------|
| 0         | 0         | NR                  | Never Recover  |
| 1         | 0         | HU                  | Hurt           |
| 0         | 1         | HE                  | Helped         |
| 1         | 1         | AR                  | Always Recover |

### 2.2 RANDOMIZATION ASSUMPTION

We make the following assumption:

$$Z \perp\!\!\!\perp \{X_{z_0}, X_{z_1}, Y_{x_0}, Y_{x_1}\} \tag{4}$$

The assumption states that the distribution of compliance and response types ( $t_X, t_Y$ ) is the same in both the  $z = 1$  and  $z = 0$  arms; in other words, that  $Z$  is (jointly) independent of the potential outcomes. This will hold whenever treatment assignment  $Z$  is physically randomized.

### 2.3 THE INSTRUMENTAL VARIABLE (IV) MODEL

The model defined by (3) and (4) is known as the Instrumental Variable (IV) model (see for example [1]). A graph corresponding to the IV model given by (3) and (4) is shown in Figure 1. The exclusion restriction (3) corresponds to the absence of a  $Z \rightarrow Y$  edge while the randomization assumption (4) is indicated by the absence of edges directed into  $Z$ .

## 2.4 AVERAGE CAUSAL EFFECT OF X ON Y

The average causal effect (ACE) of treatment exposure  $X$  on outcome  $Y$  is defined as:

$$\text{ACE}(X \rightarrow Y) \equiv E[Y_{x_1} - Y_{x_0}]. \quad (5)$$

The ACE for the sub-population of Compliers is:

$$\text{ACE}_{CO}(X \rightarrow Y) \equiv E[Y_{x_1} - Y_{x_0} \mid t_X = CO]. \quad (6)$$

Since for Compliers  $X_z = z$ , it follows that  $Y_{X=z} \equiv Y_{X_z} = Y_z$  so that

$$\text{ACE}_{CO}(X \rightarrow Y) = \text{ITT}_{CO} \equiv E[Y_{z_1} - Y_{z_0} \mid t_X = CO], \quad (7)$$

or in words, the Average Causal Effect of  $X$  on  $Y$  for Compliers is equal to the *Intent-to-Treat effect* of  $Z$  on  $Y$  for Compliers ( $\text{ITT}_{CO}$ ).

Under the assumption (1) that there are no Defiers, the global null hypothesis  $\text{ACE}(X \rightarrow Y) = 0$  holds if and only if all the principal stratum-specific null hypotheses  $\text{ACE}_{t_X}(X \rightarrow Y) = 0$  for  $t_X \in \{NT, CO, AT\}$  jointly hold. Evidence against the (narrower) null hypothesis that  $\text{ACE}_{CO}(X \rightarrow Y) = 0$  hence implies evidence against the global null hypothesis  $\text{ACE}(X \rightarrow Y) = 0$  as well.

By definition Never Takers and Always Takers always have the same observed values of  $X = 0$  and  $X = 1$  respectively (regardless of the  $Z$  arm they are assigned to). Consequently without further experimentation (to change compliance for these individuals), there is no test for the average causal effect of  $X$  on  $Y$  in either of these principal strata. Thus assuming (1) the only sub-population for which we may observe evidence that  $\text{ACE}_{t_X}(X \rightarrow Y) \neq 0$  are the Compliers ( $CO$ ).<sup>1</sup>

Furthermore, with the added assumption that there are no Always Takers, the ‘treated’ sub-population are simply the Compliers, such that the test of  $\text{ACE}_{CO}(X \rightarrow Y) = 0$  is the same test for the effect of treatment on the treated,  $E[Y_{x_1} - Y_{x_0} \mid X = 1] = 0$ .

## 2.5 MOTIVATING EXAMPLES

We consider two examples of randomized experiments with noncompliance. The first dataset is from a psychology experiment where individuals were randomly assigned to one of two groups (Table 3). The treatment group was offered a small cup of pop soda ( $Z = 1$ ), while the placebo group was offered a small cup of water ( $Z = 0$ ). Compliance was whether the individual consumed the offered soda ( $X = 1$ ) or not ( $X = 0$ ). Individuals who were not offered soda in the control group ( $Z = 0$ ) had no access to soda, as this was a closed study. There are thus two structural zeros, since

<sup>1</sup>This is why, even though our procedure is a test of the global null, we describe it as a test of the sharp null for Compliers.

$Z = 0$  implies  $X = 0$ . The response was a binary variable of whether the subject disposed of the cup after the session ( $Y = 1$ ) or left the cup on the table ( $Y = 0$ ). If we were to test the null hypothesis of  $Z \perp\!\!\!\perp Y$  with Fisher’s Exact Test for the corresponding  $2 \times 2$  table, we would get a p-value of 0.0085. However, if we disregarded the 30 individuals in the  $(Z = 1, X = 0)$  stratum and just tested  $Z \perp\!\!\!\perp Y$  among the  $(Z = X)$  stratum, we would get a p-value of 0.0546. Finally, Fisher’s Exact Test for the null hypothesis that  $X \perp\!\!\!\perp Y$  gives a p-value of 0.2157.

Table 3: Psychology Data

| $z$ | $x$ | $y$ | count | $z$ | $x$ | $y$ | count |
|-----|-----|-----|-------|-----|-----|-----|-------|
| 0   | 0   | 0   | 53    | 1   | 0   | 0   | 13    |
| 0   | 0   | 1   | 23    | 1   | 0   | 1   | 17    |
| 0   | 1   | 0   | 0     | 1   | 1   | 0   | 24    |
| 0   | 1   | 1   | 0     | 1   | 1   | 1   | 23    |

The second dataset is from a double-blind placebo-controlled randomized trial of Cholestyramine [4]. Subjects were randomly assigned to one of two arms: subjects in the treatment arm were prescribed Cholestyramine ( $Z = 1$ ), and those in the other arm were given a placebo ( $Z = 0$ ). Compliance was a continuous measure tracking the quantity of prescribed dosage consumed, over several years of treatment during the trial. The response was the average post-treatment cholesterol level, and also a continuous variable. Both continuous measures were dichotomized in [13], and the resulting counts are shown in Table 4. There are also two structural zeros in this dataset, since subjects who are not assigned treatment in the control arm ( $Z = 0$ ) could not obtain the experimental drug Cholestyramine.

Table 4: Cholestyramine/Lipid Data

| $z$ | $x$ | $y$ | count | $z$ | $x$ | $y$ | count |
|-----|-----|-----|-------|-----|-----|-----|-------|
| 0   | 0   | 0   | 158   | 1   | 0   | 0   | 52    |
| 0   | 0   | 1   | 14    | 1   | 0   | 1   | 12    |
| 0   | 1   | 0   | 0     | 1   | 1   | 0   | 23    |
| 0   | 1   | 1   | 0     | 1   | 1   | 1   | 78    |

For both studies in terms of the compliance types, there are no Defiers and no Always Takers, and both (1) and (2) hold. Furthermore, since both studies were double-blind randomized control trials, it may be safely assumed that  $Z$  has no effect on  $Y$  other than through  $X$ , so that the exclusion restriction (3) holds. Thus in this case, there are four response types  $t_Y$ , but only two compliance types  $t_X$ , which gives us eight combinations for  $(t_X, t_Y) \in \{NT, CO\} \times \{HE, HU, AR, NR\}$ . We will consider this simpler case during our main development, though the approach extends to the more general case in which there are also Always Takers.

### 3 MAXIMIZING THE LIKELIHOOD UNDER RANDOMIZATION

We first introduce the notation. Let  $n_{y_k x_j z_i}$  be the observable count of the number of individuals in the finite population who are assigned to treatment  $z = i$ , with exposure  $x = j$  and outcome  $y = k$ . We denote marginal tables similarly, for example  $n_{y_k}$  and  $n_{z_i}$ .

Let  $n_{t_Y, z_i}^{t_X}$  be the number of individuals in the finite population of compliance type  $t_X$  and response type  $t_Y$ , who are assigned to treatment  $z = i$ . Similarly, let  $n_{y_k z_i}^{t_X}$  be the number of individuals of compliance type  $t_X$  who are observed to have outcome  $y = k$  in the  $z = i$  arm, and  $n_{y_k}^{t_X} \equiv n_{y_k z_0}^{t_X} + n_{y_k z_1}^{t_X}$  be the total number of individuals in the finite population of compliance type  $t_X$  with observed outcome  $y = k$ . It should be noted that the counts  $n_{t_Y, z_i}^{t_X}$ ,  $n_{y_k z_i}^{t_X}$  and  $n_{y_k}^{t_X}$  are not all point-identified since they may not be directly observable from the data.

Our interest lies in testing the individual level (or ‘sharp’) causal null hypothesis that there is no effect of  $X$  on  $Y$  amongst Compliers:

$$H_0 : Y_{x_0} = Y_{x_1}. \quad (8)$$

Under the sharp null hypothesis (8), within the Complier sub-population, each individual would have the same observed outcome  $Y$  regardless of whether they took the treatment ( $X = Z = 1$ ) or did not do so ( $X = Z = 0$ ). Note that if the individual level causal null hypothesis (8) holds, then there is a zero average causal effect of  $X$  on  $Y$  for the sub-population of Compliers (CO) and  $ACE_{CO}(X \rightarrow Y) = 0$ .

Thus under the null (8), the number of Compliers with observed responses  $y = 0$  and  $y = 1$  are just the number of Compliers of types Never Recover (NR) and Always Recover (AR) respectively:

$$\begin{aligned} n_{y_0}^{CO} & \underset{H_0}{=} n_{NR, z_0}^{CO} + n_{NR, z_1}^{CO}, \\ n_{y_1}^{CO} & \underset{H_0}{=} n_{AR, z_0}^{CO} + n_{AR, z_1}^{CO}. \end{aligned}$$

If the number of Compliers assigned to  $z = 1$  vs.  $z = 0$  were pre-specified in advance by the experimental design then, over hypothetical replications, the margins of the  $2 \times 2$  sub-table for Compliers containing the four counts  $n_{t_Y, z_i}^{CO}$  for  $t_Y \in \{NR, AR\}$ ,  $i \in \{0, 1\}$  would be fixed. The resulting distribution for one of the cells, for example  $n_{AR, z_1}^{CO}$ , would be a hypergeometric distribution under the null hypothesis.

However, since we have no way to ensure a specific number of Compliers are assigned to treatment (or control) this may vary over hypothetical replications, hence none of the four counts  $n_{t_Y, z_i}^{CO}$  in the subtable for Compliers will follow a hypergeometric distribution. Further these counts are not directly observable from the data.

### 3.1 NUISANCE PARAMETERS

Denote  $\psi_k^{NT}$  as the total number of Never Takers with observed outcome  $y = k$ , such that the bivariate parameter  $\psi$  is:

$$\psi \equiv (\psi_0^{NT} \equiv n_{y_0}^{NT}, \psi_1^{NT} \equiv n_{y_1}^{NT}).$$

Figure 2 describes the sum relationships between the observed dataset  $\{n_{y_k x_j z_i}\}$  and counts  $n_{t_Y, z_i}^{t_X}$ ,  $n_{y_k z_i}^{t_X}$  and  $n_{y_k}^{t_X}$  under the null (8).

The counts  $n_{NR, z_1}^{CO}$  and  $n_{AR, z_1}^{CO}$  in the treatment arm ( $z = 1$ ) are directly observable from the data as  $n_{y_0 x_1 z_1}$  and  $n_{y_1 x_1 z_1}$  respectively. However, the presence of Never Takers in the finite population prevents us from point-identifying  $n_{NR, z_0}^{CO}$  and  $n_{AR, z_0}^{CO}$  in the placebo arm ( $z = 0$ ).

The unknown number of Never Takers  $\psi \equiv (\psi_0^{NT}, \psi_1^{NT})$  may thus be regarded as ‘nuisance parameters’, since if we knew these quantities, we could simply determine the unobservable counts for the Never Takers in the  $z_0$  arm:

$$\begin{aligned} n_{y_0, z_0}^{NT} & \equiv \psi_0^{NT} - n_{y_0, z_1}^{NT} = \psi_0^{NT} - n_{y_0 x_0 z_1}, \\ n_{y_1, z_0}^{NT} & \equiv \psi_1^{NT} - n_{y_1, z_1}^{NT} = \psi_1^{NT} - n_{y_1 x_0 z_1}. \end{aligned}$$

This in turn tells us what the exact values of  $n_{NR, z_0}^{CO}$  and  $n_{AR, z_0}^{CO}$  are, since  $n_{NR, z_0}^{CO}$  and  $n_{y_0, z_0}^{NT}$  add up to the observable quantity  $n_{y_0 x_0 z_0}$ , and similarly,  $n_{AR, z_0}^{CO}$  and  $n_{y_1, z_0}^{NT}$  add up to  $n_{y_1 x_0 z_0}$ .

Since  $\psi_0^{NT}$  and  $\psi_1^{NT}$  are bounded by the observable quantities in the data  $\{n_{y_k x_j z_i}\}$ , the space of possible values for the nuisance parameter  $\psi$  is the Cartesian product of the respective one-dimensional ranges for  $\psi_0$  and  $\psi_1$ :

$$\begin{aligned} \psi_0^{NT} & \in [n_{y_0 x_0 z_1}, n_{y_0 x_0 z_1} + n_{y_0 x_0 z_0}] = \Psi_0, \\ \psi_1^{NT} & \in [n_{y_1 x_0 z_1}, n_{y_1 x_0 z_1} + n_{y_1 x_0 z_0}] = \Psi_1, \\ \Psi & = \Psi_0 \times \Psi_1. \end{aligned} \quad (9)$$

### 3.2 MAXIMIZING THE HYPERGEOMETRIC PROBABILITY IN A $2 \times 2$ TABLE

Before analyzing the likelihood in our specific problem, we review the following related result: Suppose an urn contains  $N$  balls that are either red or green.  $N - k$  balls are drawn from the urn, of which  $b$  balls are red. What is the most likely number of red balls  $x$  remaining in the urn, or equivalently, the most likely total number of red balls  $b + x$  in the urn initially?

Table 5:  $2 \times 2$  Table With Unknown Column Totals

|           | Red     | Green         | Row     |
|-----------|---------|---------------|---------|
| Not drawn | $x$     | $k - x$       | $k$     |
| Drawn     | $b$     | $(N - k) - b$ | $N - k$ |
| Column    | $b + x$ | $N - (b + x)$ | $N$     |

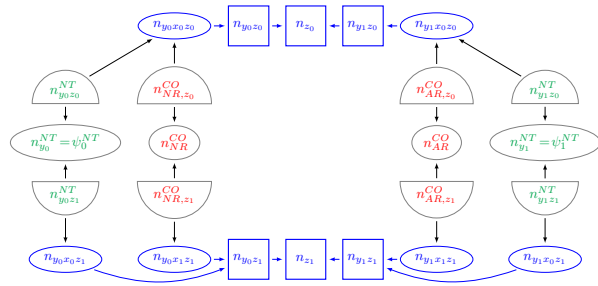

Figure 2: Sum Relationships between the Observed Dataset  $\{n_{y_k, x_j, z_i}\}$  and Possibly Unobserved Counts  $n_{t_Y, z_i}^{tX}$ ,  $n_{y_k, z_i}^{tX}$ ,  $n_{y_k}^{tX}$ , Assuming  $H_0$  (8); See Table 6.

We would thus like to maximize the hypergeometric probability corresponding to Table 5 with respect to  $x$ :

$$\Pr(x | (k, b, N)) = \binom{b+x}{x} \binom{N-(b+x)}{k-x} / \binom{N}{k}.$$

When  $b = 0$ , the most likely value of  $x$  would just be 0 as well. So if all  $N - k$  balls drawn were green, then the most likely number of red balls in the urn is 0.

**Theorem 1.** *In a  $2 \times 2$  table where the row totals  $(k, N - k)$  and the counts in one row  $(b, (N - k) - b)$  are fixed, the most likely value of  $x \in [0, k]$  under the randomization assumption is:*

$$\hat{x} = \arg \max_{x \in [0, k]} \left\{ x < (k+1) \frac{b}{N-k} \right\} = \left\lfloor \left\lceil (k+1) \frac{b}{N-k} \right\rceil \right\rfloor,$$

where the ‘basement’ function  $\lfloor \lceil a \rceil \rfloor$  is defined as:

$$\lfloor \lceil a \rceil \rfloor = \max\{0, \lceil a \rceil - 1\}.$$

Equivalently,

$$b + \hat{x} = \begin{cases} \left\lfloor b \frac{N}{N-k} \right\rfloor & \text{if } b \frac{N+1}{N-k} \leq \left\lceil b \frac{N}{N-k} \right\rceil, \\ \left\lceil b \frac{N}{N-k} \right\rceil & \text{otherwise.} \end{cases}$$

The proof for Theorem 1 is given in the supplementary material.

### 3.3 MAXIMUM LIKELIHOOD UNDER THE NULL

For some given value of the nuisance parameters  $\psi = \mathbf{u}$ , the counts  $n_{t_Y, z_i}^{tX}$ ,  $n_{y_k, z_i}^{tX}$  and  $n_{y_k}^{tX}$  are all point-identified from the observed dataset  $\{n_{y_k, x_j, z_i}\}$ . We may hence describe the exact counts in a  $2 \times 4$  full contingency table such as Table 6.

When we fix the value of  $\psi$  at the value  $\mathbf{u}$ , the total number of Never Takers with observed outcomes  $y = 0$  and  $y = 1$  ( $u_0^{NT}$  and  $u_1^{NT}$  respectively), as well as the total number

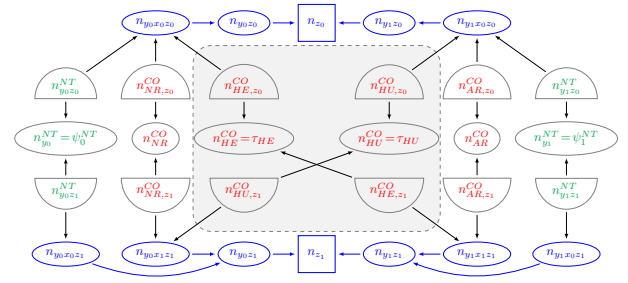

Figure 3: Sum Relationships between the Observed Dataset  $\{n_{y_k, x_j, z_i}\}$  and Possibly Unobserved Counts  $n_{t_Y, z_i}^{tX}$ ,  $n_{y_k, z_i}^{tX}$ ,  $n_{y_k}^{tX}$ , Without Assuming  $H_0$  (8); See Table 7.

of Compliers with observed responses  $y = 0$  and  $y = 1$  ( $n_{y_0} - u_0^{NT}$  and  $n_{y_1} - u_1^{NT}$  respectively) are fixed in the population, and would not change under  $H_0$  as we vary over all possible assignments of individuals to  $z = 0$  and  $z = 1$ .

Given the fixed column and row totals in Table 6 over repeated samplings, the randomization distribution under the null hypothesis (8) for the subjects assigned to the  $z = 1$  arm is thus the multiple hypergeometric distribution [9, Chapter 39]:

$$\begin{aligned} \Pr(\{n_{y_k, x_j, z_i}\} | \psi = \mathbf{u}, H_0) \\ = \frac{\binom{u_0^{NT}}{n_{y_0, x_0, z_1}} \binom{u_1^{NT}}{n_{y_1, x_0, z_1}} \binom{n_{y_0} - u_0^{NT}}{n_{y_0, x_1, z_1}} \binom{n_{y_1} - u_1^{NT}}{n_{y_1, x_1, z_1}}}{\binom{N}{n_{z_0}}} \end{aligned} \quad (10)$$

Note that the sharp null hypothesis for Compliers (8) holding places no restriction on the range of values for the nuisance parameter  $\psi$ . We shall thus consider the value of the nuisance parameter that lends the strongest support under  $H_0$  to the observed dataset  $\{n_{y_k, x_j, z_i}\}$ , by finding the maximum likelihood with respect to  $\psi$ :

$$q^{H_0}(\{n_{y_k, x_j, z_i}\}) = \max_{\psi \in \Psi} \Pr(\{n_{y_k, x_j, z_i}\} | \psi, H_0). \quad (11)$$

An exhaustive search over the two-dimensional discrete grid of the parameter space  $\Psi$  would require calculating  $|\Psi| = (n_{y_0, x_0, z_0} + 1) \times (n_{y_1, x_0, z_0} + 1)$  different hypergeometric probabilities.<sup>2</sup>

Instead, we partition Table 6 into two variation-independent  $2 \times 2$  subtables: one for the Never Takers and Compliers with observed  $y = 0$  outcomes (types  $(NT, y_0)$  and  $(CO, NR)$  respectively), and another for the Compliers and Never Takers with observed  $y = 1$  outcomes (types  $(CO, AR)$  and  $(NT, y_1)$  respectively). The joint probability (10) then factorizes into the corresponding functions of  $\psi_0^{NT}$  and  $\psi_1^{NT}$  below:

<sup>2</sup>For example in the Lipid data, the search space would be of size  $(158 + 1) \times (14 + 1) = 2,385$ .

$$\Pr(\{n_{y_k x_j z_i}\} | \boldsymbol{\psi}, H_0) = \frac{\binom{n_{y_0}}{n_{y_0 x_0 z_0}} \binom{n_{y_1}}{n_{y_1 x_0 z_0}}}{\binom{N}{n_{z_0}}} \times g_0(\psi_0^{NT} | \{n_{y_k x_j z_i}\}) \times g_1(\psi_1^{NT} | \{n_{y_k x_j z_i}\}); \quad (12)$$

$$g_0(\psi_0^{NT} | \{n_{y_k x_j z_i}\}) = \frac{\binom{\psi_0^{NT}}{n_{y_0 x_0 z_1}} \binom{n_{y_0} - \psi_0^{NT}}{n_{y_0 x_1 z_1}}}{\binom{n_{y_0}}{n_{y_0 x_0 z_0}}} \quad (13)$$

$$g_1(\psi_1^{NT} | \{n_{y_k x_j z_i}\}) = \frac{\binom{\psi_1^{NT}}{n_{y_1 x_0 z_1}} \binom{n_{y_1} - \psi_1^{NT}}{n_{y_1 x_1 z_1}}}{\binom{n_{y_1}}{n_{y_1 x_0 z_0}}}. \quad (14)$$

In both subtables, the cell counts in the  $z = 1$  arm are fixed, while the row totals for the  $z = 0$  arm are  $n_{y_0 x_0 z_0}$  and  $n_{y_1 x_0 z_0}$  respectively. We may then apply Theorem 1 directly to each subtable to find the following values of  $\psi_0^{NT}$  and  $\psi_1^{NT}$  that maximise the respective hypergeometric probabilities (13) and (14).

$$\widehat{\psi}_0^{NT} = \begin{cases} \left\lfloor \frac{n_{y_0} n_{y_0 x_0 z_1}}{n_{y_0} - n_{y_0 x_0 z_0}} \right\rfloor & \text{if } \frac{(n_{y_0} + 1) n_{y_0 x_0 z_1}}{n_{y_0} - n_{y_0 x_0 z_0}} \leq \left\lceil \frac{n_{y_0} n_{y_0 x_0 z_1}}{n_{y_0} - n_{y_0 x_0 z_0}} \right\rceil, \\ \left\lfloor \frac{n_{y_0} n_{y_0 x_0 z_1}}{n_{y_0} - n_{y_0 x_0 z_0}} \right\rfloor & \text{otherwise;} \end{cases}$$

$$\widehat{\psi}_1^{NT} = \begin{cases} \left\lfloor \frac{n_{y_1} n_{y_1 x_0 z_1}}{n_{y_1} - n_{y_1 x_0 z_0}} \right\rfloor & \text{if } \frac{(n_{y_1} + 1) n_{y_1 x_0 z_1}}{n_{y_1} - n_{y_1 x_0 z_0}} \leq \left\lceil \frac{n_{y_1} n_{y_1 x_0 z_1}}{n_{y_1} - n_{y_1 x_0 z_0}} \right\rceil, \\ \left\lfloor \frac{n_{y_1} n_{y_1 x_0 z_1}}{n_{y_1} - n_{y_1 x_0 z_0}} \right\rfloor & \text{otherwise.} \end{cases}$$

The largest value of the probability of the observed dataset under the null (11) is then:

$$q^{H_0}(\{n_{y_k x_j z_i}\}) = \Pr(\{n_{y_k x_j z_i}\} | (\widehat{\psi}_0^{NT}, \widehat{\psi}_1^{NT}), H_0).$$

### 3.4 MAXIMUM LIKELIHOOD UNDER THE ALTERNATIVE

When the null hypothesis does not hold, there may be individuals in the Complier sub-population whose treatment exposure  $X = j$  has an effect on their observed outcome  $Y = k$ . Compliers with observed responses  $y = 0$  are no longer limited to being only of response type Never Recover ( $NR$ ): they may also be of types Helped (in the  $z = 0$  arm) or Hurt (in the  $z = 1$  arm). Similarly, Compliers with observed responses  $y = 1$  may also be one of three response types: Always Recover ( $AR$ ), Helped (in the  $z = 1$  arm) or Hurt (in the  $z = 0$  arm).

Denote by  $\tau_i^{t_Y}(\boldsymbol{\psi})$  the number of Compliers in the finite population with response type  $t_Y$  assigned to treatment  $z = i$ , for some fixed value of  $\boldsymbol{\psi}$ . For example,  $\tau_0^{HE}(\boldsymbol{\psi})$  is the number of Compliers of type Helped in the  $z = 0$  arm. The parameter vector  $\boldsymbol{\tau}(\boldsymbol{\psi})$  is then:

$$\boldsymbol{\tau}(\boldsymbol{\psi}) \equiv \left( \tau_0^{HE}(\boldsymbol{\psi}) \equiv n_{HE,z_0}^{CO}(\boldsymbol{\psi}), \quad \tau_0^{HU}(\boldsymbol{\psi}) \equiv n_{HU,z_0}^{CO}(\boldsymbol{\psi}), \right. \\ \left. \tau_1^{HE} \equiv n_{HE,z_1}^{CO}, \quad \tau_1^{HU} \equiv n_{HU,z_1}^{CO} \right).$$

The sum relationships between the observed dataset  $\{n_{y_k x_j z_i}\}$  and counts  $n_{t_Y, z_i}^{t_X}$ ,  $n_{y_k, z_i}^{t_X}$  and  $n_{y_k}^{t_X}$  may then be described in Figure 3.

The space of possible values for the parameter  $\boldsymbol{\tau}(\boldsymbol{\psi})$  depends on the fixed value of  $\boldsymbol{\psi}$  and corresponds to a four-dimensional discrete grid:

$$\begin{aligned} \tau_0^{HE}(\boldsymbol{\psi}) &\in [0, n_{y_0 x_0 z_0} - (\psi_0^{NT} - n_{y_0 x_0 z_1})] \equiv \mathbf{T}_0^{HE}(\boldsymbol{\psi}), \\ \tau_0^{HU}(\boldsymbol{\psi}) &\in [0, n_{y_1 x_0 z_0} - (\psi_1^{NT} - n_{y_1 x_0 z_1})] \equiv \mathbf{T}_0^{HU}(\boldsymbol{\psi}), \\ \tau_1^{HE} &\in [0, n_{y_1 x_1 z_1}] \equiv \mathbf{T}_1^{HE}, \\ \tau_1^{HU} &\in [0, n_{y_0 x_1 z_1}] \equiv \mathbf{T}_1^{HU}, \\ \mathbf{T}(\boldsymbol{\psi}) &= \mathbf{T}_0^{HE}(\boldsymbol{\psi}) \times \mathbf{T}_0^{HU}(\boldsymbol{\psi}) \times \mathbf{T}_1^{HE} \times \mathbf{T}_1^{HU}. \end{aligned} \quad (15)$$

For some given value of the nuisance parameters  $\boldsymbol{\psi} = \mathbf{u} \equiv (u_0^{NT}, u_1^{NT})$ , and the primary parameters  $\boldsymbol{\tau}(\mathbf{u}) = \mathbf{t}(\mathbf{u}) \equiv (t_0^{HE}(\mathbf{u}), t_0^{HU}(\mathbf{u}), t_1^{HE}, t_1^{HU})$ , the counts  $n_{t_Y, z_i}^{t_X}$ ,  $n_{y_k, z_i}^{t_X}$  and  $n_{y_k}^{t_X}$  are all point-identified from the observed dataset  $\{n_{y_k x_j z_i}\}$ . The exact counts may be summarized in a  $2 \times 6$  full contingency table such as Table 7.

Given the fixed column and row totals in Table 7 over repeated samplings, the multiple hypergeometric probability of the subjects assigned to the  $z = 1$  arm, when we no longer assume  $H_0$  to hold, is:

$$\begin{aligned} \Pr(\{n_{y_k x_j z_i}\} | (\boldsymbol{\psi}, \boldsymbol{\tau}(\boldsymbol{\psi})) = (\mathbf{u}, \mathbf{t}(\mathbf{u}))) &= \frac{\binom{u_0^{NT}}{n_{y_0 x_0 z_1}} \binom{t_0^{HE}(\mathbf{u}) + t_1^{HE}}{t_1^{HE}} \binom{t_0^{HU}(\mathbf{u}) + t_1^{HU}}{t_1^{HU}} \binom{u_1^{NT}}{n_{y_1 x_0 z_1}}}{\binom{N}{n_{z_0}}} \\ &\times \binom{n_{y_0} - t_0^{HE}(\mathbf{u}) - t_1^{HU} - u_0^{NT}}{n_{y_0 x_1 z_1} - t_1^{HU}} \binom{n_{y_1} - t_0^{HU}(\mathbf{u}) - t_1^{HE} - u_1^{NT}}{n_{y_1 x_1 z_1} - t_1^{HE}}. \end{aligned} \quad (16)$$

The maximum likelihood for the observed data  $\{n_{y_k x_j z_i}\}$ , allowing for Compliers who are Helped and Hurt, is then:

$$\begin{aligned} q^{ML}(\{n_{y_k x_j z_i}\}) &= \max_{\boldsymbol{\psi} \in \boldsymbol{\Psi}} \max_{\boldsymbol{\tau}(\boldsymbol{\psi}) \in \mathbf{T}(\boldsymbol{\psi})} \Pr(\{n_{y_k x_j z_i}\} | (\boldsymbol{\psi}, \boldsymbol{\tau}(\boldsymbol{\psi}))). \end{aligned}$$

Similar to the maximization procedure under the null, we would like to circumvent an exhaustive search of the parameter space  $\{\boldsymbol{\Psi} \times \mathbf{T}(\boldsymbol{\Psi})\}$  by decomposing the joint probability (16) into separate objective functions. However, unlike the full contingency table under  $H_0$  in Table 6, we cannot simply partition Table 7 into variation-independent subtables based only on the observed  $y = 0$  and  $y = 1$  outcomes. This is because if there was an effect of the treatment  $X$  on  $Y$ , then there is a Complier individual of type Helped or Hurt who would have had a different outcome  $Y$  had they been assigned to a different level of  $Z$ , and hence received a different exposure level  $X$ .

However, when we fix the number of Compliers of types Helped and Hurt in the  $z = 1$  arm at some value  $(\tau_1^{HE}, \tau_1^{HU}) = (t_1^{HE}, t_1^{HU})$ , all six counts in the  $z = 1$  arm are now point-identified and fixed. Then Table 7 may be partitioned into two variation-independent

Table 6: Full Contingency Table Under  $H_0$  with Cell Counts that are Point-Identified Given a Value of  $\psi = \mathbf{u}$ .

$2 \times 3$  subtables: one for individuals of types  $(NT, y_0)$ ,  $(CO, NR)$  and  $(CO, HE)$ , and another for individuals of types  $(CO, HU)$ ,  $(CO, AR)$  and  $(NT, y_1)$ .

Given a fixed value of  $(t_1^{HE}, t_1^{HU})$ , the joint probability (16) then decomposes into a product of functions of  $(\psi_0^{NT}, \tau_0^{HE})$  and  $(\psi_1^{NT}, \tau_0^{HU})$ ; see (18) and (19) below. For the given value of  $(t_1^{HE}, t_1^{HU})$ , the cell counts in the  $z=1$  arm are fixed in each  $2 \times 3$  variation-independent subtable, while the row totals for the  $z=0$  arms are  $n_{y_0 x_0 z_0}$  and  $n_{y_1 x_0 z_0}$  respectively.

$$\begin{aligned} & \Pr(\{n_{y_k x_j z_i}\} | \psi, \tau_0^{HE}(\psi), \tau_0^{HU}(\psi), t_1^{HE}, t_1^{HU}) \\ &= \frac{\binom{n_{y_0} + t_1^{HE} - t_1^{HU}}{n_{y_0 x_0 z_0}} \binom{n_{y_1} + t_1^{HU} - t_1^{HE}}{n_{y_1 x_0 z_0}}}{\binom{N}{n_{z_0}}} \\ & \quad \times h_0(\psi_0^{NT}, \tau_0^{HE}(\psi_0^{NT}) | t_1^{HE}, t_1^{HU}, \{n_{y_k x_j z_i}\}) \\ & \quad \times h_1(\psi_1^{NT}, \tau_0^{HU}(\psi_1^{NT}) | t_1^{HE}, t_1^{HU}, \{n_{y_k x_j z_i}\}); \end{aligned} \quad (17)$$

$$\begin{aligned} & h_0(\psi_0^{NT}, \tau_0^{HE}(\psi_0^{NT}) | t_1^{HE}, t_1^{HU}, \{n_{y_k x_j z_i}\}) \\ &= \frac{\binom{\psi_0^{NT}}{n_{y_0 x_0 z_1}} \binom{\tau_0^{HE}(\psi_0^{NT}) + t_1^{HE}}{t_1^{HE}} \binom{n_{y_0} - \tau_0^{HE}(\psi_0^{NT}) - t_1^{HU} - \psi_0^{NT}}{n_{y_0 x_0 z_0}}}{\binom{n_{y_0} + t_1^{HE} - t_1^{HU}}{n_{y_0 x_0 z_0}}}, \end{aligned} \quad (18)$$

$$\begin{aligned} & h_1(\psi_1^{NT}, \tau_0^{HU}(\psi_1^{NT}) | t_1^{HE}, t_1^{HU}, \{n_{y_k x_j z_i}\}) \\ &= \frac{\binom{\psi_1^{NT}}{n_{y_1 x_0 z_1}} \binom{\tau_0^{HU}(\psi_1^{NT}) + t_1^{HU}}{t_1^{HU}} \binom{n_{y_1} - \tau_0^{HU}(\psi_1^{NT}) - t_1^{HE} - \psi_1^{NT}}{n_{y_1 x_1 z_1} - t_1^{HE}}}{\binom{n_{y_1} + t_1^{HU} - t_1^{HE}}{n_{y_1 x_0 z_0}}}. \end{aligned} \quad (19)$$

Since the  $2 \times 3$  subtables are now variation-independent, we

may find the values of:

$$\begin{aligned} & (\hat{\psi}_0^{NT}(t_1^{HE}, t_1^{HU}), \hat{\tau}_0^{HE}(\hat{\psi}_0^{NT}; t_1^{HE}, t_1^{HU})), \\ & (\hat{\psi}_1^{NT}(t_1^{HE}, t_1^{HU}), \hat{\tau}_0^{HU}(\hat{\psi}_1^{NT}; t_1^{HE}, t_1^{HU})) \end{aligned}$$

that maximise the respective conditional hypergeometric probabilities (18) and (19).

For each fixed value of  $(t_1^{HE}, t_1^{HU})$ , a naïve search over the discrete parameter space in each induced  $2 \times 3$  subtable would involve maximizing over  $\binom{n_{y_0 x_0 z_0} + 2}{2}$  and  $\binom{n_{y_1 x_0 z_0} + 2}{2}$  hypergeometric probabilities respectively.<sup>3</sup>

Instead, we apply the result from [12], which provides an algorithm to find the most likely values of the cells in the  $z_0$  arms of both subtables, *without calculating any hypergeometric probabilities*. Finally, we need only maximize over the parameter spaces for  $\tau_1^{HE}$  and  $\tau_1^{HU}$ , where there are  $|\mathbf{T}_1^{HE}| \times |\mathbf{T}_1^{HU}| = (n_{y_1 x_1 z_1} + 1) \times (n_{y_0 x_1 z_1} + 1)$  possible combinations for the point-identified counts in the  $Z=1$  arm.<sup>4</sup>

Allowing Compilers who are Helped and Hurt, the maximum likelihood for the observed dataset  $\{n_{y_k x_j z_i}\}$  is then:

$$\begin{aligned} & q^{ML}(\{n_{y_k x_j z_i}\}) = \\ & \max_{\substack{(\tau_1^{HE}, \tau_1^{HU}) \\ \in \mathbf{T}_1^{HE} \times \mathbf{T}_1^{HU}}} \Pr(\{n_{y_k x_j z_i}\} | \hat{\psi}, \tau_0^{HE}(\hat{\psi}), \\ & \quad \tau_0^{HU}(\hat{\psi}), \tau_1^{HE}, \tau_1^{HU}). \end{aligned} \quad (20)$$

<sup>3</sup>For example in the Lipid data, the search spaces would be of sizes  $\binom{158+2}{2} = 12,720$  and  $\binom{14+2}{2} = 120$  respectively.

<sup>4</sup>In the Lipid data example, we would need to calculate only  $(78 + 1) \times (23 + 1) = 1896$  hypergeometric probabilities.

## 4 GLR AND P-VALUE

A generalized likelihood ratio (GLR) lets us assess the evidence in the observed data both for *and against* the null hypothesis (8) respectively, by comparing the best possible fit of the observed data when  $H_0$  holds, against the best fit without the constraint of  $H_0$ . The generalized likelihood ratio for the observed dataset  $\{n_{y_k x_j z_i}\}$  is defined as:

$$G(\{n_{y_k x_j z_i}\}) = \frac{q^{H_0}(\{n_{y_k x_j z_i}\})}{q^{ML}(\{n_{y_k x_j z_i}\})}. \quad (21)$$

However, the distribution of the test statistic (21) under  $H_0$  depends on the chosen values of the column totals in the full contingency table (Table 6), which in turn correspond to some value of the nuisance parameter  $\psi$ . Under  $H_0$  the value of  $\psi = \mathbf{u}$  is sufficient to determine the distribution of (21) since the margin totals in the full contingency table (Table 6) are now fixed.

We may then enumerate all possible assignments, and consolidate each assignment to obtain the associated *possibly observable dataset*  $\{\tilde{n}_{y_k x_j z_i}\}$  based on the sum relationships depicted in Figure 2:

$$\begin{aligned} \tilde{n}_{y_0 x_0 z_0} &= \tilde{n}_{y_0, z_0}^{NT} + \tilde{n}_{NR, z_0}^{CO}; \tilde{n}_{y_1 x_0 z_0} = \tilde{n}_{y_1, z_0}^{NT} + \tilde{n}_{AR, z_0}^{CO}; \\ \tilde{n}_{y_0 x_0 z_1} &= u_0^{NT} - \tilde{n}_{y_0, z_0}^{NT}; \tilde{n}_{y_0 x_1 z_1} = (n_{y_0} - u_0^{NT}) - \tilde{n}_{NR, z_0}^{CO}; \\ \tilde{n}_{y_1 x_0 z_1} &= u_1^{NT} - \tilde{n}_{y_1, z_0}^{NT}; \tilde{n}_{y_1 x_1 z_1} = (n_{y_1} - u_1^{NT}) - \tilde{n}_{AR, z_0}^{CO}. \end{aligned}$$

For each of these possibly observable datasets  $\{\tilde{n}_{y_k x_j z_i}\}$ , we then find the corresponding generalized likelihood ratio  $G(\{\tilde{n}_{y_k x_j z_i}\}) = q^{H_0}(\{\tilde{n}_{y_k x_j z_i}\})/q^{ML}(\{\tilde{n}_{y_k x_j z_i}\})$ . Note that the parameter space, which we denote as  $(\tilde{\Psi}, \tilde{\mathbf{T}}(\tilde{\Psi}))$ , is specific to each dataset  $\{\tilde{n}_{y_k x_j z_i}\}$ , and differs from the parameter space for the actually observed data  $(\Psi, \mathbf{T}(\Psi))$ .

Given a fixed value of the nuisance parameter  $\psi$ , the corresponding  $\psi$ -specific p-value is then the total probability under  $H_0$  of all datasets  $\{\tilde{n}_{y_k x_j z_i}\}$  with generalized likelihood ratios  $G(\{\tilde{n}_{y_k x_j z_i}\})$  that are at least as extreme as that for the observed data  $\{n_{y_k x_j z_i}\}$ :

$$p^{H_0}(\{n_{y_k x_j z_i}\}; \psi) = \sum_{\substack{\{\tilde{n}_{y_k x_j z_i}\}: \\ G(\{\tilde{n}_{y_k x_j z_i}\}) \leq G(\{n_{y_k x_j z_i}\})}} \Pr(\{\tilde{n}_{y_k x_j z_i}\} \mid \psi, H_0).$$

Since each fixed value of  $\psi$  corresponds to a different number of Compliers and hence a different instance of the null hypothesis, we may report the maximum among all the  $\psi$ -specific p-values as the p-value from our significance test:

$$p^{H_0}(\{n_{y_k x_j z_i}\}) \equiv \max_{\psi \in \Psi} p^{H_0}(\{n_{y_k x_j z_i}\}; \psi). \quad (22)$$

The probability of obtaining a value of the test statistic as extreme as the one observed (21) will never be larger than  $p^{H_0}(\{n_{y_k x_j z_i}\})$ , irrespective of the number of Compliers in the population, and is thus a valid frequentist p-value.

## 5 APPLICATIONS

### 5.1 PSYCHOLOGY DATA EXAMPLE

For the observed dataset  $\{n_{y_k x_j z_i}\}$  in the motivating example from Table 3, the largest probability under  $H_0$  is  $q^{H_0}(\{n_{y_k x_j z_i}\}) = 1 \times 10^{-4}$ ; the maximum likelihood without the constraint of no Compliers who were Helped or Hurt in the population is  $q^{ML}(\{n_{y_k x_j z_i}\}) = 2.3 \times 10^{-3}$ . The generalized likelihood ratio (21) for this dataset is:  $G(\{n_{y_k x_j z_i}\}) = \frac{q^{H_0}(\{n_{y_k x_j z_i}\})}{q^{ML}(\{n_{y_k x_j z_i}\})} = 0.052$ .

There were  $1296 = (23 + 1) \times (53 + 1)$  possible values of the nuisance parameter  $\psi$ , and the maximum among all the  $\psi$ -specific p-values is:

$$p^{H_0}(\{n_{y_k x_j z_i}\}) \equiv \max_{\psi \in \Psi} \{p^{H_0}(\{n_{y_k x_j z_i}\}; \psi)\} = 0.0137.$$

### 5.2 LIPID DATA EXAMPLE

For the observed dataset  $\{n_{y_k x_j z_i}\}$  in the motivating example from Table 4, the largest probability under  $H_0$  is  $q^{H_0}(\{n_{y_k x_j z_i}\}) = 6 \times 10^{-23}$ ; the maximum likelihood without the constraint of no Compliers who were Helped or Hurt in the population is  $q^{ML}(\{n_{y_k x_j z_i}\}) = 0.0019$ . The generalized likelihood ratio (21) for this dataset is then:

$$G(\{n_{y_k x_j z_i}\}) = \frac{q^{H_0}(\{n_{y_k x_j z_i}\})}{q^{ML}(\{n_{y_k x_j z_i}\})} = 3 \times 10^{-20}.$$

There were  $2385 = (14 + 1) \times (158 + 1)$  possible values of the nuisance parameter  $\psi$ , and the maximum among all the  $\psi$ -specific p-values is:

$$p^{H_0}(\{n_{y_k x_j z_i}\}) \equiv \max_{\psi \in \Psi} \{p^{H_0}(\{n_{y_k x_j z_i}\}; \psi)\} = 2 \times 10^{-21}.$$

In comparison, using a pre-specified value of  $\gamma = 0.01$  gives a p-value of  $0.01 + (1 \times 10^{-21}) \approx 0.01$  [10].

## 6 CONCLUSIONS

We have proposed a finite population significance test of the sharp null hypothesis for Compliers using the generalized likelihood ratio. The resulting p-value may be arbitrarily close to zero and summarizes the strength of evidence against the sharp null hypothesis for Compliers (8).

While our development has assumed that there are no Always Takers, the approach extends to the more general case in which there are also Always Takers. However, this would increase the dimension of the nuisance parameter and hence the size of the nuisance parameter space, such that finding the generalized likelihood ratio test statistic would be computationally more intensive. For example, even when the sharp null hypothesis for Compliers (8) holds, the number of Compliers in the  $z = 1$  arm ( $n_{NR, z_1}^{CO}$  and  $n_{AR, z_1}^{CO}$ ) would no longer be point-identified from the observed counts  $n_{y_0 x_1 z_1}$  and  $n_{y_1 x_1 z_1}$  respectively.

## Abstract

We consider the problem of learning the structure of a Markov Random Field (MRF) when a node-specific degree distribution is provided. The problem setting is inspired by protein contact map (i.e., graph) prediction in which the contact number (i.e., degree) of an individual residue (i.e., node) can be predicted without knowing the contact graph. We formulate this problem using maximum pseudo-likelihood plus a node-specific  $\ell_1$  regularization derived from the predicted degree distribution. Intuitively, when a node have  $k$  predicted edges, we dynamically reduce the regularization coefficients of the  $k$  most possible edges to promote their occurrence. We then optimize the objective function using ADMM and an Iterative Maximum Cost Bipartite Matching algorithm. Our experimental results show that using degree distribution as a constraint may lead to significant performance gain when the predicted degree has good accuracy.

## 1. INTRODUCTION

Structure learning of a Markov Random Field (MRF) is an important problem and has been applied to many real-world problems which require study of conditional independence between a set of objects. For example, structure learning has been used to derive gene expression or regulatory network from gene expression levels [1, 6, 32, 36] and predict the contact map of a protein from a multiple sequence alignment of a protein family [9, 15, 16, 23, 24]. Two major approaches and their variants have been studied to learn the structure of a graphical model from data: Gaussian Graphical Model (GGM) [11] and maximum pseudo-likelihood [29]. Since many real-world

structures are usually sparse,  $\ell_1$  regularization is usually added to the objective function to generate a sparse structure. Empirical studies indicate that the pseudo-likelihood approach may have better prediction accuracy and is also more efficient than GGM, by dropping the Gaussian distribution assumption.

In real-world applications, the underlying structure (or graph) usually has some special properties and must satisfy some topological constraints. For example, a gene expression network is scale-free. A protein contact graph must satisfy some geometric constraints, e.g., the degree of each node is upper bounded by a constant and also depends on the properties of its corresponding amino acid. Only a few structure-learning algorithms take into consideration topological constraints of the underlying graph, which can be used to reduce the feasible solution set of the problem. From another perspective, predicted graphs without considering these constraints might contain conflicts and are physically infeasible. A predicted contact graph violating the above-mentioned geometric constraints may not correspond to a feasible protein structure. Several papers [12, 17, 30, 35] have considered some very general topological constraints describing the global properties of a graph to improve structure learning. However, these non-specific topological constraints do not help very much in practice. The reason may be that they are too loose for some nodes (graphs) and too restrictive for others and thus, the overall performance gain is limited.

The problem addressed by this paper is inspired by protein contact graph prediction. A protein sequence consists of a string of amino acids (also called residues). In nature, a protein sequence folds into a specific 3D shape to function properly. Two residues are defined to form a contact if they are close (distance  $\leq 8$  Å) in the 3D space. Therefore, we can use a contact map to model a protein 3D structure. Predicting inter-residue contacts from sequence is an important and challenging problem. Recent studies [22, 24, 25, 27] indicate that predicted inter-residue contacts could be used as a valuable constraint to improve the folding of some proteins. Baker group [16] shows that one correct long-range contact for every 12 amino acids (AAs) in a

---

<sup>1</sup> The first two authors contribute equally to the paper.

protein allows for accurate topology-level protein folding. Recent breakthroughs [9, 15, 24] apply Gaussian Graphical Model and maximum pseudo-likelihood to formulate protein contact prediction as a structure learning problem. In these formulations, a protein sequence is viewed as a sample generated from a Markov Random Field (MRF), in which an MRF node represents one AA (also called residue) and an edge indicates a contact (i.e., strong interaction) between two AAs.

Without knowing the actual contact graph of a protein, we can use a supervised learning method to predict the number of contacts (i.e., degree) of an AA from sequence information. In particular, we use  $2L$  different linear-chain  $2^{\text{nd}}$ -order Conditional Neural Fields (CNFs) [28] to predict the degree distribution for a protein of length  $L$ . A CNF is an integration of neural networks and Conditional Random Field (CRF) [20]. CNF models the relationship between the label at each node and input features by neural networks and also correlation among neighboring labels. Therefore, CNF can capture the complex relationship between node labels and features as well as the dependency between node labels. The predicted node degree distribution is then used as a regularization to help improve individual contact prediction.

## 2. RELATED WORK

To our best knowledge, there are very few published work that uses node-specific degree distribution to help with structure learning of MRFs. Motivated by the observation that many social and biological networks follow a power-law degree distribution [2, 5, 14], [21] proposed a novel non-convex reweighted  $\ell_1$  regularization by using a log surrogate to approximate the power-law distribution. The basic idea is to reduce the regularization coefficients for hub nodes (i.e., nodes with a large degree) to promote their occurrence. A convex variant of this work was developed in [7], resulting in further performance improvement. This work modeled the structure learning problem as a set-function optimization problem and approximated it by Lovasz extension [4]. The resultant objective function is another kind of reweighted  $\ell_1$  regularization. Although these methods result in a graph following a power-law degree distribution, their accuracy of the predicted edges is not much better than the simple  $\ell_1$  regularization. A very recent work [37] obtained much better accuracy by making use of a reweighted  $\ell_1$  regularization accounting for not only global degree distribution, but also the estimated degree of an individual node and the relative strength of all the edges of the same node.

Other work such as [10] takes into consideration eigenvector centrality constraints and triangle-shaped local motifs of the graph, which are properties of gene regulatory networks and protein-protein interaction networks. [33] presented a convex formulation that uses a group-sparsity penalty on the rows and columns of the data precision matrix, effectively selecting which nodes

connect with all the other nodes or no nodes at all. This formulation also results in a graph following a power-law distribution.

## 3. METHOD

### 3.1 NOTATIONS AND PRELIMINARIES

Given a protein sequence, we can run PSI-BLAST [3] to find its sequence homologs (i.e., proteins in the same family) and build a multiple sequence alignment (MSA) of homologs. By examining this MSA, we can identify evolution and co-evolution patterns in a protein family. By co-evolution, we mean the evolution of one AA is strongly impacted by the other. As shown in Figure 1, the AAs in the two red MSA columns are co-evolved. It has been observed that two co-evolved residues are likely to form a contact in the 3D space since they strongly interact with each other.

**Figure 1.** Two coevolved AAs (in red columns) may form a contact in 3D space.

We can use Markov Random Fields (MRF) to model the MSA and infer inter-residue contacts by structure learning of the MRF. In the MRF model, a node represents one MSA column and an edge represents correlation between two MSA columns. Let  $X = \{X_1, X_2, \dots, X_L\}$  be a protein sequence where  $X_i$  represents amino acid type (or gap) at column  $i$ . Let  $R$  denote the number of protein sequences (or rows) in the MSA. Let  $X_{ir}$  denote the amino acid type observed at row  $r$  ( $1 \leq r \leq R$ ) and column  $i$  ( $1 \leq i \leq L$ ). The probability of observing  $X$  can be defined as follows.

$$P(X) = \prod_{r=1}^R \frac{\exp(\sum_{i=1}^L b_i(X_{ir}) + \sum_{i<j} w_{ij}(X_{ir}, X_{jr}))}{Z} \quad (1)$$

Here  $b_i$  and  $w_{ij}$  denote the unary and binary potential functions for nodes  $i$  and  $j$ , respectively.  $Z$  is the partition function, summing over all the possible label combinations. If nodes  $i$  and  $j$  share an edge in the graph, they are correlated given all the other nodes, indicating that their corresponding AAs form a contact and interact with each other in the 3D space. Therefore, the contact number of one AA corresponds to the node degree in the graph. Both training and inference by maximizing (1) over a general graph are NP-hard. Pseudo-likelihood approximation [9, 29] is proposed to

deal with this. Substituting the original likelihood function, we have,

$$P(X_i) = \prod_{r=1}^R P(X_{i,r} | X_{\setminus i,r}) \quad (2)$$

$$= \prod_{r=1}^R \frac{\exp(b_i(X_{i,r}) + \sum_{j=1, j \neq i}^L w_{i,j}(X_{i,r}, X_{j,r}))}{\sum_{X_{i,r}} \exp(b_i(X_{i,r}) + \sum_{j=1, j \neq i}^L w_{i,j}(X_{i,r}, X_{j,r}))}$$

Each binary potential function  $w_{ij}$  is a  $21 \times 21$  matrix. We can estimate all  $w_{ij}$  by maximizing (2). We can use  $\sum_{a,b=1}^{20} |w_{i,j}(a,b)|$  to measure the interaction strength between two nodes  $i$  and  $j$ . A pair of nodes with strong interaction is predicted to share an edge or form a contact.

### 3.2 NODE-SPECIFIC DEGREE REGULARIZATION

In this section we introduce how to add a node-specific degree distribution as a prior to the above pseudo-likelihood function. Let  $P_i(k)$  be the predicted probability of node  $i$  having  $k$  contacts. Let  $W_{ij} = \sum_{a,b=1}^{20} |w_{i,j}(a,b)|$ , which indicates the interaction strength between two AAs  $i$  and  $j$ . Given a  $i$ , we exclude  $W_{ii}$  and denote the  $t$ -th largest  $W_{ij}$  as  $W_{i,(t)}$ . We use the following penalty term  $\Omega_i$  for AA  $i$ .

$$\Omega_i = \sum_{k=1}^{L-1} P_i(k) \left( -\sum_{t=1}^k W_{i,(t)} + \sum_{t=k+1}^{L-1} W_{i,(t)} \right) \quad (3)$$

Eq. (3) implies that if the degree of AA  $i$  is  $k$ , its  $k$  largest  $W_{i,(1)}, W_{i,(2)}, \dots, W_{i,(k)}$  shall be big and the remaining  $W_{i,(k+1)}, W_{i,(k+2)}, \dots$  shall be very small. The outer summation ranges from 1 to  $L-1$  since the contact number is less than  $L$ . Regrouping Eq. (3) by each  $W_{i,(k)}$  we have,

$$\Omega_i = \sum_{k=1}^{L-1} g_{i,k} W_{i,(k)} \quad (4)$$

where  $g_{i,k} = -\sum_{t=k}^{L-1} P_i(t) + \sum_{t=k+1}^{L-1} P_i(t)$ . Notice that the coefficient  $g_{i,k}$  for  $W_{i,(k)}$  can be negative, which will lead the optimization problem to be unbounded, so empirically we add a constant  $\beta$  (0.2 by default) to each  $g_{i,k}$  to make it positive. Figure 2 shows two examples. For node  $i$ , its degree is most likely to be either 1 or 3, so the coefficient for the largest interaction strength  $W_{i,(1)}$  should be reduced. For node  $j$ , its degree is most likely to be zero, so all the coefficients are increased to drive its interaction strengths to zero.

The reweighted  $\ell_1$  regularized pseudo-likelihood function is defined as,

$$\min_W L(W) + \sum_{i=1}^L \Omega_i(W) \quad (5)$$

Where  $L(W)$  is the negative log of Eq. (2) and  $\Omega_i$  is a special  $\ell_1$  penalty defined in Eq. (4). To optimize (5), we

use Alternating Direction Method of Multipliers (ADMM) [13] to separate the pseudo-likelihood function and the  $\ell_1$  penalty term. ADMM alternatively solves the following three sub-problems.

$$Z^{n+1} = \operatorname{argmin}_Z L(Z) + \frac{\rho}{2} \|Z - W^n + U^n\|_2^2 \quad (6)$$

$$W^{n+1} = \operatorname{argmin}_W \sum_{i=1}^L \Omega_i(W) + \frac{\rho}{2} \|Z^n - W + U^n\|_2^2 \quad (7)$$

$$U^{n+1} = U^n + Z^{n+1} - W^{n+1} \quad (8)$$

**Figure 2.** Node-specific degree-based  $\ell_1$  penalty. This figure shows how the regularizers are different based on the predicted degree distribution. The X-axis is the probability and the Y-axis is the degree. The colorful arrows represent the change of coefficient for the  $\ell_1$ -norm. The warmer the color the smaller the value is. Down arrows represent negative value and up arrows represent positive value.

where  $\rho > 0$  is a fixed step-size parameter (we used  $\rho = 0.01$ ) and  $U$  is the dual variable passing information between sub-problems (6) and (7). Problem (6) can be solved using conjugate gradient decent. Since the order of  $W_{i,*}$  for each  $i$  is unknown in problem (7), it is challenging to solve (7). We need to consider their order so that  $g_{i,k}$  can be used to weight the  $k$ -th largest  $W_{i,(k)}$ . Let  $M = Z + U$  and  $g_{i,k} = g_{i,k}/\rho$ . We may further divide problem (7) into  $L$  sub-problems; the  $i$ -th sub-problem is as follows.

$$\min_{W_i} \frac{1}{2} \|W_i - |M_i|\|_2^2 + \Omega_i(W_i) \quad (9)$$

To solve problem (9), we need a mapping between original  $\{W_{i,k}\}$  and  $\{g_{i,k}\}$ , as different mappings lead to different optimization problems. For a given mapping, we need to minimize the corresponding function subject to the constraints provided by the mapping. We want the mapping with the smallest optimal value. However, there are an exponential number of mappings between  $\{W_{i,k}\}$  and  $\{g_{i,k}\}$ , which makes it impossible to enumerate all the possible mappings. To make it easy, we assume  $W_{i,(k)} >$

$W_{i,(k+1)}$  for all  $k$ . That is, we only want to find a solution satisfying this condition. Next we will introduce how to use an Iterative Maximum Cost Bipartite Matching algorithm to solve the relaxation problem.

### 3.2.1 Iterative Maximum Cost Bipartite Matching Algorithm

**Theorem 1.** Let  $W_{i,(1)} > W_{i,(2)} > \dots > W_{i,(L-1)}$  be the ranking of  $\{W_{i,k}\}$ . The optimal solution  $W_{i,(k)}^* = \sum_{a,b=1}^{20} |w_{i,(k)}^*(a,b)|$  of problem (9) always has the form,

$$|w_{i,(k)}^*(a,b)| = \max\{|M_{i,(k)}(a,b)| - g_{i,k}, 0\} \quad (10)$$

**Proof.** By taking the sub-gradient with respect to each  $|w_{i,(k)}(a,b)|$  and setting it to zero we obtain Eq. (10). If the optimal solution  $|w_{i,(k)}^*(a,b)|$  of (9) does not satisfy Eq. (10), we can always decrease the objective function by adding or subtracting a small constant to (10) so that  $W_{i,(k-1)} > W_{i,(k)} > W_{i,(k+1)}$  still holds. This contradicts with our assumption that  $|w_{i,(k)}^*(a,b)|$  is the optimal solution.  $\square$

Based on Theorem 1, given a ranking of  $\{W_{i,k}\}$ , we can substitute  $\{W_{i,k}\}$  of (9) by Eq. (10) to obtain the below equation.

$$\sum_{k=1}^{L-1} \sum_{a,b=1}^{20} M_{i,(k)}(a,b)^2 - w_{i,(k)}^*(a,b)^2 \quad (11)$$

Now we need to minimize (11). Notice that the summation of all the  $M_{i,(k)}(a,b)^2$  is a constant, so minimizing (11) is equivalent to the following optimization problem.

$$\max \sum_{k=1}^{L-1} \sum_{a,b=1}^{20} w_{i,(k)}^*(a,b)^2 \quad (12)$$

Substituting (9) into (12) and considering the constraints of the mapping, we have the following optimization problem.

$$\max \sum_{k=1}^{L-1} \sum_{a,b=1}^{20} \max\{|M_{i,(k)}(a,b)| - g_{i,k}, 0\}^2 \quad (13)$$

$$s.t. \quad \forall k \quad W_{i,(k)}^* > W_{i,(k+1)}^*$$

where  $W_{i,(k)}^* = \sum_{a,b=1}^{20} \max\{|M_{i,(k)}(a,b)| - g_{i,k}, 0\}$ . Note that in this problem we are looking for a one-to-one matching between  $M_{i,(k)}$  and  $g_{i,k}$ , which can be modeled as an Integer Linear Problem (ILP) defined on variable  $E = \{e_{k,l}\}$  as follows,

$$\begin{aligned} \max \sum_{k,l} \theta_{k,l} e_{k,l} + \sum_{k \neq q,l} \theta_{k,q,l,l+1} e_{k,l} e_{q,l+1} \quad (14) \\ s.t. \quad \forall k, l \quad \sum_k e_{k,l} = 1, \sum_l e_{k,l} = 1 \end{aligned}$$

Here  $e_{k,l} = 1$  if  $M_{i,k}$  is assigned to  $g_{i,l}$ ; otherwise 0. Let  $\Lambda_{i,k,l}(a,b) = \max\{|M_{i,k}(a,b)| - g(i,l), 0\}$ , then each  $\theta_{k,l}$  and  $\theta_{k,q,l,l+1}$  can be computed as follows.

$$\begin{aligned} \theta_{k,l} &= \sum_{a,b=1}^{20} \Lambda_{i,k,l}(a,b)^2 \quad (15) \\ \theta_{k,q,l,l+1} &= \begin{cases} 0 & \sum_{a,b=1}^{20} \Lambda_{i,k,l}(a,b) > \sum_{a,b=1}^{20} \Lambda_{i,q,l+1}(a,b) \\ -\infty & \text{otherwise} \end{cases} \end{aligned}$$

Each  $\theta_{k,l}$  reflects the preference of mapping  $M_{i,k}$  to  $g_{i,l}$  while  $\theta_{k,q,l,l+1}$  reflects the constraints to be satisfied. With these definitions, we can use the ADMM algorithm by introducing an auxiliary variable  $v_{k,l}$  for each  $e_{k,l}$  and solving (14) using the following iterative procedure,

$$V^{n+1} = \operatorname{argmin}_V \sum_{q,l} C_{q,l} v_{q,l} \quad (16)$$

$$E^{n+1} = \operatorname{argmin}_E \sum_{k,l} D_{k,l} e_{k,l} \quad (17)$$

$$\eta^{n+1} = \eta^n + (E^{n+1} - V^{n+1}) \quad (18)$$

Each  $C_{q,l}$  and  $D_{k,l}$  can be computed as,

$$C_{q,l} = -\eta_{q,l} + (\sum_{k\{k \neq q\}} \theta_{k,q,l-1,l} e_{k,l-1}) + \gamma e_{q,l} \quad (19)$$

$$D_{k,l} = \theta_{k,l} + \sum_{q\{q \neq k\}} \theta_{k,q,l,l+1} v_{q,l+1} + \eta_{k,l} + \gamma v_{k,l} \quad (20)$$

Here  $\gamma > 0$  is a fixed step-size parameter (we used  $\gamma = 0.5$ ) and  $\eta$  (we used 0.1) is the dual variable passing information between sub-problems (16) and (17). Both (16) and (17) can be viewed as a bipartite matching problem, which can be solved by the Hungarian algorithm [19].

Using the above algorithm (steps 16-18), we can find a permutation of  $\{W_{i,k}\}$ ;  $|w_{i,(k)}^*(a,b)|$  is then given by (10). Notice that in order to minimize (9), if  $|w_{i,(k)}^*(a,b)| \neq 0$ , then  $w_{i,(k)}^*(a,b)$  and  $M_{i,k}(a,b)$  should have the same sign. The final solution of  $w_{i,(k)}^*(a,b)$  is therefore given by,

$$\begin{aligned} w_{i,(k)}^*(a,b) \quad (21) \\ = \begin{cases} M_{i,(k)}(a,b) - \operatorname{sign}(M_{i,(k)}(a,b)) g_{i,k} & |M_{i,(k)}(a,b)| > g_{i,k} \\ 0 & \text{otherwise} \end{cases} \end{aligned}$$

### 3.3 ESTIMATE NODE-SPECIFIC DEGREE DISTRIBUTION

Here we introduce how to predict the degree distribution of each node. Notice that in a protein sequentially-adjacent AAs must be close in the 3D space so their corresponding MRF nodes are connected. We introduce a concept called Partial Contact Number (PCN) denoted by  $B_{i,j}$  for each node pair  $i$  and  $j$ , which is defined as the number of edges formed by node  $i$  with nodes  $i+1, i+2, \dots, j$  (if  $j > i$ ) or nodes  $i-1, i-2, \dots, j$  (if  $j < i$ ). Each  $B_{i,j}$  has 15 labels indicating the degree from 0 to 13 and  $\geq 14$ . We set the maximum degree to 14 since the contact number of an AA is upper bounded by a small constant. Since  $B_{i,j}$  is correlated with its nearest neighbors  $B_{i,j-1}$  and  $B_{i,j+1}$ , we apply a Conditional Neural Field (CNF) to predict  $B_{i,j}$ . Each node  $i$  is associated with two 2<sup>nd</sup>-order CNFs, as

shown in Figure 3. A protein with  $L$  nodes (AAs) has  $2L$  different 2<sup>nd</sup>-order CNFs.

Let  $F_{i,j}$  denote the feature vector extracted from two AAs  $i$  and  $j$ , we use one CNF is to estimate  $P(B_{i,i+6} \sim B_{i,L} | F_{i,i+6} \sim F_{i,L})$  and the other for  $P(B_{i,1} \sim B_{i,i-6} | F_{i,i+6} \sim F_{i,L})$ . We ignore very short-range contacts (sequence distance  $< 6$ ) as they are less informative for structure prediction. We train CNFs by maximum likelihood. We use a  $\ell_2$  regularization to avoid over-fitting and 5-fold cross validation to choose the hyper parameters. Since CNF is non-convex, we train it starting from 5 different initial solutions and pick the best one. See [28] for more details of CNF.

After training the CNF models, we calculate the marginal probabilities  $P(B_{i,j})$  using the standard forward-backward algorithm [20] independently on each CNF. Finally, we calculate the probability of node  $i$  having degree  $K$  as follows.

$$\sum_{K_1+K_2=K} (P(B_{i,1} = K_1) + P(B_{i,L} = K_2)) \quad (22)$$

## 4. EXPERIMENTS

### 4.1 TRAINING AND TEST DATA

We use a subset of the PDB25 dataset, generated by the PISCES server [34], to train and validate our CNF models. Any two proteins in this dataset share  $< 25\%$  sequence identity. In total we used 3118 proteins with length between 40 and 500, among which 3/4 are randomly chosen for training and the remaining 1/4 for validation. To test the performance, we evaluate our results on CASP10 [18] and CASP11 [26] datasets. We rule out short proteins with fewer than 70 amino acids since they have relatively low contact number prediction accuracy. This leads to 109 test proteins in the CASP10 set and 99 proteins in the CASP11 dataset. We use the CASP official domain boundary definition for each test protein. For each test protein, we run PSI-BLAST [3] with 5 iterations and E-value 0.001 to generate sequence profile, from which we extract  $F_{i,j}$ . All the native structures of our training and validation proteins are solved before CASP10 and CASP11 and do not share high sequence identify with the CASP test proteins.

### 4.2 EVALUATION CRITERIA AND PROGRAMS TO COMPARE

Depending on the sequence distance (i.e., the number of AAs between the two ends of a contact along the protein sequence), we divide contacts into 3 categories: [6,12) for short-range contacts, [12,24) for medium-range contacts and  $\geq 24$  for long-range contacts. Generally speaking, medium- and long-range contacts are more important for structure prediction, but more challenging to predict. We

evaluate only top  $L/5$ ,  $L/10$ , and  $L/2$  predicted contacts. The accuracy is calculated as the percentage of the correctly predicted contacts. The ground truth is calculated from the experimental structure. When more predicted contacts are evaluated, the difference among methods becomes smaller since it is more likely to pick a native contact by chance. We compare our method to three other structure learning methods: PSICOV [15], plmDCA [9], and CCMpred [31]. PSICOV uses Graphical Lasso for contact prediction while plmDCA and CCMpred use maximum pseudo-likelihood with  $\ell_2$  regularization. These programs are run with their default parameters. When node-specific degree distribution is no used, our method is exactly the same as CCMpred, so we can calculate performance gain by examining the improvement of our method over CCMpred.

**Figure 3.** A Conditional Neural Field model for the prediction of Partial Contact Numbers.

### 4.3 PRE-PROCESSING AND POST-PROCESSING

We employ the same pre- and post-processing procedures as plmDCA and CCMpred to ensure our comparison with them is fair. To reduce the impact of redundant sequences, we apply the same sequence weighting method as plmDCA. In particular, duplicate sequences are removed and MSA columns containing more than 90% of gaps are deleted. The sequence is weighted using a threshold of 62% sequence identity. Similar to plmDCA and CCMpred, average-product correction (APC) [8] is applied to post-process predicted contacts.

### 4.4 PERFORMANCE

#### 4.4.1 Overall Performance

As shown in Tables 1 and 2, on both CASP10 and CASP11 test proteins, our method significantly outperforms the others in terms of the accuracy of the top  $L/10$ ,  $L/5$  and  $L/2$  predicted contacts. plmDCA and CCMpred achieve better

results than PSICOV because they drop the Gaussian distribution assumption. Our method differs from plmDCA and CCMpred in that we use a separate  $\ell_1$  regularization term for every pair of AAs instead of a universal regularization on all the AA pairs.

**Table 1.** Contact prediction accuracy on the 109 CASP10 targets

|            | Short-range |             |             | Medium-range |             |             | Long-range  |             |             |
|------------|-------------|-------------|-------------|--------------|-------------|-------------|-------------|-------------|-------------|
|            | L/10        | L/5         | L/2         | L/10         | L/5         | L/2         | L/10        | L/5         | L/2         |
| Our Method | <b>0.32</b> | <b>0.33</b> | <b>0.19</b> | <b>0.39</b>  | <b>0.34</b> | <b>0.28</b> | <b>0.37</b> | <b>0.34</b> | <b>0.25</b> |

#### 4.4.2 Impact of Predicted Contact Number Distribution

First we evaluate the accuracy of contact number prediction. The contact number is predicted by picking the label with the maximum marginal probability computed by (22). The 15-label accuracy calculated on the CASP10 and CASP11 datasets are both 0.30 while random guess (i.e., predicting all the labels to be the one with the largest background probability) is 0.21. The average Pearson correlations between the ground truth and our prediction are 0.71 and 0.74, respectively. In addition, we can predict small- or large-valued contact number labels very accurately. These two properties help suppress the contacts of those AAs with very few contacts from showing up in the final prediction and thus, decrease the false positives.

Now we evaluate the impact of contact number prediction on individual contact prediction. We compare our method (i.e., predicted contact number used) with CCMpred (i.e., predicted contact number not used) in terms of the accuracy of the top  $L/10$  predicted long-range contacts. The top  $L/10$  predicted contacts cover only a small number of AAs, so for each protein we only calculate the contact number accuracy on the AAs covered by the top  $L/10$  predicted contacts. We group the test proteins into seven bins according to their accuracy of predicted contact number. For each bin we calculate the average accuracy improvement of individual contact prediction by our method over CCMpred. As shown in Figure 4, the improvement is positively correlated with the accuracy of contact number prediction on both CASP10 and CASP11 datasets. That is, the more accurately we can predict the

contact number, the more performance gain can be obtained for individual contact prediction. In particular, when the accuracy of contact number prediction is low ( $<0.1$ ), our method cannot improve individual contact prediction accuracy because the predicted contact number has too much noise. When the accuracy of contact number prediction is above 0.5, the performance gain from the predicted contact number information is large ( $\geq 0.05$ ). This implies that our method makes a good use of predicted contact number information.

**Figure 4.** Relationship between top  $L/10$  long-range contact prediction accuracy gain and the accuracy of contact number prediction. The accuracy gain is calculated as the performance difference between our method and CCMpred.

#### 4.4.3 Case Study

Here we use two specific examples to further demonstrate the strength of our method. In particular, we want to study how the predicted contact number distribution helps with individual contact prediction. One example is a CASP10 target T0758 (PDB ID 4RM7). The other is a CASP11 target T0813 (PDB ID 4WJI). They have 366 and 302 AAs, respectively, and 9572 and 4177 similar sequences. As shown in Tables 3 and 4, our method significantly outperforms the others by at least 0.2 on the top  $L/10$  long-range contact predictions. plmDCA and CCMpred have similar results since they use the same loss function. PSICOV yields relatively low performance on T0813, most likely attributing to the default sparsity setting being too aggressive.

**Table 3.** Contact prediction accuracy of T0758 (4RM7)

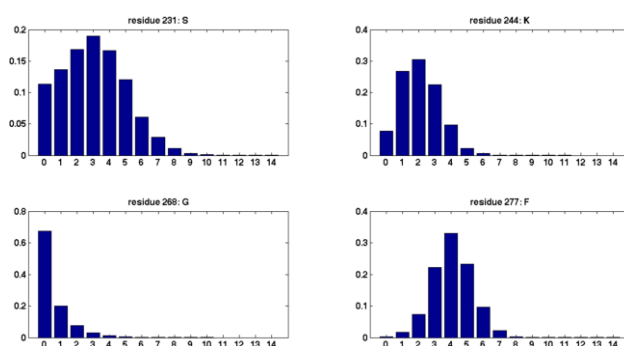

|            | Short-range |             |             | Medium-range |             |             | Long-range  |             |             |
|------------|-------------|-------------|-------------|--------------|-------------|-------------|-------------|-------------|-------------|
|            | L/10        | L/5         | L/2         | L/10         | L/5         | L/2         | L/10        | L/5         | L/2         |
| Our method | <b>0.62</b> | <b>0.39</b> | <b>0.26</b> | <b>0.67</b>  | <b>0.55</b> | <b>0.28</b> | <b>0.76</b> | <b>0.64</b> | <b>0.50</b> |
| PSICOV     | 0.50        | 0.31        | 0.19        | 0.55         | 0.41        | 0.19        | 0.50        | 0.47        | 0.40        |
| plmDCA     | 0.44        | 0.30        | 0.20        | 0.61         | 0.42        | 0.26        | 0.56        | 0.56        | 0.45        |
| CCMpred    | 0.42        | 0.32        | 0.19        | 0.64         | 0.56        | 0.30        | 0.53        | 0.48        | 0.45        |

**Table 4.** Contact prediction accuracy of T0813 (4WJI)

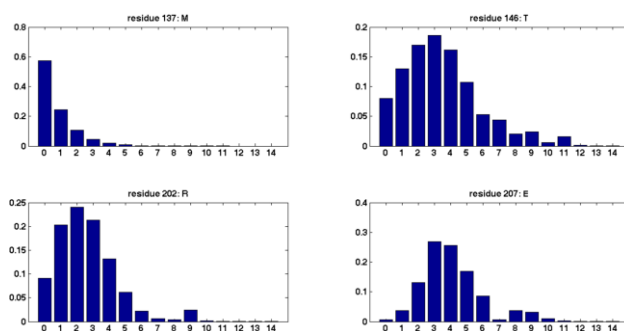

|  | Short-range |     |     | Medium-range |     |     | Long-range |     |     |
|--|-------------|-----|-----|--------------|-----|-----|------------|-----|-----|
|  | L/10        | L/5 | L/2 | L/10         | L/5 | L/2 | L/10       | L/5 | L/2 |

| Our method | 0.43 | 0.32 | 0.16 | 0.60 | 0.44 | 0.25 | 0.73 | 0.60 | 0.50 |
|------------|------|------|------|------|------|------|------|------|------|
| PSICOV     | 0.30 | 0.20 | 0.11 | 0.43 | 0.28 | 0.19 | 0.50 | 0.40 | 0.31 |
| plmDCA     | 0.37 | 0.27 | 0.14 | 0.57 | 0.40 | 0.20 | 0.53 | 0.47 | 0.40 |
| CCMpred    | 0.37 | 0.28 | 0.13 | 0.53 | 0.42 | 0.23 | 0.47 | 0.50 | 0.45 |

Now for each target we examine two AA pairs not in contact. Our method can correctly predict that they are not in contact, but the other three methods predict they are in contact. Figures 5 and 6 show the predicted contact number distributions for the eight AAs of the two targets. Most of these AAs are predicted to have very few contacts. Especially the 137th AA of T0758 and the 268th AA of T0813; the predicted probability of the contact number being zero are both over 0.5, which means all the parameters associated with these two AAs shall be forced to zero.

**Figure 5.** Predicted contact number distributions of 4 AAs of T0758 (4RM7) shown in Figure 7.

**Figure 6.** Predicted contact number distributions of 4 AAs of T0813 (4WJI) shown in Figure 8.

As shown in Figures 7 and 8, these two AAs are exposed at the protein surface and they do not form any long-range contacts. Similarly, for the other 6 AAs, the mass of predicted contact number distribution are all concentrated around 3 or 4, which means our model most likely can only allow 3 or 4 contacts for each AA. The top predicted contacts of these AAs are all short- and medium-range. That is why our method does not predict any long-range contacts for these AAs.

**Figure 7.** Two long-range false positives predicted by PSICOV, plmDCA and CCMpred for Target T0758 (4RM7): one false contact between the 146th AA and 202nd AA and the other between the 137th AA and 207th AA. Their true distances are 20.7 Å and 14.2 Å, respectively.

**Figure 8.** Two false positives predicted by PSICOV, plmDCA and CCMpred for T0813 (4WJI): one false contact between the 244th AA and 268th AA and the other between the 231st AA and 277th AA. Their true distances are 35.9 Å and 29.3 Å, respectively.

## 5. DISCUSSION AND FUTURE WORK

We have presented a new structure learning method that can make use of the predicted node-specific degree distribution to improve prediction accuracy of edges. The predicted degree distribution is used as a kind of soft topological constraints to restrict the solution space and avoid “unreasonable” predictions. Experimental results show that by using the degree distribution we can significantly improve protein contact prediction over current state-of-the-art structure learning methods.

From a computational perspective, our method provides a new framework to integrate orthogonal information into structure learning. That is, we first use supervised learning to learn node-specific local topological

constraints and then add it as a prior to learn the whole network structure. In many real-world applications, the connections of the graph are more or less influenced by the properties of nodes, so a node-specific degree distribution can be learned from local features without knowing the whole network structure. The contact number prediction is a very challenging supervised learning problem. In this work, we use multiple linear-chain graphical models to circumvent the difficulty of training and inference on loopy graphs. In the future, we will extend CNF by adding a deep learning module to further improve it.

For protein contact prediction, adding AA-specific topological constraint is only our first step. We are considering other AA- and segment-specific topological constraints, such as some geometric constraints imposed by a single secondary structure segment, two correlated secondary structure segments, or even the global structure of a protein.

## Abstract

Many modern information access problems involve highly complex patterns that cannot be handled by traditional keyword based search. Active Search is an emerging paradigm that helps users quickly find relevant information by efficiently collecting and learning from user feedback. We consider active search on graphs, where the nodes represent the set of instances users want to search over and the edges encode pairwise similarity among the instances. Existing active search algorithms are either short of theoretical guarantees or inadequate for graph data. Motivated by recent advances in active learning on graphs, namely the  $\Sigma$ -optimality selection criterion, we propose new active search algorithms suitable for graphs with theoretical guarantees and demonstrate their effectiveness on several real-world datasets.

We relate our active search setting to multi-armed bandits whose rewards are binary values indicating search hits or misses and arms cannot be pulled more than once. We also discussed theoretical guarantees for applying  $\Sigma$ -optimality as the exploration term for bandits on graphs.<sup>1</sup>

## 1 INTRODUCTION

As the world gets increasingly digitized and electronically recorded, how to quickly identify relevant pieces of information becomes a major issue. Internet search engines are

---

\* Part of this work was done while the author was with Carnegie Mellon University.

<sup>1</sup>An earlier version of this paper included results on bandit cumulative regrets with improved rates (originally Section 4.2.2). These results depended on proof strategies from Contal et al. (2014) (originally in Appendix C) which were found to be incorrect. Therefore, these results have been removed in the current version of the paper.

an integral part of modern life, serving as a probe into the diverse, complex and expanding space of human digital traces. Despite being successful in many information retrieval tasks, the keyword-based query mechanism in most search engines may fall short when targets are characterized by complex patterns or signatures beyond keywords. For example, financial transactions associated with illegal activities bear signatures involving multiple factors such as time, location, occupation of the account owner, etc. In the investigation of organizational misconduct, such as the Enron scandal, the important leads or evidences, oftentimes buried in a sea of diverse electronic and paper trails, usually involve information exchange among key individuals and their relationship. To fully understand the users' intent in these cases, keyword-based search may serve as a good starting point, but is certainly far from completing the task.

Such needs of more general search paradigms have recently motivated several efforts Garnett et al. (2012); Wang et al. (2013); Vanchinathan et al. (2013), most of which are related to the Active Search framework proposed by Garnett et al. (2012). It is an interactive search mechanism that begins with a full set of instances without supervision and a given task/keyword-specific similarity measure between these instances. Based on the similarity measure and an optional initial set of suggestions from the user, an algorithm figures out what instances the user should examine next and presents it to the user, who then decides whether the presented instance is relevant or not. Upon receiving this feedback, the algorithm updates its search strategy accordingly and selects the next instance to present. The loop continues until the user quits, and the goal is to maximize the total number of relevant instances found.

As one can see, Active Search has close connections to some well-studied machine learning paradigms. At a first glance, Active Learning (Settles, 2010) seems the most related because they both ask for user feedback incrementally and adaptively. However, Active Learning aims at improving generalization performances with as few label queries as possible, while Active Search is evaluated by how many relevant instances it found along the way, and therefore

must carefully balance exploitation and exploration. This trade-off relates Active Search to stochastic optimization in the Multi-Armed Bandit setting (Robbins, 1985; Dani et al., 2008; Kleinberg et al., 2008; Bubeck et al., 2009), where the goal is to find the maximum of an unknown function using as few function evaluations as possible. However, Active Search deviates from this setting in that it selects instances *without replacement* and is competing with the best *subset* of instances rather than the single best.

We investigate Active Search when the instances are represented by the nodes on a graph whose edges encode pairwise similarity among the instances. For a toy example, please see Figure 1. Many real-world datasets are of this type, such as web pages, citation networks, and e-mail correspondences. For data that are not naturally represented as graphs, a graph representation based on pairwise similarity can still be beneficial because it may reveal useful manifold structures (Tenenbaum et al., 2000; Belkin and Niyogi, 2001). Existing active search approaches (Wang et al., 2013; Garnett et al., 2012; Vanchinathan et al., 2013) either lack theoretical guarantees or ignore certain graph properties, thereby degrading empirical performances. By drawing ideas from recent advances in active learning on graphs (Ma et al., 2013), we proposed new active search algorithms with theoretical guarantees, and empirically demonstrate their advantages over existing methods. In particular, our new exploration criteria, motivated by  $\Sigma$ -optimality criterion (Ma et al., 2013) for active learning on graphs, favor nodes with not only high uncertainty, but also high influence on the other nodes.

Figure 1: A toy examples for active search where the goals are “ $\checkmark$ ” nodes. Suppose the yellow nodes are observed in previous rounds, which node should be searched next?

The rest of the paper is organized as follows. We describe related work in Section 2, and introduce the problem setup in Section 3. We then present our new methods in Section 4 along with theoretical guarantees, followed by experimental results in Section 5.

## 2 RELATED WORK

Wang et al. (2013) proposed an active search algorithm for graphs, building on label propagation and semi-supervised learning using Gaussian random fields (Zhu

et al., 2003a,b). Despite decent empirical performances, this approach does not have any theoretical guarantee. Vanchinathan et al. (2013) proposed a Gaussian-Process (GP) based algorithm, GP-SELECT, for sequentially selecting instances with high user scores or ratings (rewards). This algorithm extends the popular GP-UCB algorithm (Cox and John, 1997; Auer, 2003) for stochastic optimization and inherits nice theoretical guarantees (Srinivas et al., 2012). When applied to graphs, however, it tends to select nodes at the periphery of the graph because they have large predictive variances, leading to large exploration factors in the GP-UCB selection rule. Yet the rewards of these nodes reveal little information about the reward distribution over the whole graph.

Similar issues have been observed in active learning on graphs as well. In their experiments, Ma et al. (2013) found that selection rules based on mutual information gain (Krause et al., 2008), which is closely related to per-node predictive variances, usually end up selecting nodes at the periphery of a graph. Ji and Han (2012) proposed a selection criterion based on one-step lookahead decrease of the average variance of all remaining nodes, which effectively considers not only the predictive variance of the search node itself, but also its covariances with all remaining nodes. This criterion corresponds to standard V-optimality in experiment design. Ma et al. (2013) further improved the state of the art by using the  $\Sigma$ -optimality criterion, which demonstrates greater robustness against outliers and better empirical performances than V-optimality. Motivated by these recent advances, we propose new active search algorithms that combine GP-UCB with  $\Sigma$ -optimality.

Valko et al. (2014) considered bandit problems where arms correspond to nodes on a graph and the reward is a smooth function over the graph. Their algorithm can be viewed as a special case of GP-UCB with a kernel defined by the inverse of a graph Laplacian (augmented with an identity matrix). To analyze the performance of their UCB-style algorithm, they propose the notion of *effective dimension* of a graph, which can be viewed as a measure of the spectral decay of the kernel, thereby determining the performance of the algorithm (Srinivas et al., 2012). We also use the effective dimension to analyze our proposed methods.

## 3 PROBLEM SETUP

The database where active search is performed is given as a graph  $\mathcal{G}$  with known structure (edge connections). The edge connections are nonnegative and we use  $\mathbf{A}$  to represent the adjacency matrix of  $\mathcal{G}$ , such that  $A_{ij} \geq 0, \forall i, j$ . Let  $\mathcal{V} = \{v_1, \dots, v_n\}$  denote the set of all nodes in  $\mathcal{G}$ . From  $\mathbf{A}$  we can derive a graph Laplacian matrix,  $\mathcal{L} = \mathbf{D} - \mathbf{A}$ , where  $\mathbf{D} = \text{diag}(\mathbf{A} \cdot \mathbf{1}) = \text{diag}(\text{deg}(v_1), \dots, \text{deg}(v_n))$ .

Every node  $v$  in our graph holds one reward value we denote as  $f(v)$ , indicating whether the node is the search tar-

get. The reward is unknown at first and can be revealed only when it is queried explicitly. For mathematical benefits, we relax the reward to be a real value and introduce a Gaussian noise to its observation, as

$$y(v) = f(v) + \epsilon, \text{ where } \epsilon \sim \mathcal{N}(0, \sigma_n^2). \quad (1)$$

Similar to bandit problems, querying a node also means collecting the true reward of that node. Our goal is to design a query strategy, which interactively generates a query sequence  $\mathbf{v}_t = (v_1, \dots, v_t)^\top$  without any repeated selections, in order to maximize the cumulative reward

$$F_T = \sum_{t=1}^T f(v_t). \quad (2)$$

The cumulative reward is always upper-bounded by the optimal strategy with full knowledge of the true rewards on all the nodes. Let  $\mathbf{v}_t^* = (v_1^*, \dots, v_t^*)$  to be the optimal query sequence (without repeated selections), our analysis in Theorem 2 (Section 4.2) bounds the cumulative regret between our strategy and the optimal strategy,

$$R_T = \sum_{t=1}^T f(v_t^*) - f(v_t). \quad (3)$$

The above characterizes an active search problem, provided that the values of  $f(v)$  are binary and the sequences  $\mathbf{v}_t$  and  $\mathbf{v}_t^*$  do not allow repeated selections. Otherwise, the above can also model a multi-armed bandit problem if we relax  $f(v)$  to be real and  $\mathbf{v}_t$  and  $\mathbf{v}_t^*$  to allow repeated selections. In fact, our formulation discusses them together, providing analysis to the slightly more rigorous active search modeling except that  $f(v)$  is relaxed to real values.

In our notations, bold letters indicate vectors or matrices, while light letters without subscripts mean functions and light letters with subscripts represent scalars or specific elements.  $t$ ,  $\tau$ , and  $T$  are time indices, which when applied as subscripts, always mean the selection or model at that time step. Other letters as subscripts, such as  $i, j, n$ , always mean the natural indices.

### 3.1 GAUSSIAN RANDOM FIELD PRIOR

A key assumption in this work is that the reward values, or the target labels, are constrained by the graph structure in a non-trivial way. Otherwise, the input graph provides little information about the reward function, making active search extremely difficult. More specifically, we assume that the reward values of all the nodes in the graph, collectively denoted as a vector  $\mathbf{f} \in \mathbb{R}^N$ , are random variables

distributed jointly as

$$\log p(\mathbf{f}) \simeq - \sum_{i=1}^N \sum_{j=1}^N \frac{A_{ij}(f_i - f_j)^2}{2} - \sum_{j=1}^N \frac{\omega_0(f_j - \mu_0)^2}{2},$$

$$\text{i.e., } \mathbf{f} \sim \mathcal{N}\left(\boldsymbol{\mu}_0 = \mu_0 \cdot \mathbf{1}, \mathbf{C}_0 = (\boldsymbol{\mathcal{L}} + \omega_0 \mathbf{I})^{-1}\right), \quad (4)$$

where  $\mu_0$  is a prior mean, and  $\omega_0 > 0$  is a regularization parameter. According to this probabilistic model, it is more likely for connected nodes to share similar values than not. Define the initial covariance matrix as,  $\mathbf{C}_0 = (\boldsymbol{\mathcal{L}} + \omega_0 \mathbf{I})^{-1}$ , and denote  $\tilde{\boldsymbol{\mathcal{L}}}_0 = \boldsymbol{\mathcal{L}} + \omega_0 \mathbf{I}$ . The above prior model is also known as **Gaussian random fields (GRFs)**.

### 3.2 POSTERIOR INFERENCE

Assume the nature draws one sample from the prior model, (4), and we use query observations, (1), to converge to that particular draw by performing posterior inference conditioned on the history,

$$\mathcal{H}_t = \{(v_\tau, y_\tau)\}_{\tau=1}^t = \{\mathbf{v}_t, \mathbf{y}_t\},$$

which allows us to update the posterior distribution as,

$$\log p(\mathbf{f} | \mathcal{H}_t) \simeq -\frac{1}{2}(\mathbf{f} - \boldsymbol{\mu}_0)^\top \tilde{\boldsymbol{\mathcal{L}}}_0(\mathbf{f} - \boldsymbol{\mu}_0) - \sum_{\tau=1}^t \frac{(y_\tau - f_{v_\tau})^2}{2\sigma_n^2}.$$

Notice that the prior distribution and likelihood model form Gaussian conjugate pairs. Denote the posterior distribution as,  $\mathbf{f} | \mathcal{H}_t \sim \mathcal{N}(\boldsymbol{\mu}_t, \mathbf{C}_t)$ . To some readers, it is easier to express  $\boldsymbol{\mu}_t$  and  $\mathbf{C}_t$  using the prior *precision* matrix, as

$$\boldsymbol{\mu}_t = \mathbf{C}_t \left( \tilde{\boldsymbol{\mathcal{L}}}_0 \boldsymbol{\mu}_0 + \sum_{\tau=1}^t \frac{y_\tau \mathbf{e}_{v_\tau}}{\sigma_n^2} \right), \quad \mathbf{C}_t^{-1} = \tilde{\boldsymbol{\mathcal{L}}}_0 + \frac{1}{\sigma_n^2} \mathbf{H}_t \quad (5)$$

where  $\mathbf{e}_{v_\tau} = (0, \dots, 0, 1, 0, \dots, 0)^\top$  is an indicator vector of index  $v_\tau$  and  $\mathbf{H}_t$  is a diagonal matrix of index counts from  $\mathbf{v}_t$ , whose  $k$ th diagonal element is  $\sum_{\tau=1}^t e_{v_\tau}(v_k)$ .

However, for convenience in later descriptions and to connect to **Gaussian Process (GP)** literature (Rasmussen and Williams, 2006), we also use the prior *covariance* matrix to express the posterior distribution, as,

$$\mu_t(v) = \mu_0(v) + \mathbf{c}_{\mathbf{v}_t v}^\top (\mathbf{C}_{\mathbf{v}_t \mathbf{v}_t} + \sigma_n^2 \mathbf{I})^{-1} (\mathbf{y}_t - \boldsymbol{\mu}_{\mathbf{v}_t}),$$

$$C_t(v, v') = C_0(v, v') - \mathbf{c}_{\mathbf{v}_t v}^\top (\mathbf{C}_{\mathbf{v}_t \mathbf{v}_t} + \sigma_n^2 \mathbf{I})^{-1} \mathbf{c}_{\mathbf{v}_t v'}, \quad (6)$$

where the matrices can all be defined in terms of the prior:

$$\mathbf{c}_{\mathbf{v}_t v} = (C_0(v_1, v), \dots, C_0(v_t, v))^\top$$

$$\mathbf{C}_{\mathbf{v}_t \mathbf{v}_t} = (C_0(v_\tau, v_{\tau'}))_{\tau, \tau'=1}^t$$

$$\boldsymbol{\mu}_{\mathbf{v}_t} = (\mu_0(v_1), \dots, \mu_0(v_t))^\top.$$

The above update rules also applies to any time interval that starts with  $t_0$ , by replacing prior models (variables with subscript “0”) with the model at time  $t_0$ .

Define simple notations for correlation coefficients and standard deviations from the covariance matrix,  $C_t(v, v') = \rho_t(v, v')\sigma_t(v)\sigma_t(v')$ , which implies that  $\sigma_t^2(v) = C_t(v, v)$ . Define  $\mathbf{c}_t(v)$  to be the column of  $\mathbf{C}_t$  corresponding to node  $v$ .

## 4 METHOD

---

**Algorithm 1** GP-SOPT and its variants

---

**input**  $\mu_0, \mathbf{A}, \omega_0, \sigma_n, \alpha_t, T$ ; if warm start,  $\{v_\tau, y(v_\tau)\}_{\tau=1}^{t_0}$   
 1: Obtain initial  $\mathcal{N}(\mu_0, \mathbf{C}_0)$  // (4)  
 2: **for**  $t = t_0, \dots, T - 1$ , **do**  
 3: Update to posterior  $\mathcal{N}(\mu_t, \mathbf{C}_t)$  // (6)  
 4:  $v_{t+1} \leftarrow \arg \max_{v \in V \setminus S_t} \mu_t(v) + \alpha_{t+1}s_t(v)$  // (9.a, 9.b, or 9.c)  
 5: Observe  $y(v_{t+1})$ ; include  $S_{t+1} \leftarrow S_t \cup \{v_{t+1}\}$   
 6: **end for**  
**output**  $S_T$ .

---

Our proposed active search algorithms are described in Algorithm 1. They resemble general exploration-exploitation style algorithms with GPs. Here we focus on binary functions that assign value 1 to relevant or target nodes, and 0 to all other nodes. At iteration  $t + 1$ , Algorithm 1 selects the next node to query based on a deterministic selection rule of the form:

$$\arg \max_{v \in V \setminus S_t} \mu_t(v) + \alpha_{t+1} \cdot s_t(v), \quad (7)$$

where  $\mu_t(v)$  is the usual exploitation term and  $s_t(v)$  encourages exploration, with the two being balanced by a possibly iteration-dependent parameter  $\alpha_{t+1} > 0$ .

Examples from existing literature like the popular GP-UCB algorithm and its extension to Active Search, GP-SELECT (Vanchinathan et al., 2013), amount to setting  $s_t(v)^2 = \sigma_t(v)^2$ , the posterior (as well as predictive) variance of the reward value at node  $v$ . Although this is a very reasonable choice in many situations, it may lead to undesirable exploration behaviors on graphs. Under our model assumption, low-degree nodes, which usually lie at the periphery of a graph, tend to have high predictive variances. Direct applications of GP-UCB may result in the selection of many such outliers, which fail to reveal much information about the reward values of most other nodes at the core of the graph (Figure 2(a)).

Intuitively, a good exploration criterion should favor nodes that have high influences on other parts of the graph. That is, the knowledge of the function values at these nodes should reveal a lot about the function values at other nodes. Under our model assumption, this principle naturally connects with the predictive covariances of a node with others. Research in active learning on graphs has already made use of predictive covariances to construct better selection rules.

Ji and Han (2012) proposed to select nodes based on their sums of squares of predictive covariances with other nodes, which is derived from the minimization of squared prediction error, known as V-optimality in experiment design. Ma et al. (2013) observed that V-optimality can still be undesirably sensitive to outliers and used  $\Sigma$ -**optimality criterion** instead, which by itself selects a set of nodes  $\mathbf{v}_t$  to minimize the following Bayes *survey risk* on the posterior model after the selection,

$$\mathcal{R}_{t|\mathbf{v}_t}^\Sigma = \mathbb{E} \left( \sum_{v' \in \mathcal{V}} f_{t|\mathbf{v}_t}(v') - \sum_{v' \in \mathcal{V}} \mu_{t|\mathbf{v}_t}(v') \right)^2 = \mathbf{1}^\top \mathbf{C}_{t|\mathbf{v}_t} \mathbf{1}.$$

For active search, we use this criterion in a greedy sequential selection manner for exploration scoring, as

$$\begin{aligned} s_t(v) &= \sqrt{\mathcal{R}_{t|S_t}^\Sigma - \mathcal{R}_{t+1|S_t \cup \{v\}}^\Sigma} = \frac{\sum_{v'} C_t(v, v')}{\sqrt{C_t(v, v) + \sigma_n^2}} \\ &= \frac{1}{\sqrt{1 + \sigma_n^2/\sigma_t^2(v)}} \cdot \sum_{v' \in \mathcal{V}} \rho_t(v, v')\sigma_t(v'), \end{aligned} \quad (8)$$

where the second equality is easily derived from (6). If we ignore  $\sigma_n$  (set it to 0), the  $\Sigma$ -optimality criterion (8) considers the sum of a node's correlation times standard deviation of all nodes on the graph. High score nodes by this criterion are likely to provide rich information for exploration.

We propose three exploitation-exploration style algorithms with exploration criteria motivated by  $\Sigma$ -optimality, which are *vanilla*  $\Sigma$ -*optimality* and its two variants with an additional parameter  $k$  that we will describe next. All algorithms select the next node to query by the general rule (7), but use different exploration terms:

**GP-SOPT (Vanilla  $\Sigma$ -Optimality):**

$$s_t(v) = \frac{1}{\sqrt{1 + \sigma_n^2/\sigma_t^2(v)}} \cdot \sum_{v' \in \mathcal{V}} \rho_t(v, v')\sigma_t(v'). \quad (9.a)$$

**GP-SOPT.TT (Thresholded Total Covariance):**

$$s_t(v) = \min \left( k\sigma_t(v), \sum_{v' \in \mathcal{V}} \rho_t(v, v')\sigma_t(v') \right). \quad (9.b)$$

**GP-SOPT.TOPK (Top- $k$  Covariance):**

$$s_t(v) := \max_{B \subset \mathcal{V}, |B|=k} \sum_{v' \in B} \rho_t(v, v')\sigma_t(v'). \quad (9.c)$$

As one can see in Figure 2(b), the nodes selected by vanilla GP-SOPT indeed reside in more central parts of the toy graph than the nodes selected by its competitor. In a large graph with many peripheral nodes, we believe that the improved exploration criteria of GP-SOPT and its variants contribute to a better recall rate of search targets in real graphs in Section 5.

Figure 2: For the toy graph example, choices from (a) direct application of UCB (Vanchinathan et al., 2013; Valko et al., 2014) versus (b) our vanilla GP-SOPT. We observe that our method (b) tends to select more from cluster centers, which helps reduce variance of the unobserved values/rewards, whereas previous literature (a) tends to select the graph periphery.

The reason we propose the latter two variants, (9.b) and (9.c), is to both address proof difficulties and increase practical robustness. By Lemma 3 in Appendix A, we have that  $s_t(v) \geq \sigma_t(v)$  for both criteria, meaning that  $s_t(v)$  maintains the UCB property. Note that the observation noise,  $\sigma_n$ , is also dropped from (9.b) and (9.c). As we will show in our theoretical analysis, we put a threshold in (9.b) against  $k\sigma_t(v)$ , where  $k$  is a tuning parameter, in order to explicitly control the regret of the algorithm. As implied by Lemma 4 in Appendix A, the Top- $k$  Covariance criterion (9.c) is also always upper-bounded by  $k\sigma_t(v)$ .

In the next two subsections we discuss in more details the properties of various exploration criteria, and present our theoretical analysis.

#### 4.1 DISCUSSIONS

Our approach and two other popular criteria, information gain from Srinivas et al. (2012) and V-optimality of Ji and Han (2012), can also be connected by functions of the eigenvalues of the covariance matrix at each iteration.

To see this connection, assume the updated covariance matrix at iteration  $(t + 1)$  has eigen-decomposition  $\mathbf{C}_t = \sum_{j=1}^n \lambda_{t,(j)} \mathbf{q}_{t,(j)} \mathbf{q}_{t,(j)}^\top$ , where  $\boldsymbol{\lambda}_t = (\lambda_{t,(1)}, \dots, \lambda_{t,(n)})^\top$  represents the eigenvalues and  $\{\mathbf{q}_{t,(j)} : j = 1, \dots, n\}$  is the set of corresponding eigenvectors. Assume the eigenvalues are sorted by  $\lambda_{t,(1)} \geq \dots \geq \lambda_{t,(n)} \geq 0$ . We hope to connect  $s_t(v)$  to the following spectral difference,

$$\Delta h_t(v) = h(\boldsymbol{\lambda}_t) - h(\boldsymbol{\lambda}_{t+1|v}) \quad (10)$$

where  $h(\boldsymbol{\lambda}) : \mathbb{R}^n \rightarrow \mathbb{R}$  is a multivariate function defined on the eigenvalues. Further, by the one-step update rule of (6),  $\mathbf{C}_t$  has Loewner order as  $\mathbf{C}_0 \succ \mathbf{C}_1 \succ \dots \succ \mathbf{C}_T \succ \mathbf{0}$ . It is thus often desirable to require  $h(\cdot)$  to be monotone with respect to this ordering, i.e.  $\mathbf{C}_t \succ \mathbf{C}_{t'} \Rightarrow h(\boldsymbol{\lambda}_t) \geq h(\boldsymbol{\lambda}_{t'})$ .

**Case 1.**  $h(\boldsymbol{\lambda}) = \sum_j \log(\lambda_{(j)})$ . Then,  $\Delta h_t(v) = 2\mathcal{I}_t(\mathbf{f}; y(v)) = \log(1 + \frac{\sigma_t^2(v)}{\sigma_n^2})$ , twice the information gain from  $\mathbf{f} \sim \mathcal{N}(\boldsymbol{\mu}_t, \mathbf{C}_t)$  to  $\mathcal{N}(\boldsymbol{\mu}_{t+1|v}, \mathbf{C}_{t+1|v})$ . This metric

is important to **GP-UCB** (Srinivas et al., 2012), which set  $s_t(v) = \sigma_t(v)$  and used the inequality,  $\log(1 + \frac{\sigma_m^2}{\sigma_n^2}) \frac{\sigma_t^2(v)}{\sigma_m^2} \leq \log(1 + \frac{\sigma_t^2(v)}{\sigma_n^2})$ , where  $\sigma_m = \max_{v,t} \sigma_t(v)$ , in its proofs.

**Case 2.**  $h(\boldsymbol{\lambda}) = \sum_j \lambda_{(j)}$  gives  $\Delta h_t(v) = \text{tr}(\mathbf{C}_t) - \text{tr}(\mathbf{C}_{t+1|v}) = \|\mathbf{c}_t(v)\|_2^2 / (\sigma_t^2(v) + \sigma_n^2)$ . For  $\sigma_n = 0$ ,  $\Delta h_t(v)$  is used as the greedy **V-optimal** criterion for design of experiments by Ji and Han (2012).

**Case 3.**  $h(\boldsymbol{\lambda}) = \lambda_{(1)}$  connects to the greedy design for **E-optimality** (Pukelsheim, 1993). To some extent, it is also related to greedy  **$\Sigma$ -Optimality**. First, approximate  $\Delta h_t(v)$  by  $\partial \lambda_{(j)} = \mathbf{q}_{(j)}^\top \partial(\mathbf{C}) \mathbf{q}_{(j)}$  around  $\mathbf{C} = \mathbf{C}_t$ , as

$$\Delta h_t(v) \approx \mathbf{q}_{t,(1)}^\top (\mathbf{C}_t - \mathbf{C}_{t+1|v}) \mathbf{q}_{t,(1)} = \left( \frac{|\mathbf{c}_t(v)^\top \mathbf{q}_{t,(1)}|}{\sqrt{\sigma_t(v)^2 + \sigma_n^2}} \right)^2$$

The above resembles (8) if  $\mathbf{q}_{t,(1)} \propto \mathbf{1}$ , which holds true for  $t = 0$  and  $\omega_0 = 0$  and approximately so for small  $t$ s.

In all these cases, exploration is measured by how much the objective,  $h(\boldsymbol{\lambda}_T)$ , is eventually decreased after  $T$  iterations. Each definition of  $h(\boldsymbol{\lambda}_t)$  aggregates the eigenvalues of the posterior covariance matrices in a different way, which affects the relative importance of large and small eigenvalues. In **Case 1**, since  $\frac{\partial \log(\lambda)}{\partial \lambda} = \frac{1}{\lambda}$ , the same change introduced to a smaller  $\lambda$  will have a relatively larger impact on the objective. Such an effect is not evident in the other two cases. Particularly in **Case 3**, changes to small eigenvalues are ignored unless they become the largest eigenvalue.

Establishing biases to penalize larger eigenvalues more has the benefit of improving global robustness because the posterior marginal variance of every node is upper-bounded by  $\lambda_{t,(1)}$ . Compared with **Cases 2** and **3**, **Case 1** is more sensitive to changes in small eigenvalues, which may be another explanation of **GP-UCB**'s strong tendency to select peripheral nodes, as seen in Figure 4 of Krause et al. (2008) or Figure 1(d) of Gotovos et al. (2013).

Although Algorithm 1 is not built around the concept of functions on eigenvalues, it still establishes strong biases to penalize large eigenvalues in its initial explorations, per

analysis in **Case 3**. Note that  $\Sigma$ -**optimality** achieves a more complex goal than **E-optimality**; exact execution of **E-optimality** may over-simplify the model and select nodes between clusters for separation rather than inside them.

## 4.2 REGRET ANALYSIS

We present an UCB-style analysis for GP-SOPT.TT and GP-SOPT.TOPK. We combine several results on GP optimization (Srinivas et al., 2012; Vanchinathan et al., 2013) and the spectral bandit analysis (Valko et al., 2014). As in these results, our regret bounds depend on the mutual information between  $f$  and the observed values  $\mathbf{y}_S$  at a set  $S$  of nodes:

$$\mathcal{I}(\mathbf{y}_S; f) := H(\mathbf{y}_S) - H(\mathbf{y}_S | f), \quad (11)$$

where  $H(\cdot)$  denotes the entropy. If  $f$  is drawn from a GP with observation noise distributed independently as  $\mathcal{N}(0, \sigma_n)$ , the mutual information has the following analytical form:

$$\mathcal{I}(\mathbf{y}_S; f) = \mathcal{I}(\mathbf{y}_S; f_S) = \frac{1}{2} \log |I + \sigma_n^{-2} \mathbf{C}_{\mathbf{v}_S \mathbf{v}_S}|. \quad (12)$$

Let

$$\gamma_T := \max_{S \in \mathcal{V}, |S|=T} \frac{1}{2} \log |I + \sigma_n^{-2} \mathbf{C}_{\mathbf{v}_S \mathbf{v}_S}|, \quad (13)$$

i.e., the maximum information about  $f$  gained by observing  $T$  function evaluations. The regrets of our algorithms depend on the growth rate of  $\gamma_T$ , which can be linear in  $T$  for arbitrary graphs. However, real-world graphs often possess rich structures, such as clusters or communities, and practical measures of relevance are often highly correlated with these structures, resulting in slowly-growing  $\gamma_T$ . To formalize this intuition, we follow Valko et al. (2014) to consider the *effective dimension*:

$$d_T^* := \max \left\{ i \mid \lambda_i \leq \frac{\sigma_n^{-2} T}{(i-1) \log(1 + \frac{T}{\sigma_n^2 \omega_0})} \right\}, \quad (14)$$

where  $\lambda_i$  is the  $i$ th smallest eigenvalue of  $\tilde{\mathcal{L}}_0$  and  $\lambda_1 = \omega_0$ . The effective dimension is small when the first few  $\lambda_i$ 's are small and the rest increase rapidly, as is often the case for graphs with community or cluster structures. On the contrary, if all the eigenvalues are close to  $\omega_0$ , then  $d_T^*$  may be linear in  $T$ . The following lemma bounds  $\gamma_T$  in terms of  $d_T^*$ :

**Lemma 1.** *Let  $T$  be the total number of rounds. Then*

$$\gamma_T \leq 2d_T^* \log \left( 1 + \frac{T}{\sigma_n^2 \omega_0} \right).$$

*Proof.* By Lemma 7.6 of Srinivas et al. (2012) and the fact that  $\lambda_i^{-1}$  is the  $i$ th largest eigenvalue of the kernel  $\mathbf{C}_0 =$

$\tilde{\mathcal{L}}_0^{-1}$ , we have

$$\gamma_T \leq \max_{\substack{\{m_i\}_{i=1}^T, m_i \geq 0, \\ \sum_{i=1}^T m_i = T}} \sum_{i=1}^T \log \left( 1 + \frac{m_i}{\sigma_n^2 \lambda_i} \right). \quad (15)$$

Then by applying the same argument that proves Lemma 6 of Valko et al. (2014), we obtain the desired result.  $\square$

We will then derive regret bounds in terms of  $\gamma_T$ .

Recall the cumulative regret of an active search algorithm is defined as  $R_T := \sum_{t=1}^T f(v_t^*) - f(v_t)$ , where  $\{v_t\}_{t=1}^T$  is the sequence of unique nodes selected by the algorithm. For the two proposed UCB-style algorithms, GP-SOPT.TT (9.b) and GP-SOPT.TOPK (9.c), we give the following bounds on their cumulative regrets.

**Theorem 2.** *Pick  $\delta \in (0, 1)$ . Assume the vector of true node values,  $\mathbf{f}$ , has bounded quadratic norm,  $\|\mathbf{f}\|_{\tilde{\mathcal{L}}_0} = \sqrt{\mathbf{f}^\top \tilde{\mathcal{L}}_0 \mathbf{f}} \leq B$ ,<sup>2</sup> and the observation noise  $\epsilon_t$  is zero-mean conditioned on the past and is bounded by  $\sigma_n$  almost surely. If GP-SOPT.TT and GP-SOPT.TOPK use GRF prior (4) with zero-mean and graph Laplacian  $\tilde{\mathcal{L}}_0$ , the observation noise model  $\mathcal{N}(0, \sigma_n^2)$ , and  $\alpha_t := \sqrt{2B + 300\gamma_t \log^3(t/\delta)}$ , then their cumulative regrets will satisfy*

$$\Pr(\{R_T \leq k\sqrt{c_1 T \alpha_T \gamma_T} \ \forall T \geq 1\}) \geq 1 - \delta,$$

where the randomness is over the observation noise and  $c_1 := \frac{8/\omega_0}{\log(1 + \sigma_n^{-2})}$ . This implies that with high probability,

$$R_T = O(k\sqrt{T}(B\sqrt{d_T^*} + d_T^*)).$$

This result is easily derived from the regret analysis of the GP-SELECT algorithm proposed by Vanchinathan et al. (2013) because the exploration terms used by GP-SOPT.TT and GP-SOPT.TOPK both satisfy  $\sigma_t(v) \leq s_t(v) \leq k\sigma_t(v)$ , thereby maintaining the UCB property. Although our regret bound is  $k$  times worse than the GP-SELECT bound, the actual regret tends to behave more favorably as we observe in our experiments that after a few tens of rounds,  $s_t(v)$  becomes smaller than  $k\sigma_t(v)$  for almost all unqueried nodes, and the two proposed algorithm usually outperforms GP-SELECT. We give the proof in Appendix B for completeness.<sup>3</sup>

## 5 EXPERIMENTS

We conduct experiments on three graph data sets that were studied by Wang et al. (2013) and a version of the Enron e-mail data by Priebe et al..

<sup>2</sup>This is similar to a bounded RKHS norm with kernel  $C_0$  in Srinivas et al. (2012).

<sup>3</sup>An earlier version of this paper follows on to discuss bounds on vanilla GP-SOPT. These proofs used strategies from Contal et al. (2014) which were found to be incorrect. Therefore, they have been removed in the current version of the paper.

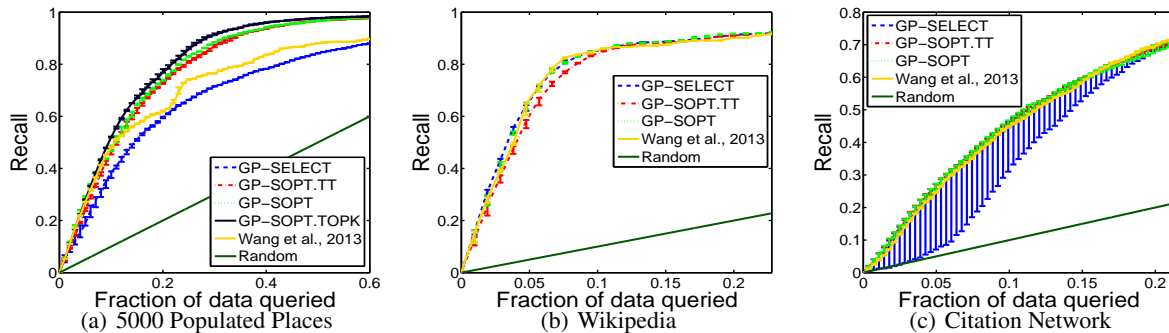

Figure 3: Recall vs. fraction of data queried

### 5.1 Three Graph Datasets of Wang et al. (2013)

We briefly summarize the datasets below.

**5000 Populated Places.** The nodes of this graph are 5000 concepts in the DBpedia<sup>4</sup> ontology marked as populated places. Each place is supported by a Wikipedia page, and an undirected edge is created between two places if either one of their two Wikipedia pages links to the other. There can be multiple edges between two places. The DBpedia ontology divides populated places into five categories: administrative regions, countries, cities, towns and villages. The 725 administrative regions are selected as our target class while all the others are considered to be in null class.

**Citation Network.** This dataset consists of 14,117 papers in top Computer Science venues available on citeseer. The graph is created by adding an undirected edge between two papers if either one cites the other. The 1844 NIPS papers are chosen as our target class.

**Wikipedia Pages on Programming Languages.** A total of 5,271 Wikipedia pages related to programming languages are the nodes of this graph, and an undirected edge exists between two pages if they are linked together. Wang et al. (2013) performed topic modeling and chose the 202 pages related to objective oriented programming as our target class.

As demonstrated by Wang et al. (2013), the three graphs and their target label distributions exhibit qualitative differences and thus serve as good benchmarks. The citation network has many small components and target nodes appear in many of them, while the Wikipedia graph has large hubs and most target nodes reside in one of them. The graph of populated places lies in between these two extremes, with components of various sizes containing target nodes.

On all of the three data sets we compare two of the proposed methods: GP-SOPT.TT and GP-SOPT against GP-SELECT (GP-UCB without replacement) and the active

search algorithm (AS-on-Graph) by Wang et al. (2013). We only evaluate GP-SOPT.TOPK on the 5000 populated places data due to its heavy computation. For each dataset we perform 5 independent runs, each with a randomly chosen target node as the warm start seed. For the proposed methods and GP-SELECT, the main tuning parameters are the exploration-exploitation trade-off parameter  $\alpha_t$  and the observation noise variance  $\sigma^2$ . For GP-SOPT.TT and GP-SOPT.TOPK there is additionally the thresholding parameter  $k$ . We consider the following values for them. Populated Places:  $\alpha_t \in \{4, 2, 1, 0.1, 0.01, 0.001\}$ ,  $\sigma^2 \in \{1, 0.5, 0.25, 0.1\}$  and  $k \in \{200, 400, 800\}$ . Wikipedia:  $\alpha_t \in \{0.1, 0.01, 0.001\}$ ,  $\sigma^2 \in \{1, 0.5, 0.25, 0.1\}$  and  $k \in \{200, 400, 800\}$ . Citation Network:  $\alpha_t \in \{1, 10^{-1}, 10^{-2}, 10^{-3}, 10^{-4}\}$ ,  $\sigma^2 \in \{1, 0.5, 0.25, 0.1\}$  and  $k \in \{400, 800, 1600\}$ . Although in theory  $\alpha_t$  should be iteration-dependent, we find that a fixed value often performs well in practice. On all data sets we set the kernel regularization parameter  $\omega_0 = 0.01$ . Wang et al. (2013) algorithm has several parameters, and we only tune the exploration-exploitation trade-off parameter  $\alpha$ . It is set to 0.1 on Populated Places and Citation Network, and 0.0001 on Wikipedia, which are the best performing values. Other parameters are set based on Wang et al. (2013).

Results are in Figure 3, where we plot the recall, i.e., the fraction of targets found by the algorithms, versus the fraction of the whole data set queried. More specifically, for each algorithm we obtain its mean recall curve over the top 15% (except for Wang et al. (2013)) parameter combinations in each experiment, as judged by the area under the recall curve. We then plot the median, maximum and minimum over the five runs in Figure 3.

The three proposed methods clearly outperform Wang et al. (2013) and GP-SELECT on Populated Places, while all methods perform equally well on Wikipedia. We think this has to do with the underlying graph structure and target distribution. As mentioned before, target nodes in the Populated Places graph are spread over sub-graphs of various

<sup>4</sup>www.dbpedia.org

sizes, and therefore exploration strategies do make a difference. We observe that the proposed methods tend to select high-degree nodes in the first few iterations, thereby gaining much information, while GP-SELECT initially selects low-degree nodes. In contrast, most target nodes in the Wikipedia graph reside in one large component, and therefore less exploration is needed. In fact, the best values for  $\alpha_t$  are very small, suggesting that an exploitation-only strategy is good enough for this data. On Citation Network, most methods perform well except that GP-SELECT performs quite poorly in one run. This may again indicate GP-SELECT is less robust against low-degree nodes.

## 5.2 Enron E-mails

We experimented on the Enron e-mail data set<sup>5</sup> with topics assigned by Priebe et al. based on the annotations by Berry and Browne. We further processed the dataset into a format suitable for active search experiments as detailed below. Each e-mail  $i$  is represented by a unique Unix time stamp  $t_i$ , a unique sender index and the set of receiver (excluding self-copying) indices, which are collectively denoted as  $U_i$ . Between e-mails  $i$  and  $j$ , we created an edge with the following weight:

$$A_{ij} := \exp(-(t_i - t_j)^2 / \tau^2) \cdot |U_i \cap U_j| / \sqrt{|U_i||U_j|},$$

where  $\tau = 12$  weeks in seconds and  $|U_i|$  denotes the size of  $U_i$ . We thus measure pairwise similarity among e-mails by the product of nearness in time and degree of overlap between users involved. The resulting e-mail graph has 20,112 nodes, and we chose the subset of 803 e-mails that are assigned topic 16 in LDC topics<sup>5</sup>, which is related to the downfall of Enron, to be the target class in this experiment.

Due to the size of the dataset, we only compared three methods: GP-SOPT.TT, GP-SELECT and Wang et al. (2013) in three independent runs each initialized with a target node chosen uniformly at random. We also limited the tuning parameters to be the following fixed values across the three runs:  $(k, \alpha, \sigma^2, \omega_0) = (800, 0.001, 0.05, 0.01)$  for GP-SOPT.TT,  $(\alpha, \sigma^2, \omega_0) = (0.01, 0.05, 0.01)$  for GP-SELECT, and  $\alpha = 0.001$  for Wang et al. (2013). These values were chosen based on a coarse parameter search to be indicative of the performance of each method on this data set. Results are in Figure 4, which shows GP-SOPT.TT is more stable across initial seeds than the other methods, and outperforms Wang et al. (2013) significantly at early iterations.

## 6 CONCLUSION AND DISCUSSIONS

In this paper, we discuss active search on a graph with known structure. Each node bears a reward, which is unknown at first but can be noisily observed upon query. An

<sup>5</sup>Available at <http://cis.jhu.edu/~parky/Enron/execs.email.linesnum.ldctopic>

Figure 4: Enron: recall vs. fraction of data queried

active search algorithm aims to accumulate as large a sum of rewards from the queried nodes as possible under limited budgets. We assume that the node rewards vary smoothly along the graph.

Popular Bayesian UCB-style algorithms (Srinivas et al., 2012; Vanchinathan et al., 2013; Valko et al., 2014) use the marginal standard deviation as their exploration criterion, leading to the undesirable tendency of selecting peripheral nodes on a graph. Instead, we consider  $\Sigma$ -optimality on graphs, which can more efficiently reduce the variance of the reward function estimate by sampling cluster centers. We show the advantage of our method in experiments with real graphs and provide a theoretical guarantee on the cumulative regret.

One interesting future direction is deriving tighter regret bounds for the proposed methods that match their empirical performances. We imagine it may be possible to bound the regret directly by the difference in  $\Sigma$ -optimality (Bayes survey risks,  $\mathcal{R}^\Sigma$ ), which may have better properties than differential information gain,  $\gamma_T$  on graphs.

An equally interesting question is the selection of graph kernels. Our discussions and experiments mainly consider Gaussian random fields with unnormalized Laplacian, which is a very popular kernel choice. It is worthwhile to explore active search with other graph kernels, such as the ones discussed in Smola and Kondor (2003).

## A Predictive Covariance Matrix

**Lemma 3.** For augmented graph Laplacian, the posterior covariance matrix,  $C_t(v, v') \geq 0, \forall v, v'$ .

*Proof.* Let  $h_k = \sum_{\tau=1}^t e_{v_\tau}(v_k)$  to be the count of queries on node  $k$ ; further define its diagonal matrix,  $\mathbf{H} =$

$\text{diag}(h_1, \dots, h_n)$ . We rewrite (5) as,

$$(\mathbf{C}_t)^{-1} = (\mathbf{C}_0)^{-1} + \sigma_n^{-2} \mathbf{H} = \mathbf{D} - \mathbf{A} + \omega_0 \mathbf{I} + \sigma_n^{-2} \mathbf{H}$$

Define  $\mathbf{D}_t = \mathbf{D} + \omega_0 \mathbf{I} + \sigma_n^{-2} \mathbf{H}$ , we have

$$\mathbf{C}_t = (\mathbf{D}_t - \mathbf{A})^{-1} = \mathbf{D}_t^{-\frac{1}{2}} \left( \sum_{k=0}^{\infty} \left( \mathbf{D}_t^{-\frac{1}{2}} \mathbf{A} \mathbf{D}_t^{-\frac{1}{2}} \right)^k \right) \mathbf{D}_t^{-\frac{1}{2}},$$

where the right hand side is always nonnegative.

The convergence of  $\|\mathbf{D}_t^{-\frac{1}{2}} \mathbf{A} \mathbf{D}_t^{-\frac{1}{2}}\|_2 < 1$  is as follows.

Define the components for the posterior as  $\mathbf{D}_t = \text{diag}(d_1^{(t)}, \dots, d_n^{(t)})$  with  $d^{(t)} = \sum_{i=1}^n d_i^{(t)}$ . Also, define for the prior model  $\mathbf{D} = \text{diag}(d_1^{(0)}, \dots, d_n^{(0)})$  with  $d^{(0)} = \sum_{i=1}^n d_i^{(0)}$ .

The following holds for any  $\mathbf{v} \in \mathbb{R}^n$ ,

$$\begin{aligned} \mathbf{v}^\top \mathbf{D}_t^{-\frac{1}{2}} \mathbf{A} \mathbf{D}_t^{-\frac{1}{2}} \mathbf{v} &= \sum_{ij} \frac{v_i v_j a_{ij}}{\sqrt{d_i^{(t)}} \sqrt{d_j^{(t)}}} \\ &\leq \sqrt{\left( \sum_{ij} \frac{v_i^2 a_{ij}}{d_i^{(t)}} \right) \left( \sum_{ij} \frac{v_j^2 a_{ij}}{d_j^{(t)}} \right)} = \sum_i v_i^2 \frac{d_i}{d_i^{(t)}} \leq \|\mathbf{v}\|_2^2. \end{aligned}$$

Further, both equalities cannot hold simultaneously, because for the first equality to hold, it is required that  $\frac{v_i^2 a_{ij}}{d_i^{(t)}} \propto \frac{v_j^2 a_{ij}}{d_j^{(t)}}$ , i.e.,  $v_j^2 \propto d_j^{(t)}$ ,  $\forall j$  in the same connected component, which then dictates that,

$$\sum_i v_i^2 \frac{d_i}{d_i^{(t)}} = \sum_i \left( \frac{d_i^{(0)}}{d^{(0)}} \|\mathbf{v}\|_2^2 \right) \frac{d_i}{d_i^{(t)}} = \frac{d^{(0)}}{d^{(t)}} \|\mathbf{v}\|_2^2 < \|\mathbf{v}\|_2^2. \quad \square$$

**Lemma 4.** *The diagonal elements in  $\mathbf{C}_t$  is always no smaller than the off-diagonal elements, i.e.,  $\sigma_t(v)^2 = C_t(v, v) \geq C_t(v, v'), \forall v, v'$ .*

*Proof.* Without loss of generality, let  $v$  be the last index of  $\mathbf{C}_t = (\tilde{\mathcal{L}}_0 + \sigma_n^{-2} \mathbf{H})^{-1}$ . For simplicity, let  $\tilde{\mathcal{L}}_t = \tilde{\mathcal{L}}_0 + \sigma_n^{-2} \mathbf{H}$  and it has the following matrix partition,

$$\tilde{\mathcal{L}}_t = \begin{pmatrix} \tilde{\mathcal{L}}_{\bar{v}\bar{v}} & \tilde{\ell}_{\bar{v}v} \\ \tilde{\ell}_{\bar{v}v}^\top & \tilde{\ell}_{vv} \end{pmatrix},$$

where  $\bar{v}$  is the complement of  $v$ . From Woodbury matrix inversion lemma, we have

$$\mathbf{C}_t = \tilde{\mathcal{L}}_t^{-1} = \begin{pmatrix} \mathbf{M} & -\frac{1}{m} \tilde{\mathcal{L}}_{\bar{v}\bar{v}}^{-1} \tilde{\ell}_{\bar{v}v} \\ -\frac{1}{m} \tilde{\ell}_{\bar{v}v}^\top \tilde{\mathcal{L}}_{\bar{v}\bar{v}}^{-1} & \frac{1}{m} \end{pmatrix}, \quad (16)$$

where  $m = \tilde{\ell}_{vv} - \tilde{\ell}_{\bar{v}v}^\top \tilde{\mathcal{L}}_{\bar{v}\bar{v}}^{-1} \tilde{\ell}_{\bar{v}v}$  and  $\mathbf{M} = \tilde{\mathcal{L}}_{\bar{v}\bar{v}}^{-1} + \frac{1}{m} \tilde{\mathcal{L}}_{\bar{v}\bar{v}}^{-1} \tilde{\ell}_{\bar{v}v} \tilde{\ell}_{\bar{v}v}^\top \tilde{\mathcal{L}}_{\bar{v}\bar{v}}^{-1}$ . To show that  $C_t(v, v) \geq C_t(v, v')$ , we need to verify that  $(-\tilde{\mathcal{L}}_{\bar{v}\bar{v}}^{-1} \tilde{\ell}_{\bar{v}v})_{v'} \leq 1$ .

In fact, since  $\tilde{\mathcal{L}}_t$  is diagonally dominant, we have  $\tilde{\mathcal{L}}_t \mathbf{1}_n \geq 0$ . Take its first  $n-1$  rows to get  $\tilde{\mathcal{L}}_{\bar{v}\bar{v}} \cdot \mathbf{1}_{n-1} + \tilde{\ell}_{\bar{v}v} \geq 0$ . Notice  $\tilde{\mathcal{L}}_{\bar{v}\bar{v}}$  is also a valid augmented graph Laplacian. By Lemma 3, we could left multiply the element-wise nonnegative matrix  $\tilde{\mathcal{L}}_{\bar{v}\bar{v}}^{-1}$  to both sides to obtain,  $\mathbf{1}_{n-1} + \tilde{\mathcal{L}}_{\bar{v}\bar{v}}^{-1} \tilde{\ell}_{\bar{v}v} \geq 0$ , which completes our proof for any  $v' \in \bar{v}$ .  $\square$

## B Active Search Regret Bound

We start by stating the following result.

**Theorem 5** (Theorem 6, Srinivas et al. (2012)). *Let  $\delta \in (0, 1)$ . Assume the observation noises are uniformly bounded by  $\sigma_n$  and  $f$  has RKHS norm  $B$  with kernel  $C_0$ , which is equivalent to  $\mathbf{f}^\top \tilde{\mathcal{L}}_0 \mathbf{f} \leq B^2$ . Define  $\alpha_t = \sqrt{2B^2 + 300\gamma_t \log(t/\delta)^3}$ , then*

$$\Pr(\forall t, \forall v \in V, |\mu_t(v) - f(v)| \leq \alpha_{t+1} \sigma_t(v)) \geq 1 - \delta.$$

We use this result to bound our instantaneous regrets.

**Lemma 6.** *Conditioned on the high-probability event in Theorem 5, the following bound holds:*

$$\forall t, r_t := f(v_t^*) - f(v_t) \leq 2\alpha_t k \sigma_{t-1}(v_t),$$

where  $v_t^*$  is the node with the  $t$ -th globally largest function value and  $v_t$  is node selected at round  $t$ .

*Proof.* At round  $t$  there are two possible situations. If  $v_t^*$  was picked at some earlier round, the definition of  $v_t^*$  implies that there exists some  $t' < t$  such that  $v_{t'}^*$  has not been picked yet. According to our selection rule, the fact that  $s_t(v) \geq \sigma_t(v)$ , and Theorem 5, the following holds:

$$\begin{aligned} \mu_{t-1}(v_t) + \alpha_t s_{t-1}(v_t) &\geq \mu_{t-1}(v_{t'}^*) + \alpha_t s_{t-1}(v_{t'}^*) \\ &\geq \mu_{t-1}(v_{t'}^*) + \alpha_t \sigma_{t-1}(v_{t'}^*) \geq f(v_{t'}^*) \geq f(v_t^*). \end{aligned}$$

If  $v_t^*$  has not been picked yet, a similar argument gives

$$\mu_{t-1}(v_t) + \alpha_t s_{t-1}(v_t) \geq \mu_{t-1}(v_t^*) + \alpha_t s_{t-1}(v_t^*) \geq f(v_t^*).$$

Thus we always have

$$\begin{aligned} f(v_t^*) &\leq \mu_{t-1}(v_t) + \alpha_t s_{t-1}(v_t) \\ &\leq f(v_t) + \alpha_t \sigma_{t-1}(v - t) + \alpha_t s_{t-1}(v_t) \\ &\leq f(v_t) + 2\alpha_t k \sigma_{t-1}(v_t). \end{aligned}$$

**Lemma 7** (Lemma 5.4, Srinivas et al. (2012)). *Let  $\alpha_t$  be defined as in Theorem 5 and  $c_1$  be defined as in Theorem 2. Conditioned on the high-probability event of Theorem 5, the following holds:*

$$\forall T \geq 1, \sum_{t=1}^T r_t^2 \leq \alpha_T k^2 c_1 \mathcal{I}(\mathbf{y}_{\mathbf{v}_T}; f_{\mathbf{v}_T}) \leq \alpha_T k^2 c_1 \gamma_T.$$

Finally, the Cauchy-Schwarz inequality gives  $R_T \leq \sqrt{T \sum_{t=1}^T r_t^2} \leq k \sqrt{T c_1 \alpha_T \gamma_T}$ .

# Off-policy learning based on weighted importance sampling with linear computational complexity

---

A. Rupam Mahmood

Richard S. Sutton

Reinforcement Learning and Artificial Intelligence Laboratory

Department of Computing Science, University of Alberta, Edmonton, AB T6G 2E8 Canada

## Abstract

Importance sampling is an essential component of model-free off-policy learning algorithms. Weighted importance sampling (WIS) is generally considered superior to ordinary importance sampling but, when combined with function approximation, it has hitherto required computational complexity that is  $O(n^2)$  or more in the number of features. In this paper we introduce new off-policy learning algorithms that obtain the benefits of WIS with  $O(n)$  computational complexity. Our algorithms maintain for each component of the parameter vector a measure of the extent to which that component has been used in previous examples. This measure is used to determine component-wise step sizes, merging the ideas of stochastic gradient descent and sample averages. We present our main WIS-based algorithm first in an intuitive acausal form (the forward view) and then derive a causal algorithm using eligibility traces that is equivalent but more efficient (the backward view). In three small experiments, our algorithms performed significantly better than prior  $O(n)$  algorithms for off-policy policy evaluation. We also show that our adaptive step-size technique can also improve the performance of *on-policy* algorithms such as TD( $\lambda$ ) and true online TD( $\lambda$ ).

## 1 Weighted importance sampling for off-policy Monte Carlo estimation

In off-policy learning problems, an agent learns about a policy while its experience is generated by following a different policy. A Monte Carlo technique known as *importance sampling* (Kahn & Marshall 1953, Rubinstein 1981) is often used to resolve this mismatch in policies (Sutton & Barto 1998, Dann, Neumann & Peters 2014, Geist & Scherrer 2014). One of the most effective variants

of importance sampling is *weighted importance sampling* (WIS), which often gives much lower variance than the ordinary form of importance sampling and is generally preferred due to its superior empirical performance (Hesterberg 1988, Precup, Sutton & Singh 2000, Shelton 2001, Liu 2001, Robert & Casella 2004, Koller & Friedman 2009).

Parametric function approximation is widely used and viewed as essential for large-scale reinforcement learning applications. However, only recently has WIS been extended to this more general setting. Mahmood, van Hasselt and Sutton (2014) have recently developed WIS-LSTD( $\lambda$ ), which extends WIS from tabular off-policy learning to linear function approximation and eligibility traces. However, WIS-LSTD( $\lambda$ ) is a least-squares algorithm that involves a matrix inversion in its update, the computational complexity of which scales  $O(n^3)$  in the number of features. In large-scale applications,  $O(n)$  algorithms, such as stochastic gradient descent, temporal-difference (TD) learning, and its gradient-based variants, are often preferred.

WIS has not yet been extended to  $O(n)$  algorithms. Modern off-policy algorithms with  $O(n)$  computational complexity, such as GTD( $\lambda$ ) (Maei 2011), GQ( $\lambda$ ) (Maei & Sutton 2010), and true online GTD( $\lambda$ ) (van Hasselt, Mahmood & Sutton 2014), all use the ordinary variant of importance sampling and can suffer severely due to the problem of large variance (Defazio & Graepel 2014).

In this work, we take several steps to bridge the gap between the Monte Carlo estimator WIS and  $O(n)$  off-policy algorithms with function approximation. The key to this endeavor is to relate stochastic gradient descent (SGD) to simple Monte Carlo estimators such as the sample average. We realize that there is a missing link in that, when the function approximation setting reduces to the tabular setting, SGD does not reduce to the sample average estimator. This is not unique to off-policy learning, and the relationship is missing even in the on-policy setting. Our first key step is to develop a new SGD that bridges this gap in an on-policy supervised-learning setting. Using insights from this step, we subsequently develop  $O(n)$  off-policy algorithms based on WIS in a general reinforcement learning setting.

## 2 Sample averages and stochastic gradient descent

In this section, we investigate the relationship between the sample average estimator and SGD. We first show that SGD does not reduce to the sample average estimator in the fully-representable case also known as the *tabular* representation. Then we propose a modification to SGD and show that it achieves the sample average estimator when the feature representation is tabular.

The sample average is one of the simplest Monte Carlo estimators. In order to introduce it, consider that data arrives as a sequence of samples  $Y_k \in \mathbb{R}$  drawn from a fixed distribution. The goal of the learner is to estimate the expected value of the samples,  $v \doteq \mathbb{E}[Y_k]$ . The sample average estimator  $\hat{V}_{t+1}$  for data given up to time  $t$  can be defined and incrementally updated in the following way:

$$\hat{V}_{t+1} \doteq \frac{\sum_{k=1}^t Y_k}{t} = \hat{V}_t + \frac{1}{t} (Y_t - \hat{V}_t); \hat{V}_1 \doteq 0. \quad (1)$$

In the incremental update,  $\frac{1}{t}$  can be viewed as a form of step size, modulating the amount of change made to the current estimate, which decreases with time in this case. In the parametric function approximation case, we have to go beyond sample average and use stochastic approximation methods such as SGD.

To introduce SGD, we use a supervised-learning setting with linear function approximation. In this setting, data arrives as a sequence of input-output pairs  $(X_k, Y_k)$ , where  $X_k$  takes values from a finite set  $\mathcal{X}$  and  $Y_k \in \mathbb{R}$ . The learner observes a feature representation of the inputs, where each input is mapped to a feature vector  $\phi_k \doteq \phi(X_k) \in \mathbb{R}^n$ . The goal of the learner is to estimate the conditional expectation of  $Y_k$  for each unique input  $x \in \mathcal{X}$  as a linear function of the features:  $\theta^\top \phi(x) \approx v(x) \doteq \mathbb{E}[Y_k | X_k = x]$ . SGD incrementally updates the parameter vector  $\theta \in \mathbb{R}^n$  at each time step  $t$  in the following way:

$$\theta_{t+1} \doteq \theta_t + \alpha_t (Y_t - \theta_t^\top \phi_t) \phi_t, \quad (2)$$

where  $\alpha_t > 0$  is a scalar step-size parameter, which is often set to a small constant. The per-update time and memory complexity of SGD is  $O(n)$ .

Linear function approximation includes tabular representations as a special case. For example, if the feature vectors are  $|\mathcal{X}|$ -dimensional standard basis vectors, then each feature uniquely represents an input, and the feature representation becomes tabular.

We are interested in finding whether SGD degenerates to sample average when the linear function approximation setting reduces to the tabular setting. Both incremental updates are in a form where the previous estimate is incremented with a product of an error and a step size. In the

SGD update, the product also has the feature vector as a factor, but in the tabular setting it simply selects the input for which an update is made.

A major difference between SGD and sample average is the ability of SGD to track under non-stationarity through the use of a constant step size. Typically, the step size of SGD is set to a constant value or decreased with time, where the latter does not work well under non-stationarity but is similar to how sample average works. While we attempt to accommodate sample average estimation more closely within SGD, it is also desirable to retain the tracking ability of SGD.

SGD clearly cannot achieve sample average with a constant step size. On the other hand, if we set the step-size parameter in the SGD update as  $\alpha_t = \frac{1}{t}$ , the SGD update still does not subsume the sample average. This is because, in the SGD update (2), time  $t$  is the total number of samples seen so far, whereas, in the sample average update (1), it is the number of samples seen so far only for one specific input.

We take two important steps to bridge the gap between the sample average update and the SGD update. First, we extend the sample average estimator to incorporate tracking through recency weighting, where the amount of weight assigned to the recent samples is modulated by a scalar recency-weighting constant. This new *recency-weighted average* estimator subsumes sample average as a special case and hence unifies both tracking and sample averaging. Second, we propose a variant of SGD that reduces to recency-weighted average in the tabular setting and still uses only  $O(n)$  per-update memory and computation.

Our proposed recency-weighted average estimator can be derived by minimizing an empirical mean squared objective with recency weighting:

$$\tilde{V}_{t+1} \doteq \arg \min_v \frac{1}{t} \sum_{k=1}^t (1-\eta)^{t-k} (Y_k - v)^2; 0 \leq \eta < 1.$$

Here, the recency-weighting constant  $\eta$  exponentially weights the past observations down and thus gives more weight to the recent samples. When  $\eta = 0$ , all samples are weighted equally. The recency-weighted average can be defined and incrementally updated as follows:

$$\tilde{V}_{t+1} = \frac{\sum_{k=1}^t (1-\eta)^{t-k} Y_k}{\sum_{k=1}^t (1-\eta)^{t-k}} = \tilde{V}_t + \frac{1}{\tilde{U}_{t+1}} (Y_t - \tilde{V}_t), \quad (3)$$

$$\tilde{U}_{t+1} \doteq (1-\eta)\tilde{U}_t + 1; \quad \tilde{U}_1 \doteq 0, \quad \tilde{V}_1 \doteq 0. \quad (4)$$

It is easy to see that the recency-weighted average is an unbiased estimator of  $v$ . Moreover, when  $\eta = 0$ , it reduces to the sample average estimator.

Now, we propose a modified SGD in the supervised-learning setting that for tabular representation reduces to the recency-weighted average. The updates are as follows:

$$\mathbf{u}_{t+1} \doteq (\mathbf{1} - \eta \phi_t \circ \phi_t) \circ \mathbf{u}_t + \phi_t \circ \phi_t, \quad (5)$$

$$\alpha_{t+1} \doteq \mathbf{1} \oslash \mathbf{u}_{t+1}, \quad (6)$$

$$\theta_{t+1} \doteq \theta_t + \alpha_{t+1} \circ (Y_t - \theta_t^\top \phi_t) \phi_t, \quad (7)$$

where  $\eta \geq 0$  is the recency-weighting factor,  $\circ$  is component-wise vector multiplication,  $\oslash$  is component-wise vector division where a division by zero results in zero, and  $\mathbf{1} \in \mathbb{R}^n$  is a vector of all ones. Here,  $\alpha_{t+1} \in \mathbb{R}^n$  is a vector step-size parameter, set as the vector division of  $\mathbf{1}$  by  $\mathbf{u}_{t+1} \in \mathbb{R}^n$ , which parallels  $\tilde{U}$  of the recency-weighted average. We call  $\mathbf{u}$  the *usage vector*, as it can be seen as an estimate of how much each feature is ‘‘used’’ over time by the update. We call this algorithm the *usage-based SGD* (U-SGD). Replacing a division by zero with zero in the step-size vector amounts to having no updates for the corresponding component. This makes sense because a zero in any component of  $\mathbf{u}$  can occur only at the beginning when  $\mathbf{u}$  is initialized to zero and the corresponding feature has not been activated yet. Once a feature is nonzero, the corresponding component of  $\alpha$  becomes positive and, with sufficiently small  $\eta$ , it always remains so.

In the following theorem, we show that U-SGD reduces to recency-weighted average in the tabular setting and hence is a generalization of the sample average estimator as well.

**Theorem 1** (Backward consistency of U-SGD with sample average). *If the feature representation is tabular, the vectors  $\mathbf{u}$  and  $\theta$  are initially set to zero, and  $0 \leq \eta < 1$ , then U-SGD defined by (5)-(7) degenerates to the recency-weighted average estimator defined by (3) and (4), in the sense that each component of the parameter vector  $\theta_{t+1}$  of U-SGD becomes the recency-weighted average estimator of the corresponding input.*

(Proved in Appendix A.1).

### 3 WIS and off-policy SGD

In this section, we carry over weighted importance sampling (WIS) to off-policy SGD, drawing from the ideas developed in the previous section. We introduce two new off-policy SGD algorithms based on WIS. The first one subsumes WIS fully but does not lead to an  $O(n)$  implementation, whereas the other algorithm is more amenable to an efficient implementation.

First we introduce both the ordinary importance sampling (OIS) and WIS. Importance sampling is a technique for estimating an expectation under one distribution using samples drawn from a different distribution. OIS estimates the expectation by forming a special kind of sample average. Consider that samples  $Y_k \in \mathbb{R}$  are drawn from a sample distribution  $l$ , but the goal of the learner is to estimate the expectation  $v_g \doteq \mathbf{E}_g [Y_k]$  under a different distribution  $g$ . OIS

estimates  $v_g$  by scaling each sample  $Y_k$  by the importance-sampling ratio  $W_k \doteq \frac{g(Y_k)}{l(Y_k)}$  and forming a sample average estimate of the scaled samples:

$$\tilde{V}_{t+1} \doteq \frac{\sum_{k=1}^t W_k Y_k}{t} = \tilde{V}_t + \frac{1}{t} (W_t Y_t - \tilde{V}_t); \quad \tilde{V}_1 \doteq 0.$$

WIS, on the other hand, estimates  $v_g$  by forming a weighted average estimate of the original samples. Its definition and incremental update are as follows:

$$\hat{V}_{t+1} \doteq \frac{\sum_{k=1}^t W_k Y_k}{\sum_{k=1}^t W_k} = \hat{V}_t + \frac{1}{\hat{U}_{t+1}} W_t (Y_t - \hat{V}_t),$$

$$\hat{U}_{t+1} \doteq \hat{U}_t + W_t; \quad \hat{U}_1 \doteq 0, \quad \hat{V}_1 \doteq 0.$$

If there is no discrepancy between the sample and the target distribution, then  $W_k = 1, \forall k$ , and both OIS and WIS become equivalent to the sample average estimator.

We derive the *recency-weighted WIS* as a solution to a mean squared objective with recency weighting and additionally importance sampling:

$$\bar{V}_{t+1} \doteq \arg \min_v \frac{1}{t} \sum_{k=1}^t (1 - \eta)^{t-k} W_k (Y_k - v)^2; \quad 0 \leq \eta < 1,$$

$$= \frac{\sum_{k=1}^t (1 - \eta)^{t-k} W_k Y_k}{\sum_{k=1}^t (1 - \eta)^{t-k} W_k}.$$

It is easy to see that, when  $\eta = 0$ , the recency-weighted WIS estimator reduces to WIS. Recency-weighted WIS can be updated incrementally in the following way:

$$\bar{V}_{t+1} = \bar{V}_t + \frac{1}{\bar{U}_{t+1}} W_t (Y_t - \bar{V}_t); \quad \bar{V}_1 \doteq 0, \quad (8)$$

$$\bar{U}_{t+1} \doteq (1 - \eta) \bar{U}_t + W_t; \quad \bar{U}_1 \doteq 0. \quad (9)$$

Now we introduce two variants of SGD based on WIS in a more general off-policy reinforcement learning setting with linear function approximation. In this setting, a learning agent interacts with an environment by taking an action  $A_k \in \mathcal{A}$  in a state of the environment  $S_k \in \mathcal{S}$  on each time step  $k$ . Here  $\mathcal{A}$  and  $\mathcal{S}$  are considered finite. Upon taking an action, the agent receives a scalar reward  $R_{k+1}$  and transitions to state  $S_{k+1}$ . Instead of observing the states directly, the agent observes a feature representation of the states where each state is mapped to a feature vector  $\phi_k \doteq \phi(S_k) \in \mathbb{R}^n$ . In an off-policy policy-evaluation problem, the agent takes actions based on a fixed behavior policy  $b(\cdot | S_k)$ . The goal is to estimate  $v_\pi(s)$  (the expected sum of the future discounted reward when starting in  $s$  and following  $\pi$ ) as a linear function of the features:

$$\theta^\top \phi(s) \approx v_\pi(s) \doteq \mathbf{E} [G_k | S_k = s, A_i \sim \pi(\cdot | S_i), \forall i],$$

$$G_k \doteq \sum_{i=k}^{\infty} \gamma^i R_{i+1} \prod_{j=k+1}^i \gamma(S_j),$$

where  $\theta \in \mathbb{R}^n$  is the parameter vector to learn, and  $\gamma_k \doteq \gamma(S_k) \in [0, 1]$  denotes a state-dependent discounting. In a general value-function setting, such state-dependent discounting can be used to denote termination in a state  $s$  by setting  $\gamma(s) = 0$  (Sutton et al. 2011).

In order to learn  $\theta$  model-free from samples, we need to use an importance sampling technique since the behavior policy and the target policy can be different. Given a partial trajectory from time  $k$  to  $t + 1$ :  $S_k, A_k, R_{k+1}, \dots, S_{t+1}$ , the importance-sampling ratio  $\rho_k^{t+1}$  is defined as the likelihood ratio of this trajectory starting at  $S_k$  under the target policy and the behavior policy:

$$\begin{aligned} \rho_k^{t+1} &\doteq \frac{\prod_{i=k}^t p(S_{i+1}|S_i, A_i) \pi(A_i|S_i)}{\prod_{i=k}^t p(S_{i+1}|S_i, A_i) b(A_i|S_i)} = \prod_{i=k}^t \frac{\pi(A_i|S_i)}{b(A_i|S_i)} \\ &= \prod_{i=k}^t \rho_i; \quad \rho_i \doteq \rho_i^{i+1}, \end{aligned}$$

where  $p$  is the state-transition probability function. The value  $v_\pi(s)$  can be estimated using returns scaled by the corresponding importance-sampling ratios. Consider that data is available up to step  $t + 1$  and no termination or discounting occurs by that time. A return originating from state  $S_k$  can be approximated by using a full discounting at the final step:  $\gamma_{t+1} = 0$ . Then a flat truncated return can be defined as (Sutton et al. 2014):

$$G_k^{t+1} \doteq \sum_{i=k}^t R_{i+1}.$$

When the states are visible and the number of states are small, the value  $v_\pi(s)$  for each state  $s$  can be estimated using importance sampling such as OIS, WIS or recency-weighted WIS by setting  $Y_k \doteq G_k^{t+1}$  and  $W_k \doteq \rho_k^{t+1}$ .

Now, we propose the first off-policy SGD based on WIS, which we call *WIS-SGD-1*. With  $0 \leq k < t + 1$  and  $\theta_0^t \doteq \theta_0, \forall t$ , the following updates define WIS-SGD-1:

$$\mathbf{u}_{k+1}^{t+1} \doteq (\mathbf{1} - \eta \phi_k \circ \phi_k) \circ \mathbf{u}_k^{t+1} + \rho_k^{t+1} \phi_k \circ \phi_k, \quad (10)$$

$$\alpha_{k+1}^{t+1} \doteq \mathbf{1} \circ \alpha_{k+1}^{t+1}, \quad (11)$$

$$\theta_{k+1}^{t+1} \doteq \theta_k + \alpha_{k+1}^{t+1} \circ \rho_k^{t+1} (G_k^{t+1} - \phi_k^\top \theta_k^{t+1}) \phi_k. \quad (12)$$

Similar to U-SGD, WIS-SGD-1 maintains a vector step size through the update of a usage vector, which in this case also includes the importance-sampling ratios. Unlike U-SGD, the parameters of WIS-SGD-1 use two time indices. The time index in the subscript corresponds to the time step of the prediction, and the time index in the superscript stands for the data horizon. In the following, we show that WIS-SGD-1 reduces to recency-weighted WIS, and hence to WIS as well, in the tabular setting.

**Theorem 2** (Backward consistency of WIS-SGD-1 with WIS). *If the feature representation is tabular, the vectors*

$\mathbf{u}$  and  $\theta$  are initially set to zero, and  $0 \leq \eta < 1$ , then *WIS-SGD-1 defined by (10)-(12) degenerates to recency-weighted WIS defined by (8) and (9) with  $Y_k \doteq G_k^{t+1}$  and  $W_k \doteq \rho_k^{t+1}$ , in the sense that each component of the parameter vector  $\theta_{t+1}^{t+1}$  of WIS-SGD-1 becomes the recency-weighted WIS estimator of the corresponding input. (Proved in Appendix A.2.)*

Now we focus on whether and how WIS-SGD-1 can be implemented efficiently. The updates as defined above cannot be computed in  $O(n)$  per time step. An update for step  $k$  requires computing an importance-sampling ratio and a flat truncated return that are available only at  $t + 1 > k$ . It can be computed by looking ahead into the future from  $k$ , but then the update becomes acausal. It can alternatively be computed by waiting until time  $t + 1$  and iterating for each  $k$ . But then the update made at  $t + 1$  becomes expensive, scaling linearly with  $t$ , that is,  $O(tn)$ .

Such updates, where samples are available in future from the time step when the update is made, are often known as *forward-view* updates (Sutton & Barto 1998). Forward-view updates are typically expensive, but for some forward-view updates it is possible to derive causal and efficient updates, known as *backward-view* updates, that compute exactly the same estimate at each time step. Classically these equivalences were achieved for offline updating. Van Seijen and Sutton (2014) showed that such equivalences can also be achieved in the online case.

Converting a forward-view update into an efficient backward-view update depends on combining the extra data available at  $t + 1$  with the current estimate  $\theta_t^t$  in an efficient way to give the next estimate  $\theta_{t+1}^{t+1}$ . For linear recursive updates, it is tantamount to unrolling both  $\theta_{t+1}^{t+1}$  and  $\theta_t^t$  and expressing their difference in a form that can be computed efficiently. It is often not possible to achieve such efficient backward-view updates, and we believe WIS-SGD-1 is one such case.

To appreciate why an efficient backward-view update of WIS-SGD-1 is not plausible, consider the update of  $\theta_t^t$  unrolled back to the beginning of time:

$$\begin{aligned} \theta_t^t &= (\mathbf{I} - \rho_{t-1}^t (\alpha_{t-1}^t \circ \phi_{t-1}) \phi_{t-1}^\top) \theta_{t-1}^t + \rho_{t-1}^t G_{t-1}^t \phi_{t-1} \\ &= \prod_{k=0}^{t-1} (\mathbf{I} - \rho_k^t (\alpha_{k+1}^t \circ \phi_k) \phi_k^\top) \theta_0^t \\ &\quad + \sum_{k=0}^{t-1} \rho_k^t G_k^t \prod_{j=k+1}^{t-1} (\mathbf{I} - \rho_j^t (\alpha_{j+1}^t \circ \phi_j) \phi_j^\top) \phi_k. \end{aligned}$$

In order to obtain  $\theta_{t+1}^{t+1}$  by combining the new data  $\phi_t$  and  $R_{t+1}$  with  $\theta_t^t$ , it is evident that each of the  $\rho_k^t (\alpha_{k+1}^t \circ \phi_k) \phi_k^\top$  terms in the first product needs to be replaced by  $\rho_{k+1}^{t+1} (\alpha_{k+1}^{t+1} \circ \phi_k) \phi_k^\top$ , which is unlikely to be achieved in an inexpensive way. This problem does not appear in previous algorithms with online equivalence such as true online

TD( $\lambda$ ) (van Seijen & Sutton 2014) or true online GTD( $\lambda$ ) (van Hasselt, Mahmood & Sutton 2014), because the terms involved in the product of the unrolled update in those algorithms do not involve *forward-view* terms, that is, they contain  $\rho_k$  and  $\alpha_{k+1}$  in those products instead of  $\rho_k^{t+1}$  and  $\alpha_{k+1}^{t+1}$ . This specific problem with WIS-SGD-1 is due to the fact that the error of the update in (12) is multiplied by the forward-view terms  $\rho_k^{t+1}$  and  $\alpha_{k+1}^{t+1}$ .

The observation we made in the above leads us to develop a second off-policy SGD. In this algorithm, first we replace the forward-view term  $\alpha_{k+1}^{t+1}$  from the update of  $\theta$  with  $\alpha_{k+1}^{k+1}$ . Second, instead of multiplying the terms in the error  $G_k^{t+1} - \phi_k^\top \theta_k^{t+1}$  with the same forward-view term  $\rho_k^{t+1}$ , we multiply the first term  $G_k^{t+1}$  by  $\rho_k^{t+1}$  and the second term  $\phi_k^\top \theta_k^{t+1}$  by  $\rho_k$ . To account for this discrepancy, we add two more terms in the error, and the resultant error of the new update becomes  $\rho_k^{t+1} G_k^{t+1} - \rho_k^{t+1} \phi_k^\top \theta_{k-1}^{k-1} + \rho_k \phi_k^\top \theta_{k-1}^{k-1} - \rho_k \phi_k^\top \theta_k^{t+1}$ . Here, the first two terms are approximating the WIS-SGD-1 error  $\rho_k^{t+1} (G_k^{t+1} - \phi_k^\top \theta_k^{t+1})$ , whereas the last two terms are adding a bias. Although this new algorithm no longer reduces to WIS in the tabular setting, it is developed based on WIS and still retains the main ideas behind recency-weighted WIS. Hence, we call this algorithm *WIS-SGD-2*. The following updates define WIS-SGD-2, with  $0 \leq k < t + 1$ :

$$\mathbf{u}_{k+1}^{t+1} \doteq (\mathbf{1} - \eta \phi_k \circ \phi_k) \circ \mathbf{u}_k^{t+1} + \rho_k^{t+1} \phi_k \circ \phi_k, \quad (13)$$

$$\alpha_{k+1} \doteq \mathbf{1} \oslash \mathbf{u}_{k+1}^{k+1}, \quad (14)$$

$$\delta_k^{t+1} \doteq \rho_k^{t+1} G_k^{t+1} - \rho_k^{t+1} \phi_k^\top \theta_{k-1} + \rho_k \phi_k^\top \theta_{k-1} - \rho_k \phi_k^\top \theta_k^{t+1}, \quad (15)$$

$$\theta_{k+1}^{t+1} \doteq \theta_k^{t+1} + \alpha_{k+1} \circ \delta_k^{t+1} \phi_k. \quad (16)$$

Here,  $\theta_k \doteq \theta_k^k$ , and  $\theta_{-1} = \mathbf{0}$ . It can be easily verified that, in the on-policy case, WIS-SGD-2 degenerates to U-SGD and hence retains the backward consistency with the sample average estimator.

Although this algorithm has much more plausibility of having an efficient backward view due to the careful modifications, it is not yet immediately clear how such a backward-view update can be obtained. Van Hasselt, Mahmood and Sutton (2014) introduced an online equivalence technique from which both true online TD( $\lambda$ ) and true online GTD( $\lambda$ ) can be derived. Their technique requires the target in the error to have a specific recurrence relation. Unfortunately, that specific relation does not hold for the target in WIS-SGD-2. A new technique is needed in order to derive an efficient backward view for WIS-SGD-2.

## 4 A new online equivalence technique

In this section, we introduce a new technique for deriving efficient backward views from online forward-view updates. We show that this technique subsumes the existing

technique for online equivalences (van Hasselt, Mahmood & Sutton 2014). The following theorem describes the new online equivalence technique (Proved in Appendix A.3).

**Theorem 3** (Online equivalence technique). *Consider any forward view that updates toward an interim scalar target  $Y_k^t$  with*

$$\theta_{k+1}^{t+1} \doteq \mathbf{F}_k \theta_k^{t+1} + Y_k^{t+1} \mathbf{w}_k + \mathbf{x}_k, \quad 0 \leq k < t + 1,$$

where  $\theta_0^t \doteq \theta_0$  for some initial  $\theta_0$ , and both  $\mathbf{F}_k \in \mathbb{R}^{n \times n}$  and  $\mathbf{w}_k \in \mathbb{R}^n$  can be computed using data available at  $k$ . Assume that the temporal difference  $Y_k^{t+1} - Y_k^t$  at  $k$  is related to the temporal difference at  $k + 1$  as follows:

$$Y_k^{t+1} - Y_k^t = d_{k+1} (Y_{k+1}^{t+1} - Y_{k+1}^t) + b_t g_k \prod_{j=k+1}^{t-1} c_j, \quad 0 \leq k < t,$$

where  $b_k, c_k, d_k$  and  $g_k$  are scalars that can be computed using data available at time  $k$ . Then the final weight  $\theta_{t+1} \doteq \theta_{t+1}^{t+1}$  can be computed through the following backward-view updates, with  $\mathbf{e}_{-1} \doteq \mathbf{0}$ ,  $\mathbf{d}_0 \doteq \mathbf{0}$ , and  $t \geq 0$ :

$$\mathbf{e}_t \doteq \mathbf{w}_t + d_t \mathbf{F}_t \mathbf{e}_{t-1},$$

$$\theta_{t+1} \doteq \mathbf{F}_t \theta_t + (Y_t^{t+1} - Y_t^t) \mathbf{e}_t + Y_t^t \mathbf{w}_t + b_t \mathbf{F}_t \mathbf{d}_t + \mathbf{x}_t,$$

$$\mathbf{d}_{t+1} \doteq c_t \mathbf{F}_t \mathbf{d}_t + g_t \mathbf{e}_t.$$

This equivalence technique allows producing backward views that contain a *dutch trace*  $\mathbf{e}$  (van Hasselt et al. 2014) and an extra set of weights  $\mathbf{d}$  known as *provisional weights* (Sutton et al. 2014) at the same time. In previous works (Sutton et al. 2014, Mahmood et al. 2014), the provisional weights appeared only in offline updates. Due to this online equivalence technique, this is the first time the provisional weights have emerged in online updates.

In the following theorem, we show that the new equivalence technique is a generalization of the existing equivalence technique developed by van Hasselt et al. (2014). Hence, it readily follows that the existing algorithms with an online equivalence, such as true online TD( $\lambda$ ) and true online GTD( $\lambda$ ), can be derived using the new equivalence technique. The proof is given in Appendix A.4.

**Theorem 4** (Generality of the new equivalence technique). *The online equivalence technique by van Hasselt et al. (2014, Theorem 1) can be retrieved as a special case of the online equivalence technique given in Theorem 3.*

## 5 A new off-policy TD( $\lambda$ ) based on WIS

In this section, we develop a new off-policy algorithm that generalizes WIS-SGD-2 to partial termination and bootstrapping. Then we use the new online equivalence technique to derive an equivalent  $O(n)$  backward-view update. We use a state-dependent bootstrapping parameter  $\lambda_k \doteq \lambda(S_k) \in [0, 1]$  in developing the new algorithm.

First, we construct the target, and then we define a new update for the usage vector  $\mathbf{u}$  in this more general setting.

Based on the general off-policy forward view by Sutton et al. (2014), we combine truncated returns  $G_k^{t+1}$  and truncated corrected returns  $G_k^{t+1} + \phi_{t+1}^\top \theta_t$  scaled by corresponding weights due to discounting, bootstrapping and importance sampling to develop an overall return:

$$\begin{aligned} G_{k,t+1}^\rho &\doteq \rho_k C_k^t \left( (1 - \gamma_{t+1}) G_k^{t+1} + \gamma_{t+1} (G_k^{t+1} + \phi_{t+1}^\top \theta_t) \right) \\ &+ \sum_{i=k+1}^t \rho_k C_k^{i-1} \left( (1 - \gamma_i) G_k^i + \gamma_i (1 - \lambda_i) (G_k^i + \phi_i^\top \theta_{i-1}) \right) \\ &- \rho_k \left( C_k^t + \sum_{i=k+1}^t C_k^{i-1} (1 - \gamma_i \lambda_i) - 1 \right) \phi_k^\top \theta_{k-1}, \quad (17) \end{aligned}$$

where  $C_k^t \doteq \prod_{j=k+1}^t \gamma_j \lambda_j \rho_j$ ,  $\theta_k \doteq \theta_k^k$ ,  $0 \leq k < t + 1$  and  $\theta_{-1} = \mathbf{0}$ . It can be readily verified that, when no bootstrapping is used, that is,  $\lambda_k = 1, \forall k$  and discounting occurs only at the data horizon  $t + 1$ , that is,  $\gamma_0 = \gamma_1 = \dots = \gamma_t = 1$  and  $\gamma_{t+1} = 0$ , then  $G_{k,t+1}^\rho = \rho_k^{t+1} G_k^{t+1} - \rho_k^{t+1} \phi_k^\top \theta_{k-1} + \rho_k \phi_k^\top \theta_{k-1}$ . Hence  $G_{k,t+1}^\rho$  is a strict generalization of the WIS-SGD-2 target to the state-dependent discounting and bootstrapping.

The usage vector  $\mathbf{u}$  of the WIS-SGD algorithms rescales the components of the parameter updates in order to clamp down the updates proportionally when they become large due to large importance-sampling ratios. However, when bootstrapping is used, larger trajectories are given smaller weights, and hence their corresponding importance-sampling ratios will have less severe effect on the updates. For example, when full bootstrapping is used, that is,  $\lambda_k = 0, \forall k$ , the overall return becomes  $G_{k,t+1}^\rho = \rho_k (R_{k+1} + \gamma_{k+1} \phi_{k+1}^\top \phi_k)$ , with an importance-sampling ratio of a one-transition long trajectory. In such cases, updating  $\mathbf{u}$  with the importance-sampling ratio of the full trajectory  $\rho_k^{t+1}$  is unnecessary. Hence, the amount of importance weighting in  $\mathbf{u}$  at each step should be modulated by the amount of discounting and bootstrapping.

Based on the overall return in (17) and the idea of discounting and bootstrapping-aware update of  $\mathbf{u}$  discussed above, we propose a new off-policy TD algorithm based on WIS, which we call *WIS-TD*( $\lambda$ ). It consists of the following forward-view updates:

$$\tilde{\rho}_k^{t+1} \doteq \rho_k \sum_{i=k+1}^t C_k^{i-1} (1 - \gamma_i \lambda_i) + \rho_k C_k^t; \quad \tilde{\rho}_t^t \doteq 0, \quad (18)$$

$$\mathbf{u}_{k+1}^{t+1} \doteq (\mathbf{1} - \eta \phi_k \circ \phi_k) \circ \mathbf{u}_k^{t+1} + \tilde{\rho}_k^{t+1} \phi_k \circ \phi_k, \quad (19)$$

$$\alpha_{k+1} \doteq \mathbf{1} \circ \mathbf{u}_{k+1}^{k+1}, \quad (20)$$

$$\theta_{k+1}^{t+1} \doteq \theta_k^{t+1} + \alpha_{k+1} \circ \left( G_{k,t+1}^\rho - \rho_k \phi_k^\top \theta_k^{t+1} \right) \phi_k. \quad (21)$$

It can be easily verified that, when no bootstrapping is used, that is,  $\lambda_k = 1, \forall k$  and discounting occurs only at the data

horizon  $t + 1$ , that is,  $\gamma_0 = \gamma_1 = \dots = \gamma_t = 1$  and  $\gamma_{t+1} = 0$ , then  $\tilde{\rho}_k^{t+1} = \rho_k^{t+1}$ , and we already showed that the target of WIS-TD( $\lambda$ )  $G_{k,t+1}^\rho$  reduces to the WIS-SGD-2 target in this case. Hence, WIS-TD( $\lambda$ ) subsumes WIS-SGD-2, establishing a direct backward consistency to sample average.

In the following, we apply the new online equivalence technique to the above forward-view update to derive an  $O(n)$  backward-view update computing the same parameter vector  $\theta_t$  at each  $t$ . For that, first we derive an  $O(n)$  backward-view update for the step size that computes the same  $\alpha_t$  as in the above algorithm at each  $t$ .

**Theorem 5** (Backward view update for  $\alpha_t$  of WIS-TD( $\lambda$ )). *The step-size vector  $\alpha_t$  computed by the following backward-view update and the forward-view update defined by (18) – (20) are equal at each step  $t$ :*

$$\begin{aligned} \mathbf{u}_{t+1} &\doteq (\mathbf{1} - \eta \phi_t \circ \phi_t) \circ \mathbf{u}_t + \rho_t \phi_t \circ \phi_t \\ &+ (\rho_t - 1) \gamma_t \lambda_t (\mathbf{1} - \eta \phi_t \circ \phi_t) \circ \mathbf{v}_t, \quad (22) \end{aligned}$$

$$\mathbf{v}_{t+1} \doteq \gamma_t \lambda_t \rho_t (\mathbf{1} - \eta \phi_t \circ \phi_t) \circ \mathbf{v}_t + \rho_t \phi_t \circ \phi_t, \quad (23)$$

$$\alpha_{t+1} \doteq \mathbf{1} \circ \mathbf{u}_{t+1}. \quad (24)$$

(Proved in Appendix A.5.)

Now, we derive an  $O(n)$  backward-view update that computes the same  $\theta_t^t$  as the above forward view.

**Theorem 6** (Backward view update for  $\theta_t^t$  of WIS-TD( $\lambda$ )). *The parameter vector  $\theta_t$  computed by the following backward-view update and the parameter vector  $\theta_t^t$  computed by the forward-view update defined by (17) and (21) are equal at every time step  $t$ :*

$$\begin{aligned} \mathbf{e}_t &\doteq \rho_t \alpha_{t+1} \circ \phi_t \\ &+ \gamma_t \lambda_t \rho_t (\mathbf{e}_{t-1} - \rho_t (\alpha_{t+1} \circ \phi_t) \phi_t^\top \mathbf{e}_{t-1}), \quad (25) \end{aligned}$$

$$\begin{aligned} \theta_{t+1} &\doteq \theta_t + \alpha_{t+1} \circ \rho_t (\theta_{t-1}^\top \phi_t - \theta_t^\top \phi_t) \phi_t \\ &+ (R_{t+1} + \gamma_{t+1} \theta_t^\top \phi_{t+1} - \theta_t^\top \phi_t) \mathbf{e}_t \\ &+ (\rho_t - 1) \gamma_t \lambda_t (\mathbf{d}_t - \rho_t (\alpha_{t+1} \circ \phi_t) \phi_t^\top \mathbf{d}_t), \quad (26) \end{aligned}$$

$$\begin{aligned} \mathbf{d}_{t+1} &\doteq \gamma_t \lambda_t \rho_t (\mathbf{d}_t - \rho_t (\alpha_{t+1} \circ \phi_t) \phi_t^\top \mathbf{d}_t) \\ &+ (R_{t+1} + \theta_t^\top \phi_{t+1} - \theta_{t-1}^\top \phi_t) \mathbf{e}_t. \quad (27) \end{aligned}$$

(Proved in Appendix A.6.)

The overall backward view of WIS-TD( $\lambda$ ) is defined by (22) – (27), and its complete description is given in Appendix A.7. Note that, Theorem 6 does not depend on how  $\alpha_{t+1}$  is set. The per-update time and memory complexity of WIS-TD( $\lambda$ ) is  $O(n)$ . An auxiliary parameter vector might be included in WIS-TD( $\lambda$ ) by making use of the  $\mathbf{x}_k$  vector of the online equivalence technique as was done by van Hasselt et al. (2014), but we do not explore this possibility here.

A seemingly related algorithm is fLSTD-SA (Prashanth, Korda & Munos 2014), which is an on-policy stochastic approximation method derived based on the on-policy

LSTD algorithm (Bradtke & Barto 1996) by randomizing the transition samples. One might speculate whether an  $O(n)$  off-policy stochastic-approximation algorithm based on WIS can be derived from WIS-LSTD( $\lambda$ ) by applying the techniques used in fLSTD-SA. However, the application of fLSTD-SA in the off-policy case does not appear to achieve any form of WIS. Updating a vector step size based on the usage of the features and importance-sampling weights is a distinctive aspect of our new algorithm and is essential for obtaining the benefits of WIS, which is absent in existing stochastic-approximation methods.

## 6 Extending existing algorithms based on the new adaptive step size

The vector step-size adaptation based on the update of the usage vector  $\mathbf{u}$  is only loosely coupled with WIS-TD( $\lambda$ ) and can be freely combined with existing off-policy algorithms as well as the on-policy ones. When combined with the existing algorithms, this step-size adaptation is expected to yield benefits due to the rescaling it performs according to the magnitude of importance-sampling weights and the frequency of feature activation.

We propose two new off-policy algorithms: *WIS-GTD*( $\lambda$ ) and *WIS-TO-GTD*( $\lambda$ ), based on GTD( $\lambda$ ) (Maei 2011) and true online GTD( $\lambda$ ) (van Hasselt et al. 2014), respectively. In both algorithms, we propose replacing the scalar step size of the main parameter vector with the vector step size according to (22) – (24). The scalar step-size parameter of the auxiliary parameter vector of GTD( $\lambda$ ) and true online GTD( $\lambda$ ) could also be replaced with the vector step size with a different recency-weighting factor, but we leave it out here. The descriptions of these two algorithms are given in Appendix A.7.

We propose two new on-policy algorithms: *usage-based TD*( $\lambda$ ) (U-TD( $\lambda$ )) and *usage-based true online TD*( $\lambda$ ) (U-TO-TD( $\lambda$ )), by combining the vector-step-size adaptation with two existing on-policy algorithms: TD( $\lambda$ ) (Sutton & Barto 1998) and true online TD( $\lambda$ ) (van Seijen & Sutton 2014), respectively. There are interesting interrelationships between these on-policy and off-policy algorithms. For example, WIS-GTD( $\lambda$ ) becomes equivalent to U-TD( $\lambda$ ) in the on-policy case when the second step-size parameter  $\beta = 0$ . On the other hand, WIS-TD( $\lambda$ ) directly degenerates to U-TO-TD( $\lambda$ ) in the on-policy case, whereas WIS-TO-GTD( $\lambda$ ) reduces to U-TO-TD( $\lambda$ ) in the on-policy case with  $\beta = 0$ . We provide the description of U-TD( $\lambda$ ) and U-TO-TD( $\lambda$ ) in Appendix A.7.

## 7 Experimental results

In this section we evaluate the new algorithms using two sets of experiments with off-policy and on-policy policy-evaluation tasks, respectively. Source code for both the

off-policy and on-policy experiments are available online<sup>1</sup>. In the first set of experiments, we compared the new off-policy algorithms: WIS-TD( $\lambda$ ), WIS-GTD( $\lambda$ ) and WIS-TO-GTD( $\lambda$ ) with two existing  $O(n)$  algorithms: GTD( $\lambda$ ) and true online GTD( $\lambda$ ) (TO-GTD( $\lambda$ )), and with two least squares algorithms: LSTD-TO( $\lambda$ ), an off-policy algorithm proposed by Dann, Neumann and Peters (2014), and WIS-LSTD( $\lambda$ ), an ideal extension of WIS. For evaluation, we created three off-policy policy-evaluation tasks.

The first task was constructed based on a random-walk Markov chain where the states can be imagined to be laid out on a horizontal line. There were 11 non-terminal states and two terminal states: on the left and the right ends of the chain. From each non-terminal state, there were two actions available: `left`, leads to the state to the left, and `right`, leads to the state to the right. The initial state was always set to the state in the middle of the chain. The reward was sparse: 0 for all transitions except for the right-most transition to the terminal state, where it was +1. The behavior policy was uniformly random between the two actions and the target policy chose `right` with 0.99 probability. No discounting was used. The feature vectors were binary representations of state indices. For 11 non-terminal states, each feature vector was of length  $\lfloor \log_2(11) \rfloor + 1 = 4$ , and these vectors for the states from left to right were  $(0, 0, 0, 1)^\top$ ,  $(0, 0, 1, 0)^\top$ ,  $(0, 0, 1, 1)^\top$ ,  $\dots$ ,  $(1, 0, 1, 1)^\top$ . The features were all zero for the terminal states.

The second and the third tasks were constructed using randomly generated MDPs. We represent a randomly generated MDP as  $(N, m, b, \Gamma)$  where  $N$  and  $m$  stand for the number of states and actions, respectively, and  $b$  is a branching factor denoting the number of next states for a given state-action pair. Here,  $\Gamma \in \mathbb{R}^{N \times N}$  is a diagonal matrix where the entries are the state-dependent discounting  $\gamma(\cdot)$  for each state. We use such a state-dependent discounting to denote termination under the target policy while experience continues seamlessly under the behavior policy. For each state, the next  $b$  states were chosen from total  $N$  states randomly without replacement, and the transition probabilities were generated by partitioning the unit interval at  $b - 1$  cut points which were selected uniformly randomly from  $[0, 1]$ . The rewards for a transition from a state-action pair to the next state were selected uniformly randomly from  $[0, 1]$  and kept deterministic. The behavior policy probabilities for different actions in a particular state were set using uniform random numbers from  $[10^{-15}, 1 + 10^{-15}]$  and normalized to sum to one. The target policy is much less stochastic: one of the actions in a particular state is chosen to have probability 0.99 and the rest of the actions are equiprobable.

<sup>1</sup>Source code for off-policy experiments is available at <http://github.com/armahmood/wis-td-experiments> and for on-policy experiments at <http://github.com/armahmood/usage-td-experiments>.

Figure 1: Empirical comparison of the new WIS-based  $O(n)$  algorithms with two existing  $O(n)$  algorithms and two LSTD algorithms on three off-policy policy-evaluation tasks. Performance is shown in the empirical normalized MSE (NMSE) measured by averaging over 50 independent runs and 100 episodes for the first task, 500 steps for the second, and 5000 steps for the third. The new WIS-based algorithms performed significantly better than both existing  $O(n)$  algorithms in all three off-policy tasks and competitively with one of the LSTD algorithms.

We constructed the second task by randomly generating an MDP with parameters  $(10, 3, 3, \Gamma)$ , where  $\gamma(\cdot) = 0$  for 2 randomly chosen states to denote termination under the target policy and  $\gamma(\cdot) = 0.99$  for the rest of the 8 states. For the third task, we randomly generated an MDP with parameters  $(100, 3, 10, \Gamma)$ , where  $\gamma(\cdot) = 0$  for 5 randomly chosen states and  $\gamma(\cdot) = 0.99$  for the rest. The feature vectors were binary representations of the indices of all states including those for which  $\gamma(\cdot) = 0$ . In these two tasks, the feature vectors were normalized to have unit length.

We tested all algorithms for different values of constant  $\lambda$ , from 0 to 0.9 in steps of 0.1 and from 0.9 to 1.0 in steps of 0.01. The first step-size parameter  $\alpha$  of  $\text{GTD}(\lambda)$  and  $\text{TO-GTD}(\lambda)$  was varied by powers of 10 with powers chosen from  $-3$  to 0 in steps of 0.25. The second step-size parameter  $\beta$  of both algorithms was varied among values  $[0, 0.001, 0.01, 0.1]$ . The initial value  $u_0$  of the components of the usage vector  $\mathbf{u}$  for  $\text{WIS-TD}(\lambda)$ ,  $\text{WIS-GTD}(\lambda)$  and  $\text{WIS-TO-GTD}(\lambda)$  was varied by powers of 10 with powers chosen from 0 to 3 in steps of 0.25. The recency-weighting factor  $\eta$  of the same algorithms was set as  $\eta = \mu/u_0$ , where  $\mu$  was varied among values  $[0, 0.001, 0.01, 0.1, 1]$ . The second step-size parameter  $\beta$  for  $\text{WIS-GTD}(\lambda)$  and  $\text{WIS-TO-GTD}(\lambda)$  was set to zero. The matrix to be inverted in  $\text{LSTD-TO}(\lambda)$  and  $\text{WIS-LSTD}(\lambda)$  was initialized to  $\epsilon \mathbf{I}$ , where  $\epsilon$  was varied by powers of 10 with powers chosen from  $-3$  to  $+3$  in steps of 0.2. The initial parameter vector  $\theta_0$  was set to  $\mathbf{0}$ .

Performance was measured as the empirical mean squared error (MSE) between the estimated values of the states and their true values under the target policy projected to the space spanned by the given features. The error was weighted according to the state-visitation distribution under the behavior policy. As the scale of this MSE measure can vary between these tasks, we normalized it by

the squared weighted L2 norm of the projected true value, which is equivalent to the MSE under  $\theta = \mathbf{0}$ . As a result, the initial normalized MSE (NMSE) for each algorithm was 1. For each run, we averaged this error over 100 episodes measured at the end of each episode for the first task, over 500 steps for the second task, and over 5000 steps for the third. We produced the final estimate by further averaging over 50 independent runs.

Figure 1 shows the empirical performance together with the standard error on the three off-policy policy-evaluation tasks with respect to different  $\lambda$  and optimized over all other parameters. In all three tasks, the new algorithms significantly outperformed both  $\text{GTD}(\lambda)$  and  $\text{TO-GTD}(\lambda)$  indicating the effectiveness of the adaptive vector step size in retaining the advantage of WIS. The new algorithms also performed competitively with  $\text{LSTD-TO}(\lambda)$  in all tasks. Among the new algorithms,  $\text{WIS-GTD}(\lambda)$  had superior performance with large values of  $\lambda$ .

We also studied the sensitivity of the new algorithms with respect to their parameters. Although these algorithms replace the scalar constant step-size parameter of their base learner with an adaptive vector step size based on feature usage, the estimate of the usage depends on two new parameters: the initial value  $u_0$  and the recency weighting constant  $\eta$ . The initial value  $u_0$  of the usage vector can be interpreted as the inverse of the initial step size, and its tuning can be as extensive as that of the scalar step-size parameter in other algorithms. On the other hand,  $\eta$  can be viewed as the desired final step size. As a result, their product  $\mu = u_0\eta$  is unit free and requires less rigorous tuning.

In our final set of experiments, we compared the new  $O(n)$  on-policy algorithms:  $\text{U-TD}(\lambda)$  and  $\text{U-TO-TD}(\lambda)$ , with two  $O(n)$  on-policy algorithms:  $\text{TD}(\lambda)$  with accumulating traces and true online  $\text{TD}(\lambda)$ , which we call  $\text{TO-TD}(\lambda)$ .

Figure 2: Empirical comparison of the new  $O(n)$  usage-based algorithms with two existing  $O(n)$  TD algorithms on on-policy policy-evaluation tasks. Performance is measured in empirical normalized MSE (NMSE).

We used randomly generated MDPs to produce two on-policy policy-evaluation tasks. As the TD algorithms here estimate state-value functions, it sufficed to construct Markov Reward Processes (MRPs), which we obtained by choosing the number of actions  $m$  to be 1 in both tasks. Our first task used an MDP with 10 states:  $(10, 1, 3, 0.99\mathbf{I})$  and the second task used an MDP with 100 states:  $(100, 1, 10, 0.99\mathbf{I})$ . The feature vectors were binary representations of the state indices as in the off-policy tasks and were normalized to have unit length.

For each task, the performance of each algorithm was measured for different parameter values. For  $\text{TD}(\lambda)$  and  $\text{TO-TD}(\lambda)$ , the scalar step-size parameter  $\alpha$  was varied by powers of 10 with powers chosen from  $-3$  to  $1$  in steps of  $0.25$ . For  $\text{U-TD}(\lambda)$  and  $\text{U-TO-TD}(\lambda)$ , the parameter  $u_0$  was varied by powers of 10 with powers chosen from  $-1$  to  $3$  in steps of  $0.25$ . The rest of the parameters for all four algorithms were varied using the same values as in the off-policy tasks. Performance was measured using NMSE as in the off-policy tasks. For each run, we averaged this error over 100 steps for the first task and 1000 steps for the second. The final estimate is produced again by averaging over 50 independent runs.

Figure 2 shows the performance on both tasks for different  $\lambda$  with the rest of the parameters optimized. Left plot corresponds to MDP  $(10, 1, 3, 0.99\mathbf{I})$  and the right plot corresponds to MDP  $(100, 1, 10, 0.99\mathbf{I})$ . On both tasks, the new algorithms performed significantly better than their base learning algorithms for higher values of  $\lambda$  and performed equally well for the smaller ones. The standard error in each case was smaller than the width of the curves shown. This set of experiments suggests that the step-size adaptation based on the usage of features can be useful in both off-policy and on-policy tasks.

## 8 Discussion and Conclusions

Weighted importance sampling (WIS), one of the most effective variants of importance sampling, has long been ne-

glected in off-policy learning with parametric function approximation. Recently introduced WIS-LSTD( $\lambda$ ) extends WIS to linear function approximation and eligibility traces but is  $O(n^3)$  in computational complexity in the number of features. In this paper, we took this endeavor one step further and carried over much of the benefit of WIS to  $O(n)$  off-policy algorithms. In the process, we developed modifications of stochastic gradient descent that are more closely related to sample averages. This endeavor also resulted in developing a new online equivalence technique for deriving causal efficient updates from acausal intuitive updates, which was deemed essential for achieving  $O(n)$  updates for our new algorithms. On three off-policy policy-evaluation experiments, the new algorithms outperformed the existing  $O(n)$  off-policy algorithms and performed competitively with LSTD-TO( $\lambda$ ).

An intriguing outcome of our work is an adaptive vector step size that is updated based on the *usage* of features, which has emerged naturally from our goal to incorporate the sample average within SGD. It is distinct from the existing adaptive step-size algorithms but not the only possible one that can achieve a Monte Carlo equivalence. An interesting direction for future work would be to explore the other possible variants. Although beyond the scope of this work, it is interesting to investigate how the insights from the new step-size adaptation idea can be incorporated in existing step-size adaptation algorithms such as Autostep (Mahmood et al. 2012), vSGD (Schaul et al. 2013) or Adam (Kingma et al. 2014). Convergence analysis of the new algorithms is another interesting direction for future work.

## Abstract

We present results from an empirical evaluation of the impact of Bayesian network structure learning strategies on the learned structures. In particular, we investigate how learning algorithms with different optimality guarantees compare in terms of structural aspects and generalisability of the produced network structures. For example, in terms of generalization to unseen testing data, we show that local search algorithms often benefit from a tight constraint on the number of parents of variables in the networks, while exact approaches tend to benefit from looser parent restrictions. Overall, we find that learning strategies with weak optimality guarantees show good performance on synthetic datasets, but, compared to exact approaches, perform poorly on the more “real-world” datasets. The exact approaches, which guarantee to find globally optimal solutions, consistently generalize well to unseen testing data, motivating further work on increasing the robustness and scalability of such algorithmic approaches to Bayesian network structure learning.

## 1 INTRODUCTION

This work focuses on the well-known problem of learning the structure of a Bayesian network (BN) from data (Heckerman et al., 1995). The BN structure learning problem (BNSL) is to find a BN structure which optimizes a decomposable scoring function—typically, either a Bayesian posterior probability such as the Bayesian Dirichlet (BD) score or a penalized likelihood function. BNSL is NP-hard (Chickering, 1996), which poses challenges for developing algorithmic solutions for this important problem.

Methods proposed for solving BNSL on real-world datasets divide into approximate, local search methods, e.g., (Heckerman et al., 1995; Chickering, 2002; Teyssier and Koller,

2005; Tsamardinos et al., 2006), which do not offer quality guarantees (in terms of how well a given decomposable scoring function is optimized), and exact algorithms (Ott and Miyano, 2003; Koivisto and Sood, 2004; Silander and Myllymäki, 2006; Parviainen and Koivisto, 2009; de Campos and Ji, 2011; Yuan and Malone, 2013; Bartlett and Cussens, 2013) which produce guaranteed optimal solutions with respect to the scoring function. Often, the local search methods are computationally efficient, while the exact algorithms can require an exponential amount of time (and in cases, even memory).

The score of a BN structure is ideally a reflection of how well it models a training dataset. The general assumption has been that networks which model the training data well should also accurately reflect new data. However, it is well-known that a model can describe a training set very well, yet generalize poorly to new data (Mitchell, 1997). Thus, there is no guarantee that a network which optimizes a score for a training set will generalize well to new data.

There is currently no clear empirical evidence (for or against) on whether the increased computational efforts required by exact approaches to BNSL are justifiable in terms of performance of learned BNs on unseen testing data. All in all, the relationship between the chosen learning algorithm and the quality of the learned BN structures in terms of generalisability is not well understood. Furthermore, the choice of the learning algorithm used can affect structural properties of the learned networks in other ways. For example, for many of the exact algorithmic solutions to be applicable, in practice structural restrictions must be placed on the classes of BN structures considered during search. A commonly-applied restriction is a hard constraint on the number of parents allowed for each vertex in the network structures (Friedman et al., 1999). Since most scores incorporate a complexity penalty as a “soft constraint” favoring sparser networks, this is a practically-motivated restriction, as computing the scoring function for an arbitrary number of parents is in general infeasible (though pruning rules (de Campos and Ji, 2011) may in cases permit computing all necessary scores for datasets with few records).

However, the influence of such choices combined with the choice of the learning algorithm used—we refer to the combination of the two as a *learning strategy*—has not received much attention.

The aim of this work is to establish a more in-depth understanding of the aforementioned, currently not well-understood aspects of BNSL via an extensive empirical evaluation. Our aim is to shed light on the relationship of different learning strategies, based on four popular score-based structure learning algorithms, and the unknown discrepancy between training set scores and generalization. In particular, we address the following research questions for different fixed learning algorithms and training sets.

- Q1** How similar are structures found using different learning strategies?
- Q2** How do hard constraints on the number of parents in learned structures affect their generalization?
- Q3** How does the amount of training data affect the generalization of learned structures?
- Q4** Which learning strategies result in networks with the best generalization?

Our main contributions, based on a rigorous experimental setup, are the following. For Q1, we show that the different learning strategies tend to learn dissimilar network structures. With respect to Q2, we show that for small datasets, hard constraints limiting the maximum number of parents to 2 improves generalization on a few datasets for local search algorithms; however, optimal algorithms usually benefit from a higher limit. We answer Q3 by using increasingly large subsets of available training data. Regardless of the algorithms’ guarantees, more training data results in more accurate predictions on testing data. Finally, we address Q4 by considering all of the data collected during the evaluation. For some datasets, simple strategies such as the tractable Chow-Liu algorithm can provide good generalization. However, the simple strategies fail to generalize well on other datasets. Predictive likelihood results show that the optimal algorithms consistently generalize well.

While some of the observations made in this work, based on concrete empirical data, may appear to the reader as common knowledge, we note that to our best knowledge this is the first work which studies all of the question listed above thoroughly via empirical means. A previous related study is (Acid et al., 2004), which focuses on a case study of the choice of BNSL learning strategies for data from an emergency medical service. That study focused on Q1 for that particular domain and, orthogonally to the present work, the impact of the choice of scoring functions on the learning results. Furthermore, focusing on causal Bayesian networks, an evaluation of structural distance measures was presented in (de Jongh and Druzdzal, 2009). (Ueno, 2010;

Ueno, 2011) studied the effect of the equivalent sample size of BD on learned structures but did not consider predictive likelihood.

## 2 BACKGROUND

A Bayesian network (BN) (Pearl, 1988) is a compact representation of a joint probability distribution over random variables  $\mathbf{X} = \{X_1, \dots, X_n\}$ . It consists of a directed acyclic graph (DAG)  $G$ , in which each vertex in the graph corresponds to one of the random variables, and conditional probability distributions  $P(X_i|PA_i)$ , where  $PA_i$  is the set of parents of  $X_i$  in  $G$ . The (log) joint probability distribution over all of the variables is

$$\log P(X_1, \dots, X_n|G) = \sum_i^n \log P(X_i|PA_i).$$

Given a BN  $\mathcal{N}$  and a dataset  $d = \{d_1, \dots, d_N\}$ , where each  $d_r$  (record) is independent of the others, and a complete instantiation of  $\mathbf{X}$ , the likelihood of  $d$  given  $\mathcal{N}$  is

$$\log P(d|\mathcal{N}) = \sum_r^N \log P(d_r|\mathcal{N}) = \sum_r^N \sum_i^n \log P(X_i^r|PA_i^r), \quad (1)$$

where  $X_i^r$  and  $PA_i^r$  are the instantiations of  $X_i$  and its parents in record  $d_r$ , respectively. In total, Equation 1 consists of  $N \cdot n$  terms, each of which corresponds to the likelihood of one variable in one record given  $\mathcal{N}$ . We will refer to this as the *predictive likelihood* of  $\mathcal{N}$  on  $d$  and use the notation  $\ell^d$  when  $\mathcal{N}$  is clear from context.

Given a training dataset  $d_t$  and a scoring function  $s$ , the *Bayesian network structure learning problem* (BNSL) is to find a BN  $\mathcal{N}^* \in \arg \max_{\mathcal{N}} s(d_t, \mathcal{N})$ , i.e., a Bayesian network structure with the best score in terms of the scoring function  $s$ . The scoring function  $s$  is usually a Bayesian posterior probability or penalized likelihood function which measures how well  $\mathcal{N}$  “fits”  $d_t$ . In practice,  $s$  is *decomposable* (Heckerman et al., 1995), i.e.,  $s(d_t, \mathcal{N}) = \sum_i s(d_t, X_i, PA_i)$ . The  $s(d_t, X_i, PA_i)$  terms are often called *local scores*.

## 3 LEARNING ALGORITHMS

Our primary goal is to compare the impact of the guarantees of structure learning algorithms to the generalization of learned networks to unseen testing data. For this, we use four popular score-based learning algorithms with a range of optimality guarantees. In the following discussion, optimality guarantees refer to behavior with respect to the scoring function and a training dataset. In particular, optimality *does not* refer to behavior on unseen testing data.

**Hill climbing with a tabu list and random restarts** (*tabu*). Hill climbing is a widely-used local search technique in discrete optimization (Russell and Norvig, 2003)

that typically finds local optima for an objective function  $f$  by maintaining a *current* solution and applying *search operators*. At each step, all search operators are tentatively applied to the current solution to find its *neighborhood*. The member of the neighborhood which results in the biggest improvement to  $f$  is selected as the new current solution. This process is repeated until a local optimum is found, that is, when the current solution is better than everything in its neighborhood. *Random restarting* is a strategy to escape from a local optimum by randomly changing a locally optimal solution and restarting the search from the new random solution. The *tabu list* strategy (Glover, 1990) augments random restarts by keeping track of recently visited solutions; solutions in the tabu list are ignored when considering new neighborhoods. Even with random restarts and the tabu list, the algorithm is unable to provide guarantees on how close the found local optima are to the globally optimal solutions in terms of their scores.

In the context of Bayesian networks, each solution corresponds to a network; the search operators considered here are edge addition, deletion and reversal (as long as the resulting structure is a DAG). The objective function  $f$  is exactly the scoring function  $s$ .

**Max-min hill climbing (*mmhc*).** Max-min hill climbing (Tsamardinos et al., 2006) is a two-phase hybrid learning algorithm. During the first phase, it uses a set of statistical independence tests to identify arcs that are forbidden from appearing in the learned network. The second phase uses *tabu* to find local optima within this restricted space. Here we use a mutual information statistical test during the first phase. The first phase of *mmhc* is similar to constraint-based methods such as *pc* (Spirtes et al., 2000). Empirically, *mmhc* has been shown to outperform several other state-of-the-art algorithms, including PC, sparse candidate, three phase dependency analysis, optimal reinsertion and greedy equivalence search (Tsamardinos et al., 2006). While *mmhc* does guarantee to recover BN structures when the data are faithful to a DAG in the large sample limit (Tsamardinos et al., 2006), it does not offer any non-trivial guarantees about the generalization quality of the learned network for unfaithful, finite datasets.

**Chow-Liu (*cl*).** The Chow-Liu algorithm (Chow and Liu, 1968) is an exact, polynomial-time algorithm for finding an optimal tree-structured BN. The algorithm calculates the mutual information between all pairs of variables to form a weighted graph. The maximum spanning tree through the graph corresponds to the optimal tree-structured BN.

**Provably optimal (*opt*).** Several algorithms have been developed which are guaranteed to find a network which optimizes  $s$  (Ott and Miyano, 2003; Koivisto and Sood, 2004; Silander and Myllymäki, 2006; de Campos and Ji, 2011; Parviainen and Koivisto, 2009; Cussens, 2011; Yuan and Malone, 2013). In practice, these algorithms take as input

a set of local scores for each variable and find an optimal network with respect to these scores. In this work, we use two of these algorithms which have previously (Malone et al., 2014) been shown to perform well on a variety of datasets. The first (Yuan and Malone, 2013) is based on casting BNSL as a shortest-path finding problem; it then uses  $A^*$  to solve the shortest path problem, which gives the optimal network for the given local scores. The second algorithm (Bartlett and Cussens, 2013) creates an integer linear program (ILP) based on the local scores. The solution to the ILP corresponds to the optimal network for the local scores. Both  $A^*$  and ILP are guaranteed to find (equivalent) optimal network structures. In this work, our goal is to understand the impact of the optimality guarantee on generalization. Since we are not interested in the relative performance in terms of running time or memory consumption among the algorithms, we make no distinction between the different optimal algorithms.

## 4 QUALITY MEASURES

In order to address our research question Q1, we propose a normalized version of the structural Hamming distance to quantify structural similarity. Research questions Q2–Q4 concern generalization; we propose measures based on the predictive likelihood of Equation 1 to evaluate these results.

### 4.1 Structural Similarity

We evaluate the structural similarity of two networks with structural Hamming distance (SHD) (Tsamardinos et al., 2006). The SHD between two networks is calculated by transforming the two networks into the partially directed acyclic graphs (PDAGs) representing their equivalence classes. The number of edge additions, deletions, reversals, and orientation changes (converting an undirected edge into a directed edge and vice versa) to transform one PDAG into the other is the SHD. The motivation behind SHD lies in equivalence classes of BNs; using different conditional probability distributions, different DAG structures can describe exactly the same set of joint probability distributions (Chickering, 1995); these DAGs belong to the same *equivalence class*. The SHD is 0 between DAGs in the same equivalence class. Thus, in a sense, SHD serves as an imperfect proxy for measuring the distance between the distributions represented by two DAGs. In order to facilitate comparison across datasets with differing numbers of variables, we use a normalized form  $\widehat{SHD}$  of SHD:

$$\widehat{SHD}_d = \frac{SHD_d}{\binom{n_d}{2}/2}, \quad (2)$$

where  $SHD_d$  is the structural Hamming distance between two networks for dataset  $d$ ,  $n_d$  is the number of variables in dataset  $d$  and  $\binom{n_d}{2}$  is the binomial coefficient. The normalization constant  $\binom{n_d}{2}/2$  is approximately the maximum

number of edges present in a network structure, and hence also in the order of the SHD between two networks learned for dataset  $d$ .

## 4.2 Predictive Likelihood

We use the predictive likelihood to evaluate the generalization capability of the learned networks. In particular, for a dataset  $d$  and learning strategy  $l$  we calculate the per-prediction-likelihood,  $\ell_{pp}^{d,l}$ , which is the likelihood of each prediction on the test set:

$$\ell_{pp}^{d,l} = -\frac{\sum_i^{10} \ell_i^{d,l}}{N_d \cdot n_d}, \quad (3)$$

summing over the folds  $i = 1..10$ , where  $\ell_i^{d,l}$  is the predictive likelihood according to Equation 1 on the test set for fold  $i$  using learning strategy  $l$  (see Section 5.1 for cross-validation discussion),  $N_d$  is the number of records in the test set, and  $n_d$  is the number of variables in the dataset.

The numerator of Equation 3 is the sum over all of the test set predictive likelihoods for learning strategy  $l$  and dataset  $d$ . As discussed in Section 2, each  $\ell_i^{d,l}$  term comprises  $\frac{N_d}{10} \cdot n_d$  terms. In total, the sum in the numerator includes  $N_d \cdot n_d$  terms, each of which corresponds to the log probability of one variable of one record from the test set. Consequently, the denominator serves as a normalizing constant, and  $\ell_{pp}^{d,l}$  is the average log probability of each prediction.

In order to compare learning strategies, we normalize the  $\ell_{pp}^{d,l}$  values for each dataset between 0 and 1 to obtain

$$\hat{\ell}_{pp}^{d,l} = 1 - \frac{\ell_{pp}^{d,l} - \min_{l'} \{\ell_{pp}^{d,l'}\}}{\max_{l'} \{\ell_{pp}^{d,l'}\} - \min_{l'} \{\ell_{pp}^{d,l'}\}} \quad (4)$$

where  $l'$  ranges over all learning strategies. Note that, after normalization, the learning strategy with the best  $\ell_{pp}^{d,l}$  has  $\hat{\ell}_{pp}^{d,l} = 0$  while the worst learning strategy has  $\hat{\ell}_{pp}^{d,l} = 1$ .

It is important to note that  $\ell_{pp}^{d,l}$  and  $\hat{\ell}_{pp}^{d,l}$  consider all variables equally. In particular, they do not consider a special “class” variable.

## 5 EXPERIMENTAL SETUP

We continue by describing the experiment setup.

### 5.1 Datasets

We used datasets from a previous wide-scale empirical study that focused on predicting the efficiency of BNSL algorithms (Malone et al., 2014)<sup>1</sup>. In total, we obtained

<sup>1</sup>The datasets are available at <http://bnportfolio.cs.helsinki.fi/>. Please see the original study for data pre-processing.

Table 1: Basic dataset characteristics

| Dataset                     | Type       | $n$ | $N$    |
|-----------------------------|------------|-----|--------|

| zoo                         | <i>uci</i> | 17  | 100    |

29 datasets from two categories used in that study: 16 are “real” datasets from the UCI Machine Learning Repository (*uci*), and further 13 are generated using logic sampling from well-known benchmark networks (*sam*).

As Table 1 shows, the number of variables in the datasets ranges from 17 to 60, and the number of records ranges from about 30 to 20 000. We used standard 10-fold cross-validation in order to evaluate the learning strategies. Datasets were randomly split into 10 folds. Unless otherwise noted, all results are averages over all 10 folds. For a few datasets, not all learning strategies completed on all folds. In these cases, the averages were adjusted to properly account for the number of completed folds.

### 5.2 Learning and Inference

Most of the learning algorithm implementations are publicly available. In all cases, default parameter values were used (excluding number of parents).

**Exact algorithms.** The previous study (Malone et al., 2014) found that the ILP algorithm usually ran faster than A\* for datasets with up to 10 000 local scores. In order to limit the computational requirements of this study, we used this simple decision rule to select either ILP or A\* for each dataset. We used a time limit of 2 hours. If the selected algorithm failed, the other one was used.

**Parent limit.** For all algorithms except *cl*, we used hard limits of 2 and 8 on the number of parents. This constraint serves two purposes. First, a hard limit on the complexity of the learned network allows evaluation of the learning algorithms in the different search spaces. In particular, the space defined by a parent limit of 2 is a subset of the space defined by a parent limit of 8. Thus, the optimal solution for the at-most-8-parents space is always at least as good as that of the at-most-2-parents space. Second, calculating all local scores for large parent limits is impractical.

Table 2 outlines the seven combinations of learning algorithms and parent limits used in the evaluation.

**Scoring function.** We selected the commonly-used Bayesian Dirichlet with score equivalence and uniform structure prior (BDeu) scoring function (Heckerman et al., 1995) with an equivalent sample size (ESS) of 1 as the scoring function. Note that, while several previous studies (Sillander et al., 2008; Liu et al., 2012; Korucuoglu et al., 2014) have demonstrated that BDeu is sensitive to the ESS, BDeu with an ESS of 1 is a commonly-used score (Acid et al., 2004), which motivates this choice.

**Inference.** For all learned structures, parameter values were set using a symmetric Dirichlet prior with a concentration parameter of 1 (which is equivalent to Laplacian smoothing). All testing likelihood calculations were performed by multiplying relevant family factors.

## 6 RESULTS

In this section, we address each of the research questions Q1–Q4. In Section 6.1, we answer Q1 by showing that  $\widehat{\text{SHD}}$  is typically high among networks learned using different algorithms, particularly for *uci* datasets. In Section 6.2, we show that, surprisingly, the answer to Q2 depends upon learning algorithm and dataset. We address Q3 in Section 6.3, where we find that increasing training data both improves prediction accuracy and reduces variance among cross-validation folds. In Section 6.4 we demonstrate that somewhat unexpectedly, for *sam* datasets simple learning strategies like *cl* perform well. The *opt* strategy consistently generalizes better for *uci* datasets. These observations suggest fundamental differences in the *uci* and *sam* datasets.

### 6.1 Structural Similarity

We address Q1 by evaluating the similarity of learned structures using  $\widehat{\text{SHD}}$  in two different settings. We first consider the similarity of structures learned using the same algorithm on different cross-validation folds. We then investigate the similarity of structures learned using different algorithms on the same cross-validation fold. As a trivial baseline learning “result,” the empty network with no edges, *empty*, is also included. We stress that the goal of Q1

is to evaluate the structural similarity of learned networks to each other; we do not consider e.g. similarity to “gold standard” networks which do not exist for *uci* datasets.

**Variation within a learning algorithm.** Due to the cross-fold validation strategy, each algorithm results in multiple networks on each dataset. We compared the  $\widehat{\text{SHD}}$  among all pairs of networks learned using a single learning strategy. Figure 1(top) shows that, for *sam* datasets, the difference among learned networks was usually small. In contrast, Figure 1(bottom) shows that *uci* datasets result in more varied networks. The variation for *cl* in Figure 1(bottom, right) is much lower than those of either *opt*<sub>8</sub> (left) or *tabu*<sub>2</sub> (center). This highlights how the reduced search space decreases variability among optimal structures.

Interestingly, for *uci* datasets, *opt*<sub>8</sub> networks tend to have a slightly higher  $\widehat{\text{SHD}}$  than those of *tabu*<sub>2</sub>. However, the variance for *opt*<sub>8</sub> is smaller than that of *tabu*<sub>2</sub>. One interpretation is that *opt*<sub>8</sub> networks are, in terms of  $\widehat{\text{SHD}}$ , “equally spaced.” On the other hand, some pairs of the *tabu*<sub>2</sub> networks are quite similar, while others have more pronounced differences. An explanation for this phenomenon is the greedy search strategy of *tabu*<sub>2</sub>. In the beginning stages of the search, *tabu*<sub>2</sub> is likely to select the same dominant edges, regardless of the nuances of the dataset at hand. In contrast, *opt*<sub>8</sub> selects accurate substructures and optimally combines them, so it may disregard single strong edges in favor of more informative structures. Another explanation is that the search space for *tabu*<sub>2</sub> is more constrained than that of *opt*<sub>8</sub>. As further evidence for the more constrained space leading to more similar networks, both *cl* (Figure 1(bottom, right)) and *opt*<sub>2</sub> on *uci* datasets (not shown) typically result in smaller  $\widehat{\text{SHD}}$  than *tabu*<sub>2</sub>.

**Variation between learning algorithm.** We additionally compared the average  $\widehat{\text{SHD}}$  among networks learned using different strategies on the same training set. Figure 2 shows that some of the strategies learn quite similar networks, while for other strategies the networks differ quite a bit. Perhaps unsurprisingly, the same learning algorithm with different parent limits often result in similar networks. The *mmhc* networks are quite similar to *empty*, which suggests that they are very sparse. Many of the datasets have fewer than 1 000 records. So the statistical tests employed at the beginning of *mmhc* are often unable to detect dependencies, and thus many possible edges are discarded before beginning the score-based search.

In general, all of the learning strategies tend to learn similar networks for the *sam* datasets, while the *uci* datasets result in more diverse structures. Despite this, some patterns among the pairs of learning strategies are consistent among both types of datasets. For example, *opt*<sub>8</sub> and *cl* exhibit the highest average  $\widehat{\text{SHD}}$ . On the other hand, *tabu*<sub>2</sub> and *opt*<sub>2</sub> are more similar than most other pairs for the *uci* datasets, but not for *sam* datasets. This again suggests that the more

Table 2: Learning algorithms used in the study

| Algorithm   | Parent limits | Abbreviation                                      | Availability   |
|-------------|---------------|---|--|
| <i>tabu</i> | 2, 8          | <i>tabu<sub>2</sub></i> , <i>tabu<sub>8</sub></i> | <a href="http://www.bnlearn.com/">http://www.bnlearn.com/</a>  |

Figure 1: The  $\widehat{SHD}$  values for *opt<sub>8</sub>* (left), *tabu<sub>2</sub>* (center) and *cl* (right). The top row contains *sam* datasets, and the bottom row contains *uci* datasets. The datasets are sorted in ascending number of records. Note the different scale for *sam* and *uci*.

constrained search space leads to more similar structures.

In summary for Q1, the similarity of learned network structures depends upon the nature of the training dataset. Typically, though, both within and between learning algorithms, *sam* datasets result in similar learned structures, while structures learned from *uci* datasets are more diverse.

## 6.2 Impact of Restricting Parent Set Size

We study question Q2 by comparing the  $\hat{\ell}_{pp}^{d,l}$  among datasets when using  $k = 2$  and  $k = 8$  as the maximum number of parents for each learning algorithm. The BDeu score implicitly restricts the maximum number of selected parents as a soft constraint by integrating over all parameterizations of parent instantiations. Other scores, such as MDL, explicitly incorporate a complexity penalty to discourage large parent sets. In both cases, though, this restriction is a soft constraint. Here consider the maximum number of parents as a *hard constraint*.

**Optimal.** Figure 3 (left) shows the performance (in terms of  $\hat{\ell}_{pp}^{d,l}$ ) of generalization using *opt<sub>k</sub>* for parent limits  $k = 2, 8$ . The (left, top) and (left, bottom) plots show distinctly

different patterns. Figure 3 (left, top) clearly shows that *opt<sub>2</sub>* results in better generalization for *sam* datasets with 100 records. However, as the number of records increases, *opt<sub>8</sub>* yields better performance. In contrast, for *uci* datasets, *opt<sub>8</sub>* is almost always better.

**Tabu.** Contrasting the results for *opt*, Figure 3 (center, bottom) shows that *tabu<sub>2</sub>* generalizes better than *tabu<sub>8</sub>* for *uci* datasets. One possible explanation for this difference is that the greedy strategy of *tabu<sub>8</sub>* favors structures which improve the likelihood while increasing the complexity of the learned structures. Thus, the learned structure overfits the training data and does not generalize well to testing data. In contrast, as *opt* is guaranteed to find the best-scoring structure, it finds structures which better balance training set likelihood and complexity. The hard constraints on the number of parents for *tabu<sub>2</sub>* forbid it from selecting the complex structures. Both *tabu<sub>2</sub>* and *tabu<sub>8</sub>* typically generalize well on *sam* datasets.

**MMHC.** Figure 3 (right) shows that the hard parent limit has little effect on  $\hat{\ell}_{pp}^{d,l}$  for *mmhc*. The first phase of *mmhc* uses a set of statistical independence tests to restrict the learned network structures. For many of the datasets, the

Figure 2: The average  $\widehat{\text{SHD}}$  values between networks learned using the same training set among all algorithms for *sam* (top) and *uci* (bottom) datasets. Lighter colors indicate more similar structures. The lower triangle is left empty due to  $\widehat{\text{SHD}}$  being symmetric.

relatively small number of records restricts the power of these tests and leads to a very small search space in the second phase, despite initially allowing many more structures for the 8-parent space.

Based on these observations, in the rest of this study we will focus on  $opt_8$ ,  $tabu_2$  and  $mmhc_8$ .

In summary, the answer to Q2 clearly depends both on the training datasets and learning algorithm; the global guarantees of  $opt$  allow it to fully take advantage of the larger  $k = 8$  search space, but the local search strategy of  $tabu$  performs better in the more restricted  $k = 2$  space.

More data is required to accurately estimate the conditional probability distributions for complex structures (with more parameters). This may explain why  $opt_2$  generalizes better than  $opt_8$  for datasets with a small number of records.

### 6.3 Impact of Amount of Training Data

To investigate the impact of the amount of available training data, to answer Q3 we compared how  $\ell_{pp}^{d,l}$  of  $opt_8$ ,  $tabu_2$  and  $cl$  behave as the number of records available for training increases. Figure 4 shows that for all algorithms on both *sam* and *uci* datasets, more records lead to better  $\ell_{pp}^{d,l}$ . Furthermore, the plots also show that with more records, the variance of  $\ell_{pp}^{d,l}$  decreases. Interestingly, the plot also shows that  $cl$  performs better than  $opt_8$  and  $tabu_2$  on *carpo*, a *sam* dataset, when only 100 records are available. This again

highlights that restricted model classes can generalize better than those with more parameters, especially when little data is available to estimate the parameter values. Despite the differences in guarantees,  $opt_8$ ,  $tabu_2$  and  $cl$  perform similarly for *carpo*<sub>1 000</sub> and *carpo*<sub>10 000</sub>.

As with *carpo*, for the *uci agaricus* dataset, the likelihood improves and variance decreases as the number of records increases. However,  $opt_8$  improves from  $\ell_{pp}^{d,l} \approx 0.7$  for 81 records to  $\ell_{pp}^{d,l} \approx 0.48$  with 812 records. In contrast,  $tabu_2$  only improves from  $\ell_{pp}^{d,l} \approx 0.7$  to about  $\ell_{pp}^{d,l} \approx 0.55$ , and  $cl$  exhibits even less improvement. For *agaricus*,  $opt_8$  using only 812 records results in better generalization than  $tabu_2$  or  $cl$  with all 8 123 records.

We observed similar behavior on other *sam* and *uci* datasets as the amount of training data was varied. Unlike in the case of Q1 and Q2, the same general trends hold for all algorithms and datasets with respect to Q3. Namely, the predictive likelihood improves and variance decreases as the size of the training set increases.

### 6.4 Comparison Across Learning Strategies

Finally, based on the previous results, we studied Q4 by choosing the best learning strategies and comparing their  $\hat{\ell}_{pp}^{d,l}$  across all of the datasets. In essence, we fix the training set while varying the learning strategy. Additionally, *empty* (with no edges) was included as a baseline. The results in Figure 5 show several expected trends and a few surprises. As expected, *empty* is the worst on almost all of the datasets. Due to its structural similarity to *empty*,  $mmhc_8$  was typically worse than the other strategies. These trends are consistent for both *sam* and *uci* datasets. For *sam* datasets,  $tabu_2$  and  $opt_8$  have very similar  $\hat{\ell}_{pp}^{d,l}$  for most datasets; the  $\hat{\ell}_{pp}^{d,l}$  of  $cl$  is also surprisingly similar to that of the two more “sophisticated” strategies.

For *uci* datasets,  $opt_8$  continues to consistently have good  $\hat{\ell}_{pp}^{d,l}$ . On the other hand,  $cl$  and  $tabu_2$  exhibit much more inconsistency in their generalization relative to  $opt_8$ . For some datasets, such as *dermatology* and *kredit*, they match  $opt_8$ ; on others, such as *credit* and *tumor*,  $cl$  and  $tabu_2$  do not generalize well. Surprisingly,  $cl$  exhibits the best  $\hat{\ell}_{pp}^{d,l}$  for *letter*, the *uci* dataset with the most records.

For Q4,  $opt$  guarantees consistently translate into networks with good generalization. Algorithms with weaker guarantees produce networks with inconsistent generalization.

**Comments on Datasets.** Besides the behavior of the learning algorithms, these results also suggest differences in the datasets themselves. In particular, it seems that *sam* datasets are “easier,” in the sense that many learning strategies find networks which generalize well. On the other hand, only the strategy with strong guarantees consistently generalizes well on *uci* datasets. In some sense, this result is not surprising. The *sam* data is by construction accurately

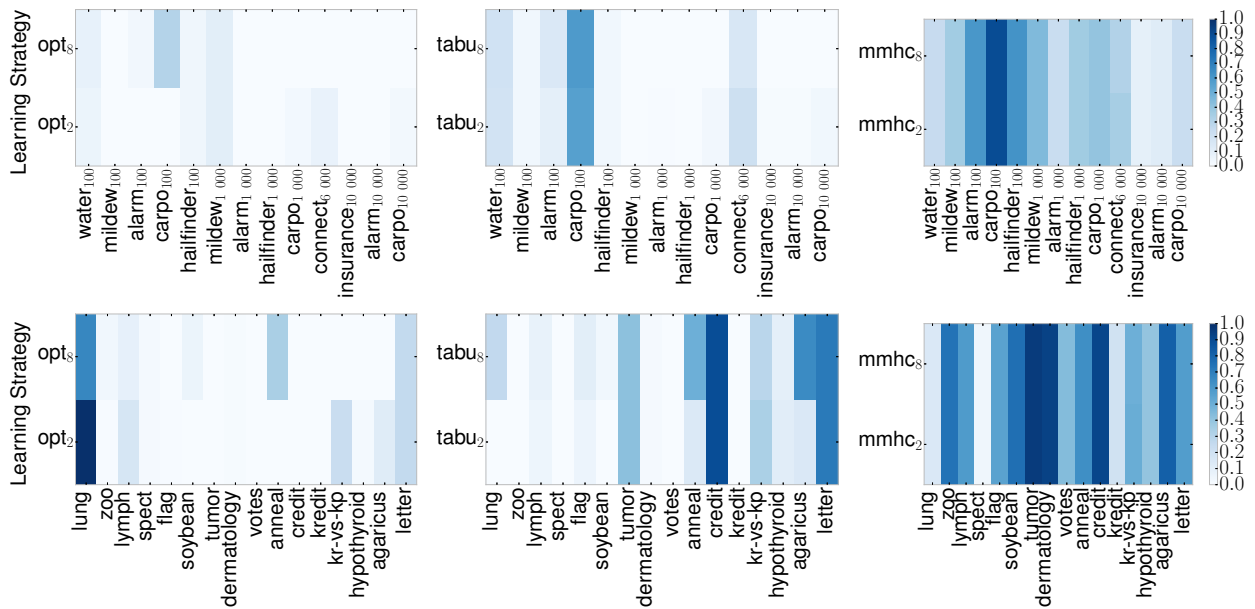

Figure 3: The  $\hat{\ell}_{pp}^{d,l}$  values for  $opt$  (left),  $tabu$  (center) and  $mmhc$  (right) with a hard limit of  $k = 2$  and  $k = 8$  for  $sam$  (top) and  $uci$  (bottom) datasets. The datasets are sorted in ascending number of records. Lighter colors indicate better performance. Close inspection of the  $mmhc$  strategies show some slight difference; however, they are difficult to discern in the scaled image.

Figure 4: The  $\hat{\ell}_{pp}^{d,l}$  values for using the  $opt_8$  (left),  $tabu_2$  (center), and  $cl$  (right) learning strategies as the number of records increases. The top row is for the  $carpo$  dataset ( $sam$ ); the bottom row is for the  $agaricus$  dataset ( $uci$ ). Note the different y-axes for the plots. Lower values and smaller boxes are better.

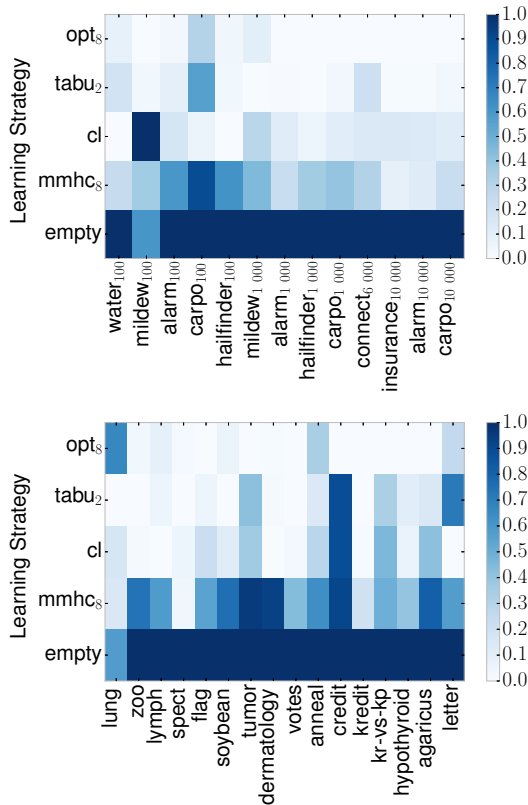

Figure 5: The  $\hat{\rho}_{pp}^{d,l}$  values for the best learning strategies. The empty network is included as a baseline. The *sam* datasets are shown in the top heatmap, and *uci* datasets are in the bottom. The datasets are sorted in ascending number of records. Lighter colors indicate better performance.

modeled by a BN, while it is very unlikely that *uci* datasets are faithful to any BN. These caveats are also important for future evaluations.

## 7 CONCLUSIONS

In this work, we systematically evaluated the impact of learning strategy, including choice of learning algorithm and hard constraints on the number of parents for variables in the network, on the properties of the learned network. Our experiments address the four research questions introduced in Section 1. In particular, we answered Q1 by showing that different learning strategies result in dissimilar structures, particularly for *uci* datasets. For Q2, we showed that for small *sam* datasets, *opt* generalizes better when constrained to 2 parents; however, for all other datasets considered in this study, *opt*<sub>8</sub> performed better. In contrast, *tabu*<sub>2</sub> almost always outperformed *tabu*<sub>8</sub>. Q3 had the clearest answer of the four questions; increasing the size of the training set consistently both improved the predictive likelihood and decreased its variance across cross-validation

folds. Finally, with respect to Q4, for the datasets in this evaluation, *opt* consistently results in networks with good generalization. Nevertheless, for some of the *sam* datasets, simpler strategies such as the polynomial-time Chow-Liu algorithm yielded nearly as good generalization. In our view, these results justify the research into learning optimal BN structures in large, complex spaces.

The aim of the study was to better understand how the combination of learning strategy and dataset affect generalization. Consequently, we deliberately disregarded the runtime and memory usage of the studied learning strategies. These are important constraints, especially for *opt*, i.e., exact algorithms which provide provably optimal network structures with respect to the score-based objective function. However, the results clearly show that, whenever possible (as long as the computational resources allow it), it is worthwhile to use *opt*. Similarly, we did not evaluate the SHD between learned network structures and a “gold standard” network because this does not directly reflect generalization. Also, trustworthy “gold standard” networks do not generally exist for real-world datasets.

This empirical study clarifies some common assumptions about relationship between structure learning algorithms and learned Bayesian network structures, including empirically observed conditions for strong theoretical guarantees translating into improved empirical results. The results suggest many interesting questions for further study. For example, the finding that quite simple networks can generalize well suggests that a scoring function with a high complexity penalty, such as the Bayesian Information Criterion (BIC), might yield networks with good predictive capabilities. Another interesting question concerns the impact of more sophisticated restrictions on learned networks structures. For example, recently several algorithms (Korhonen and Parviainen, 2013; Berg et al., 2014; Parviainen et al., 2014) have been proposed which find provably optimal BNs with bounded treewidth, resulting in networks for which exact inference is provably tractable. As bounded treewidth represents another well-principled approach to constraining complexity of the learned networks, an interesting question is whether the quality of the learned (optimal) networks is affected by such a stringent constraint. Other extensions of this work would be to involve yet more structure learning algorithms (such as the Greedy Equivalence Search (Chickering, 2002)), and extending from using single structure for predictive inference to a more Bayesian approach by collecting several high-scoring networks and averaging their predictions. Additionally, the predictive likelihood analysis is not restricted to Bayesian networks; extensions to other generative models, like Markov random fields, would also be of interest.

## Abstract

Many real-world domains are inherently *relational* and *temporal*—they consist of heterogeneous entities that interact with each other over time. Effective reasoning about causality in such domains requires representations that explicitly model relational and temporal dependence. In this work, we provide a formalization of temporal relational models. We define temporal extensions to abstract ground graphs—a lifted representation that abstracts paths of dependence over all possible ground graphs. Temporal abstract ground graphs enable a sound and complete method for answering *d*-separation queries on temporal relational models. These methods provide the foundation for a constraint-based algorithm, TRCD, that learns causal models from temporal relational data. We provide experimental evidence that demonstrates the need to explicitly represent time when inferring causal dependence. We also demonstrate the expressive gain of TRCD compared to earlier algorithms that do not explicitly represent time.

## 1 INTRODUCTION

Recent work in artificial intelligence has devoted increasing attention to learning and reasoning with causal knowledge. Causality is central to understanding the behavior of complex systems and to selecting actions that will achieve particular outcomes. Thus, causality is implicitly or explicitly central to mainstream AI areas such as planning, cognitive modeling, computational sustainability, game playing, multiagent systems, and robotics. Causal inference is also central to many areas beyond AI, including medicine, public policy, and nearly all areas of science.

Substantial research advances have been made over the past several decades that allow the structure and param-

eters of causal graphical models to be learned from observational data. As early as the 1990s, researchers developed constraint-based algorithms, such as the IC [Pearl and Verma, 1991] and PC [Spirtes *et al.*, 2000] algorithms, that leverage the connection between the graphical criterion of *d*-separation and the conditional independencies that are inferred to hold in the underlying distribution, in order to learn the structure of causal graphical models from data.

In this work, we significantly extend the expressiveness of the models learnable with constraint-based algorithms. Specifically, we provide a formalization of temporal relational models, an expressive class of models that can capture probabilistic dependencies between variables on different types of entities within and across time points. We extend the notion of abstract ground graphs [Maier *et al.*, 2013b]—a lifted representation that allows reasoning about the conditional independencies implied by a relational model—for temporal relational models, and we show that temporal abstract ground graphs are a sound and complete abstraction for ground graphs of temporal relational models. Temporal abstract ground graphs can be used to answer *d*-separation queries for temporal relational models. We also extend an existing constraint-based algorithm for inferring causal dependence in relational data—the relational causal discovery (RCD) algorithm—to incorporate time, thus providing a constraint-based method that learns causal models from temporal relational data.

## 2 RELATIONAL MODELS

Propositional representations, such as Bayesian networks, describe domains containing a single entity class. Many real world systems comprise instances from multiple entity classes whose variables are interdependent. Such domains are often referred to as *relational*. In this section, we introduce basic concepts of relational representations that exclude time.

A *relational schema*  $\mathcal{S} = (\mathcal{E}, \mathcal{R}, \mathcal{A}, \text{card})$  specifies the types of entities, relationships, and attributes that exist in a domain. It includes a cardinality function that constrains

$[Course, Takes, Student].gpa \rightarrow [Course].difficulty$

Figure 1: Relational model for the example domain. The underlying relational schema (ER diagram) is shown in gray.

Figure 2: Example relational skeleton for the schema shown in Figure 1.

the number of times an entity instance can participate in a relationship. A relational schema can be depicted with an Entity-Relationship (ER) diagram. Figure 1 shows an example ER diagram (in gray) that describes a simplified university domain. The domain consists of two entity classes (*Student* and *Course*), and one relationship class (*Takes*). The entity class *Student* has one attribute, *gpa*, and the entity class *Course* has one attribute, *difficulty*. The cardinality constraints are shown with crow’s feet notation—students can enroll in multiple courses and a course can be taken by multiple students. A *relational skeleton* is a partial instantiation of a relational schema. It specifies the entity and relationship instances that exist in the domain. Figure 2 shows an example relational skeleton for the relational schema of Figure 1. The skeleton consists of two *Student* instances, Alice and Bob, and two *Course* instances, CS101 and CS201. Alice is taking CS101 and Bob is taking both courses.

Given a relational schema, we can specify *relational paths*, which intuitively correspond to ways of traversing the schema. For the schema shown in Figure 1, possible paths include  $[Student, Takes, Course]$  (the courses a student takes), as well as  $[Student, Takes, Course, Takes, Student]$  (other students that take the same courses). *Relational variables* consist of a relational path and an attribute that can be reached through that path. For example, the relational variable  $[Student, Takes, Course].difficulty$  corresponds to the difficulty of the courses that a student takes. Probabilistic dependencies can be defined between relational variables. Dependencies are said to be in canonical form when the path of the effect (or *outcome*) relational variable is a single item. For canonical dependencies, the path of the cause (or *treatment*) relational variable describes how dependence is induced. As an example, consider the

Figure 3: Ground graph for the model of Figure 1 applied on the relational skeleton of Figure 2.

following *relational dependency*

$$[Course, Takes, Student].gpa \rightarrow [Course].difficulty$$

which states that the *difficulty* of a course is affected by the *gpa* of students taking that course. Presumably, instructors adjust the difficulty of the course based on the grade-point average of enrolled students.

A *relational model*  $\mathcal{M} = (\mathcal{S}, \mathcal{D}, \Theta)$  is a collection of relational dependencies defined over a single relational schema along with their parameterizations (a conditional probability distribution for each attribute given its parents). The structure of a relational model can be depicted by superimposing the dependencies on the ER diagram of the relational schema, as shown in Figure 1, and labeling each arrow with the corresponding relational dependency.

Given a relational model  $\mathcal{M}$  and a relational skeleton  $\sigma$ , we can construct a *ground graph*  $GG_{\mathcal{M}\sigma}$  by applying the relational dependencies as specified in the model to the specific instances of the relational skeleton. Figure 3 shows the ground graph for the model of Figure 1 applied on the relational skeleton of Figure 2. In this work, we restrict our attention to relational models that do not contain the kind of relational autocorrelation that gives rise to cycles in the ground graph.

### 3 TEMPORAL RELATIONAL MODELS

Relational models can be extended with a temporal dimension to model probabilistic dependencies over time. Such an extension is similar to the way in which dynamic Bayesian networks (DBNs) extend Bayesian networks [Murphy, 2002]. A temporal relational model can be thought of as a sequence of time points, each of which is associated with a (non-temporal) relational model, and a set of dependencies that cross time points. Because dependencies in this model have a causal interpretation, dependencies across time points are only directed from the past to the future.

In this section, we extend the relational notions presented in Section 2 to include time. We assume that (1) time is discrete; (2) the schema is static; (3) relational dependencies do not change over time; (4) the temporal relational skeleton is given *a priori*; (5) the first-order Markov assumption

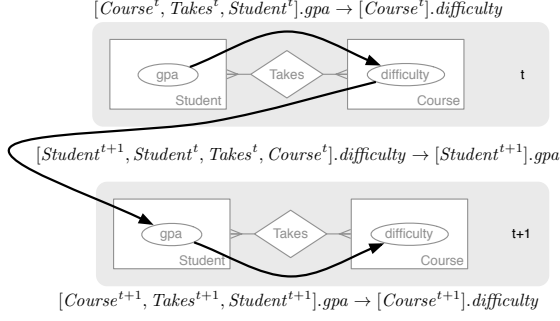

Figure 4: Example structure of a temporal relational model.

Figure 5: Example temporal relational skeleton for the schema shown in Figure 4.

holds (i.e., treatment and outcome can be at most one time point apart); and (6) all entities participating in a relationship are contemporaneous with the relationship.

Under these assumptions, the structure of a temporal relational model can be represented by using only two time points, as shown in Figure 4. Every time point has the same relational schema, shown in gray. A *temporal relational skeleton* provides a partial instantiation of a temporal relational schema. It specifies the entity and relationship instances that exist in each time point. Note that different sets of entity and relationship instances may be present in each time step. An example temporal relational skeleton is shown in Figure 5. In this case, both time points have the same set of entity instances (Alice and Bob are instances of the *Student* entity, CS101 and CS201 are instances of the *Course* entity). However, the instances of the relationship *Takes* differ. In  $t = 0$ , Alice takes CS101 and Bob takes CS201. In  $t = 1$ , Alice takes CS201 and Bob takes no classes.

*Temporal relational paths* capture possible ways to traverse the temporal schema; therefore, they can cross time points. For example, a temporal relational path is  $[Student^{t+1}, Student^t, Takes^t, Course^t]$ , which describes the classes that a student took in the previous semester. More formally, a temporal relational path is a sequence of non-temporal relational paths (relational paths within a time point) and “jumps” between neighboring time points. These jumps can happen at both entities and relationships because each choice encodes a distinct semantics. For example, the relational path  $[Student^{t+1}, Student^t, Takes^t, Course^t]$  describes the courses that a student took in the previous semester, while the path  $[Student^{t+1}, Takes^{t+1}, Course^{t+1}, Course^t]$

first finds the courses that a student is taking this semester, and then finds those courses in the previous semester. In the example skeleton of Figure 5, for Alice, the first path would reach CS101 at  $t = 0$ , while the second path, will reach CS201 at  $t = 0$ .

**Definition 1.** A *temporal relational path*  $P$  is a sequence of non-temporal relational paths  $P_0^{t_0}, \dots, P_k^{t_k}$  ( $k \geq 0$ ) such that for any two consecutive paths  $P_i^{t_i}, P_j^{t_j}$  in  $P$  the following hold:

1.  $|t_i - t_j| = 1$
2. The last item class of  $P_i^{t_i}$  is the same as the first item class of  $P_j^{t_j}$ .
3. No subpath of  $P$  is of the form  $[I_k^t, \dots, I_k^t]$ , where all relations in the subpath are one-to-one.

We use the notation  $time(P)$  to denote the set of all time points that appear in path  $P$ .

*Temporal relational variables* consist of a temporal relational path and an attribute that can be reached through that path. *Temporal relational dependencies* define probabilistic dependencies between two temporal relational variables. Temporal probabilistic dependencies are never directed backwards in time. Therefore, at the model level, there are no dependencies going back in time. However, the temporal constraints associated with a dependency are also implicitly encoded by the temporal relational path that annotates the dependency. To account for this, we forbid the temporal relational path of the treatment to go through any time points later than the time point of the outcome.

**Definition 2.** A *temporal relational dependency* consists of two temporal relational variables with a common base item,  $[I_1^t, \dots, I_k^t].V_k \rightarrow [I_1^t].V_1$  such that

$$\max \left( time([I_1^t, \dots, I_k^t]) \right) \leq t$$

The first-order Markov assumption for temporal causal models implies that for every probabilistic dependency, if the treatment is in time point  $t$ , then the outcome is either in  $t$  or in  $t + 1$ . In the case of relational domains, the relational path of the treatment carries some temporal information since it can contain multiple time points. For the first-order Markov condition to hold, we require the relational path of the treatment to only go through the current and the next time points. More formally, a temporal relational dependency  $[I_1^t, \dots, I_k^t].V_k \rightarrow [I_1^t].V_1$  follows the first-order Markov assumption if the following two conditions hold:

$$t = t' \text{ or } t = t' + 1 \quad (1)$$

$$time([I_1^t, \dots, I_k^t]) \subseteq \{t, t - 1\} \quad (2)$$

The structure of a 2-slice temporal relational model is defined as a set of temporal relational dependencies over a relational schema.

Figure 6: Relational schema for the reality mining dataset.

**Definition 3.** The structure of a 2-slice temporal relational model is a pair  $\mathcal{M} = \langle \mathcal{S}, \mathcal{D}_T \rangle$ , where  $\mathcal{S}$  is a relational schema and  $\mathcal{D}_T$  is a set of temporal relational dependencies that adhere to the first-order Markov assumption.

Figure 4 shows the structure of a 2-slice temporal relational model for the university domain. The temporal dependency shows that the difficulty of a course in the fall semester affects the spring GPA of the students that took this class in the fall. If, for example, a student takes many difficult classes, it is more likely that the student’s GPA will drop in the next semester. Finally, given a temporal relational skeleton  $\sigma_T$  and a temporal relational model  $\mathcal{M}$ , we can construct a temporal ground graph  $GG_{\mathcal{M}\sigma_T}$  in the same way as in the non-temporal case.

## 4 EXPRESSIVENESS OF TEMPORAL RELATIONAL MODELS

The temporal relational model described so far subsumes propositional directed networks (Bayesian networks), propositional temporal directed networks (dynamic Bayesian networks), and relational non-temporal models. This added expressivity comes at the cost of increased complexity. This raises an obvious and important question: What is the value of this added expressivity?

As an example of the practical utility of this added expressivity, we consider a real dataset and show how a path with temporal jumps leads to different terminal sets. Specifically, we used the Reality Mining dataset [Eagle and Pentland, 2006]. The dataset contains two entities, *Tower* and *Cellphone*, and one relationship, *Connects*. The relational schema for this domain is shown in Figure 6. For this dataset, entity instances (i.e., the set of towers and cellphones) do not change over time. However, the set of relationship instances (the connections) are different at every time point. In total, there are 95 cellphones, 32,579 towers, and 3,308,709 connections. Every connection is time-stamped with precision of 1 second. For our work, the time granularity was coarsened to a day.

We computed the terminal sets for the following three paths:

- $P1 : [Tower^{t+1}, Tower^t, Connects^t, Cellphone^t]$
- $P2 : [Tower^{t+1}, Connects^{t+1}, Connects^t, Cellphone^t]$
- $P3 : [Tower^{t+1}, Connects^{t+1}, Cellphone^{t+1}, Cellphone^t]$

The first path corresponds to the cellphones that were con-

Table 1: Jaccard distance between the terminal sets of the different paths for the reality mining dataset (100 sample dates, distance is averaged across dates and across towers).

| Jaccard distance | P1 vs. P3 | P1 vs. P2 | P2 vs. P3 |
|------------------|-----------|-----------|-----------|
| mean             | 0.47      | 0.31      | 0.31      |
| min              | 0         | 0         | 0         |
| max              | 1         | 1         | 1         |
| median           | 0.5       | 0         | 0         |

nected to a tower in the previous timestep. The second path corresponds to the cellphones that connected to a tower both in the current and in the previous timestep. The third path corresponds to the cellphones that connected to a tower in the current time step, and gets the state of those cellphones in the previous timestep.

We randomly selected 100 dates from the dataset. For each of these dates and for each tower that was used in these dates, we computed the terminal sets for the above paths. For a given tower and date, we computed the Jaccard distance between the different terminal sets. The Jaccard distance between two sets  $A$  and  $B$  is defined as  $J(A, B) = 1 - \frac{|A \cap B|}{|A \cup B|}$ . Intuitively, this quantifies the overlap of two sets, while accounting for the size of both. Table 1 shows the average Jaccard distance between the terminal sets, averaged across the dates and the towers. The results indicate that, on average, the terminal sets reached through the three paths will be different; therefore, this more expressive representation could be of use in real data.

## 5 TEMPORAL ABSTRACT GROUND GRAPHS

An abstract ground graph is a lifted representation that abstracts paths of dependence over all possible ground graphs for a given relational model [Maier *et al.*, 2013b]. Abstract ground graphs are shown to be sound and complete in the sense that every edge in the abstract ground graph corresponds to an edge in some ground graph, and every edge in an arbitrary ground graph is represented by an edge in an abstract ground graph. In this section we adapt the definition of abstract ground graphs for the case of a 2-slice temporal relational model.

**Definition 4.** A temporal abstract ground graph  $tAGG_{\mathcal{M}Bh} = \langle V, E \rangle$  for a 2-slice temporal relational model  $\mathcal{M} = \langle \mathcal{S}, \mathcal{D}_T \rangle$ , perspective  $B \in \mathcal{E} \cup \mathcal{R}$ , and hop threshold  $h \in \mathbb{N}^0$  is an abstraction of the dependencies  $\mathcal{D}_T$  for all possible ground graphs  $GG_{\mathcal{M}\sigma_T}$  of  $\mathcal{M}$  on arbitrary temporal skeletons  $\sigma_T$ . The temporal abstract ground graph is a directed graph with the following nodes and edges:

1.  $V = RV \cup IV$ , where

(a)  $RV$  is the set of *temporal relational variables* with a path of length at most  $h + 1$ .

$$RV = \{[B^t, \dots, I_j^t].V \mid \text{length}([B^t, \dots, I_j^t]) \leq h + 1\}$$

(b)  $IV$  are *intersection variables* between pairs of temporal relational variables that could intersect<sup>1</sup>.

$$IV = \{X \cap Y \mid X, Y \in RV\}$$

$$\text{and } X = [B^t, \dots, I_k^t, \dots, I_j^t].V$$

$$\text{and } Y = [B^t, \dots, I_l^t, \dots, I_j^t].V \text{ and } I_k^t \neq I_l^t\}$$

2.  $E = RVE \cup IVE$ , where

(a)  $RVE \subset RV \times RV$  are the *relational variable edges*:

$$RVE = \{[B^t, \dots, I_k^t].V_k \rightarrow [B^t, \dots, I_j^t].V_j \mid \\ [I_j^t, \dots, I_k^t].V_k \rightarrow [I_j^t].V_j \in \mathcal{D}_T \text{ and} \\ [B^t, \dots, I_k^t] \in \text{extend}([B^t, \dots, I_j^t], [I_j^t, \dots, I_k^t])\}$$

(b)  $IVE \subset (IV \times RV) \cup (RV \times IV)$  are the *intersection variable edges*. This is the set of edges that intersection variables “inherit” from the relational variables that they were created from.

The *extend* method converts dependencies of the model, specified in the canonical form, into dependencies from the perspective of the abstract ground graph.

Temporal abstract ground graphs can be shown to be a correct abstraction over all possible temporal ground graphs. The proof follows the one provided for the non-temporal abstract ground graphs, as presented by Maier *et al.* [2013b].

The temporal abstract ground graph for a model on the student-courses domain with the dependency

$$[Student^{t+1}, Student^t, Takes^t, Course^t].difficulty \rightarrow [Student^{t+1}].gpa$$

is shown in Figure 7. This abstract ground graph is from the perspective of *Student* and for hop threshold  $h = 4$ . Disconnected nodes are omitted.

## 6 $d$ -SEPARATION IN TEMPORAL ABSTRACT GROUND GRAPHS

The rules of  $d$ -separation provide a graphical criterion that specifies whether two sets of variables in a directed acyclic graph are conditionally independent given a third set of variables. Specifically, let  $\mathbf{X}, \mathbf{Y}, \mathbf{Z}$  be disjoint sets of variables in a directed acyclic graph.  $\mathbf{X}$  is  $d$ -separated from  $\mathbf{Y}$

<sup>1</sup>Only relational variables in the same time point can intersect.

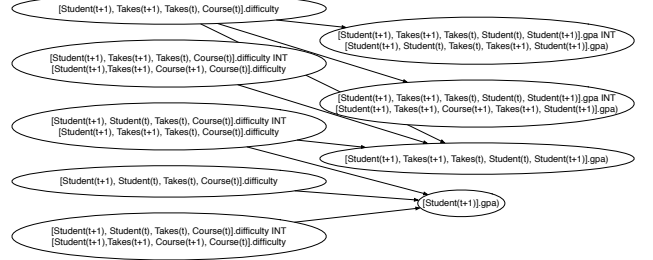

Figure 7: Temporal abstract ground graph from the perspective of *Student* and hop threshold  $h = 4$  for a model with one dependency:  $[Student^{t+1}, Student^t, Takes^t, Course^t].difficulty \rightarrow [Student^{t+1}].gpa$ . INT denotes intersection variables between pairs of temporal relational variables.

given  $\mathbf{Z}$  if every path between variables in  $\mathbf{X}$  and  $\mathbf{Y}$  is not a  $d$ -connecting path given  $\mathbf{Z}$ . A path is  $d$ -connecting given  $\mathbf{Z}$  if for every collider  $W$  on the path, either  $W \in \mathbf{Z}$  or a descendant of  $W$  is in  $\mathbf{Z}$ , and every non-collider on the path is not in  $\mathbf{Z}$ . Geiger and Pearl [1988] and Verma and Pearl [1988] showed that  $d$ -separation is sound and complete.

Ground graphs (and temporal ground graphs) are directed acyclic graphs; therefore, the rules of  $d$ -separation can be applied to them. In the case of domains where the first-order Markov assumption holds, a  $d$ -separating set for variables in the same time point can be found by examining only one time point in the past.

**Proposition 5.** Let  $G$  be a temporal directed acyclic graph that follows the first-order Markov assumption. (i) If  $X^{t+1}$  and  $Y^{t+1}$  are conditionally independent given some set  $\mathbf{Z}$ , then there exists a separating set  $\mathbf{W}$  such that  $\text{time}(\mathbf{W}) \subseteq \{t, t + 1\}$ . (ii) Similarly, if  $X^t$  and  $Y^{t+1}$  are conditionally independent given some set  $\mathbf{Z}$ , then there exists a separating set  $\mathbf{W}$  such that  $\text{time}(\mathbf{W}) \subseteq \{t, t + 1\}$ .

*Proof.* For each case, we will construct an appropriate separating set:

(i) Let  $\mathbf{W} = \text{parents}(X^{t+1}) \cup \text{parents}(Y^{t+1})$ . Because of the first-order Markov assumption,  $\text{time}(\mathbf{W}) \subseteq \{t, t + 1\}$ . Moreover, conditioning of  $\mathbf{W}$  renders  $X^{t+1}, Y^{t+1}$  independent because of the local Markov property (either  $X^{t+1}$  is a descendant of  $Y^{t+1}$  or vice versa, or none of them is a descendant of the either).

(ii) In this case, let  $\mathbf{W} = \text{parents}(Y^{t+1})$ . Because of the temporal semantics,  $X^t$  is a non-descendant of  $Y^{t+1}$ ; therefore,  $Y^{t+1}$  is conditionally independent of its non-descendants (that include  $X^t$ ) given  $\mathbf{W}$ .  $\square$

The significance of the above proposition is that, given a model where the first-order Markov assumption holds, we

could infer conditional independencies (and use them to learn the structure of the model) by only considering consecutive time points.

Maier *et al.* [2013b] showed that  $d$ -separation cannot be applied directly to a relational model. To correct for that, they introduced *relational  $d$ -separation*, a graphical criterion that can be applied to abstract ground graphs and used to infer conditional independencies that hold across all possible ground graphs of the model. Here, we show that the notion of relational  $d$ -separation can be generalized for temporal abstract ground graphs as well. In the following definition,  $X|_b$  denotes the terminal set of  $X$  starting at  $b$ , i.e., the set of  $X$  instances that can be reached if we start from instance  $b$  and follow the relational path of  $X$  on the relational skeleton.

**Definition 6** (Temporal relational  $d$ -separation). Let  $\mathbf{X}$ ,  $\mathbf{Y}$ , and  $\mathbf{Z}$  be three disjoint sets of temporal relational variables from perspective  $B$  for a 2-slice temporal relational model  $\mathcal{M}$  such that not both  $\mathbf{X}$  and  $\mathbf{Y}$  contain variables in  $t$ . Then  $\mathbf{X}$  and  $\mathbf{Y}$  are  $d$ -separated by  $\mathbf{Z}$  if and only if, for any temporal skeleton  $\sigma_T$ ,  $\mathbf{X}|_b$  and  $\mathbf{Y}|_b$  are  $d$ -separated by  $\mathbf{Z}|_b$  in ground graph  $GG_{\mathcal{M}\sigma_T}$  for all  $b \in \sigma_T(B)$ .

The following theorem shows that temporal relational  $d$ -separation is sound and complete up to a specified hop threshold. We use the notation  $\bar{\mathbf{X}}$  to denote the set of relational variables  $\mathbf{X}$  augmented with the set of intersection variables they participate in.

**Theorem 7.** Let  $\mathbf{X}$ ,  $\mathbf{Y}$ , and  $\mathbf{Z}$  be three disjoint sets of temporal relational variables for perspective  $B$  such that not both  $\mathbf{X}$  and  $\mathbf{Y}$  contain variables in  $t$ . Then, for any temporal skeleton  $\sigma_T$  and for all  $b \in \sigma(B)$ ,  $\mathbf{X}|_b$  and  $\mathbf{Y}|_b$  are  $d$ -separated by  $\mathbf{Z}|_b$  up to  $h$  in ground graph  $GG_{\mathcal{M}\sigma_T}$  if and only if  $\bar{\mathbf{X}}$  and  $\bar{\mathbf{Y}}$  are  $d$ -separated by  $\bar{\mathbf{Z}}$  on the abstract ground graph  $tAGG_{\mathcal{M}Bh}$ .

*Proof.* We prove this by defining a non-temporal relational model that is equivalent to the given temporal model. Since  $d$ -separation is sound and complete for non-temporal relational models, the result extends to the equivalent model, and therefore, the temporal relational model. Given a 2-slice temporal relational model  $\mathcal{M}_T = \langle \mathcal{S}, \mathcal{D}_T \rangle$ , construct a relational model  $\mathcal{M} = \langle \mathcal{S}', \mathcal{D} \rangle$  as follows:

- For every item in  $\mathcal{S}$ , add an item in  $\mathcal{S}'$  with superscript  $t$  and one with superscript  $t + 1$ :  $\mathcal{S}' = \{I^t, I^{t+1} \mid I \in \mathcal{S}\}$ .
- For every entity  $E \in \mathcal{S}$ , add in  $\mathcal{S}'$  a 1-1 relation between  $E^t$  and  $E^{t+1}$ .
- The set of relational dependencies is the set of temporal relational dependencies:  $\mathcal{D} = \mathcal{D}_T$ .

It can be shown that these two models are equivalent in the sense that there is a one-to-one correspondence between valid paths in  $\mathcal{M}_T$  and  $\mathcal{M}$ . Leveraging the temporal constraints of  $d$ -separation described by Proposition 5

and the soundness and completeness of  $d$ -separation for abstract ground graphs, we conclude that  $d$ -separation is sound and complete (up to a hop threshold) in temporal abstract ground graphs.  $\square$

## 7 TEMPORAL RCD

The theory of temporal relational  $d$ -separation allows us to derive all conditional independence facts that are consistent with the structure of a temporal relational model, the same way that  $d$ -separation connects the structure of a Bayesian network and the conditional independencies of the underlying distribution. This is precisely the connection that constraint-based algorithms leverage in order to learn the structure of models. Thus, temporal relational  $d$ -separation (and temporal abstract ground graphs) enable a constraint-based algorithm, TRCD<sup>2</sup>, that learns the structure of temporal and relational causal models from data.

TRCD extends RCD [Maier *et al.*, 2013a] to operate over a 2-slice temporal relational model. More specifically, it constructs a set of temporal abstract ground graphs, one from the perspective of each entity, and uses the theory of temporal relational  $d$ -separation on temporal abstract ground graphs to decide conditional independence facts. TRCD uses the temporal abstract ground graphs to determine which conditional independence facts should be checked in the data and which dependencies (edges) in the temporal relational model are implied by those facts. As in the case of RCD, for practical reasons, the space of potential dependencies is limited by a domain-specific hop threshold.

TRCD operates in two phases. Phase I learns a set of undirected dependencies and Phase II employs a set of orientation rules to orient those dependencies. Phase II of TRCD uses the same orientation rules as RCD—collider detection, known non-colliders (KNC), cycle avoidance (CA), Meek rule 3 (MR3), and relational bivariate orientation (RBO). Additionally, TRCD orients dependencies that cross time points from the past to the future.

RCD was shown to be sound and complete in the sample limit (i.e., with perfect tests of conditional independence) and for infinite hop threshold, under the standard assumptions of the causal Markov condition, faithfulness, and causal sufficiency for relational domains. By leveraging the soundness and completeness of temporal relational  $d$ -separation, TRCD can be shown to be sound and complete (under the same assumptions).

## 8 EXPERIMENTS

### 8.1 ORACLE EXPERIMENTS

The goal of this set of experiments is twofold. First, we evaluate the theoretical performance of TRCD in the large sample limit. Towards that end, we employ an oracle for answering  $d$ -separation queries in the place of statistical tests of independence. Second, these experiments provide experimental evidence about the correctness of temporal relational  $d$ -separation.

We generated synthetic schemas with number of entities varying from 1 to 3, number of relationships fixed to one less than the number of entities, and number of attributes for each item drawn from  $Poisson(\lambda = 1) + 1$ . The cardinalities were uniformly selected at random. For each number of entities specified, we generated 500 different schemas. This generating process yielded 1,500 different schemas. For a given schema, we generated 10 different models with number of dependencies ranging from 1 to 10. Specifically, we generated all possible dependencies, up to hop-threshold  $h = 3$ . Then, we chose the desired number of dependencies from that space at random, subject to the following constraints: Each relational variable has at most 3 parents and the generated model contains no cycles. Moreover, every model must contain at least one dependency with a temporal relational path that contains more than one time point. This procedure resulted in a total of 15,000 models.

We ran TRCD with a  $d$ -separation oracle for each model. Figure 8 shows average precision and recall after Phase I (unoriented dependencies) and after Phase II (partially oriented dependencies). As expected, given that these experiments use an oracle, the algorithm always learns the correct set of unoriented dependencies (unoriented precision and recall are always 1). The algorithm makes no mistakes in the orientation (oriented precision is always 1); however,

Table 2: Frequency of the most-used orientation rules during Phase II of TRCD for the oracle experiments. For the rest of the rules, the frequency was less than 1%. Temporal dependencies are not oriented by the orientation rules.

| Number of entities | Collider detection | KNC | RBO | Percent of temporal dependencies |
|--------------------|--------------------|-----|-----|----------------------------------|
| 1                  | 71%                | 28% | 0%  | 66%                              |
| 2                  | 66%                | 11% | 23% | 68%                              |
| 3                  | 53%                | 11% | 36% | 65%                              |

it is not possible to orient all dependencies (oriented recall is lower than 1). Note that comparing to an oracle version of RCD is not straightforward. The oracle requires a true model that is fully directed. Converting the true temporal model to a non-temporal one would often result in cycles or undirected edges, and the relational  $d$ -separation oracle cannot be used.

Table 2 shows how often each orientation rule was used in Phase II. Collider detection, known non-colliders (KNC), and relational bivariate orientation (RBO) are orienting the majority of the edges. As expected, in the case of propositional models (one entity), the relational bivariate orientation rule, a rule for edge orientation that is unique to relational data, is never used. We observe that the other two rules—cycle avoidance and Meek’s rule 3—do not fire often. That can be explained by the fact that those rules would never fire in the presence of a temporal edge. Consider cycle avoidance in the propositional case: If the pattern  $X \rightarrow Y \rightarrow Z$  and  $X - Y$  is encountered, then cycle avoidance orients  $X \rightarrow Y$ . If any of the dependencies  $X \rightarrow Y \rightarrow Z$  crosses time points, then  $X$  and  $Y$  would be in different time points and the edge between them would be oriented based on temporal precedence. A similar argument can be made for the case of Meek’s rule 3.

## 8.2 EXPERIMENTS ON SYNTHETIC DATA

This experiment showcases the use of TRCD on data, i.e., without the use of an oracle to decide conditional independence. Towards that end, we generated synthetic models, generated data from these models, and applied TRCD on them. The use of synthetic data allows us to have access to the ground truth, so we can measure the accuracy of the learned models. The data-generating process is described in detail below.

Using the same process as described in 8.1, we generated 5 synthetic schemas with 2 entities and 5 synthetic schemas with 3 entities. For each schema, we generated 10 models with number of dependencies ranging from 1 to 10. This resulted in 100 different models. For each model we created 3 different relational skeletons over 300 timepoints. The number of entity instances at each time point was drawn from  $Poisson(\lambda) + 1$ , where  $\lambda \sim \mathcal{U}(5, 10)$ . The degree distribution for the relationship instances was drawn from  $Poisson(\lambda) + 1$ , where  $\lambda \sim \mathcal{U}(1, 5)$ . Regarding the parameters of the graphical model, the marginals were parameterized as normal distributions  $\mathcal{N}(\mu, \sigma)$ , where  $\mu \sim \mathcal{U}(0, 5)$  and  $\sigma \sim \mathcal{U}(0, 1)$ . The conditional distribution for a relational variable  $X$  was  $\sum_{Y \in \text{parents}(X)} (\text{avg}(Y)) + 0.1 * \mathcal{N}(0, 1)$ . This resulted in 300 datasets, each over 300 time points.

In order to assess statistical independence, we fitted a standard linear least-squares regression equation to the outcome variable using the treatment and the variables in the conditioning set as covariates. For relational variables in the conditioning set, we used the average as the aggregation function. Then, we directly used the t-test of the coefficient of the treatment variable to assess independence ( $p > 0.05$  or effect size  $< 0.01$ ). Figure 9 shows average precision and recall of TRCD after Phase I and Phase II, when applied to the synthetic datasets. While precision after Phase I is more than 0.75 in most cases, the recall after Phase I is relatively low. That implies that we concluded independence (and therefore we removed an edge) more often than we should. This corresponds to Type II errors and can be attributed to the lack of good conditional independence tests for relational data.

Finally, to demonstrate the difference in expressiveness between TRCD and RCD (the only constraint-based algorithm for relational data), we ran RCD on a “temporally flattened”<sup>3</sup> version of the synthetic data. The true model and the model that TRCD learned are shown in Figure 10. The model learned by RCD is shown in Figure 11. TRCD correctly learns and orients three of the edges, with the correct path specification. Those dependencies cannot even be expressed in the space of dependencies for RCD.

<sup>3</sup>RCD is ignoring temporal information. An instance is uniquely identified by instance id and time point.

Figure 10: True temporal relational model. The dotted edge was not learned by TRCD, while the dashed edge was left unoriented.

Figure 11: Model learned by RCD for data generated from the temporal model of Figure 10.

## 9 RELATED WORK

For the propositional case, there are several approaches for learning the structure of temporal probabilistic models. Most of them are not constraint-based methods, but follow the search-and-score paradigm. Friedman *et al.* [1998] present an algorithm to learn the structure of DBNs from complete data using a search-and-score algorithm, and from incomplete data using structural EM. Lähdesmäki and Shmulevich [2008] use Bayesian methods to learn the structure of a DBN from steady state measurements or from time-series data and steady state measurements. Robinson and Hartemink [2010] present an MCMC algorithm to learn the structure of a DBN that changes over time. A different approach that learns a causal temporal model from time series data is the difference-based causal learner [Voortman *et al.*, 2010]. This framework is based on dynamic Structural Equation Models.

A constraint-based method for temporal propositional domains is presented by Entner and Hoyer [2010] who extend the FCI algorithm [Spirtes *et al.*, 2000] to temporal domains. FCI relaxes the causal sufficiency assumption, i.e., it allows the presence of latent common causes. Our approach is the first approach that uses a constraint-based algorithm for data that is both temporal *and* relational (although under the assumption of causal sufficiency).

Another widely used method for inferring causal relationships from temporal data is Granger causality [Granger, 1969]. The main idea underlying Granger causality is that

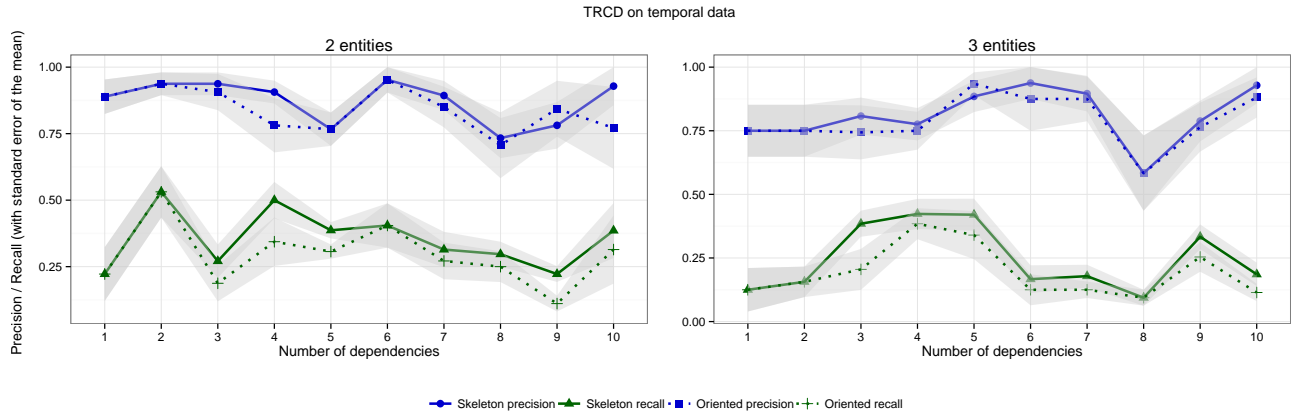

Figure 9: TRCD on synthetic temporal data.

a cause should improve the predictive accuracy of its effect, compared to predictions based solely on the effect’s past values. There has been work in extending Granger causality for multivariate settings, as well as in combining Granger causality with graphical models [Eichler, 2012]. Liu *et al.* [2010] propose a regularized Hidden Markov Random Field regression to learn the structure of a temporal causal graph from multivariate time-series data. However, the methods used for learning the structure of the causal model are not constraint-based.

Another line of work in learning temporal and relational models stems from combining first-order logic with probabilistic frameworks. Logical Hidden Markov Models extend Hidden Markov Models to handle relational (non-flat data) [Kersting *et al.*, 2006]. Kersting and Raiko [2005] provide an EM-based algorithm to learn the structure of LHMMs.

In terms of representation, Manfredotti [2009] introduces relational dynamic Bayesian networks (RDBNs), a first-order logic-based extension of dynamic Bayesian networks. RDBNs are similar to the relational model we define; however, we provide an explicit characterization for the space of relational paths, and subsequently, the space of relational dependencies. To be more specific, temporal relational paths in our framework are restricted to conjunctions of predicates that correspond to possible traversals of the relational schema. This restriction, together with the domain specific hop threshold, allows us to enumerate the space of potential dependencies to learn.

## 10 CONCLUSIONS AND FUTURE WORK

In this paper we presented a formalization of temporal relational models, and we extended the theory of relational  $d$ -separation to the temporal domain. We presented a constraint-based algorithm, TRCD, that leverages the notion of temporal relational  $d$ -separation to learn the causal

structure of temporal relational models from data. We showed that the algorithm is sound and complete, and we provided experimental evidence that showcases the correctness of TRCD. Finally, we showed the improvement that TRCD achieves compared to RCD when applied to domains with a temporal component.

TRCD makes certain simplifying assumptions. Future work could focus on relaxing some of those assumptions, specifically, allowing the structure of the causal model to change over time (change point detection for relational data). Another avenue for future research is relaxing the causal sufficiency assumption by employing techniques such as blocking [Rattigan *et al.*, 2011] for temporal relational domains. Finally, an important issue that arises when modelling time as a discrete quantity is how to choose the appropriate granularity of time points. Ribeiro *et al.* [2012] provide an analysis on how aggregating at a given time granularity affects the characterization of the underlying temporal process. Continuous time Bayesian networks [Nodelman *et al.*, 2002, 2003] provide a way around this by allowing each variable to be modeled at a different time granularity.

## Abstract

Approximate Bayesian computation (ABC) is a powerful and elegant framework for performing inference in simulation-based models. However, due to the difficulty in scaling likelihood estimates, ABC remains useful for relatively low-dimensional problems. We introduce Hamiltonian ABC (HABC), a set of likelihood-free algorithms that apply recent advances in scaling Bayesian learning using Hamiltonian Monte Carlo (HMC) and stochastic gradients. We find that a small number forward simulations can effectively approximate the ABC gradient, allowing Hamiltonian dynamics to efficiently traverse parameter spaces. We also describe a new simple yet general approach of incorporating random seeds into the state of the Markov chain, further reducing the random walk behavior of HABC. We demonstrate HABC on several typical ABC problems, and show that HABC samples comparably to regular Bayesian inference using true gradients on a high-dimensional problem from machine learning.

## 1 INTRODUCTION

In simulation-based science, models are defined by a simulator and its parameters. These are called *likelihood-free* models because, in contrast to probabilistic models, their likelihoods are either intractable to compute or must be approximated by simulations. To perform inference in likelihood-free models, a broad class of algorithms called Approximate Bayesian Computation [3, 13, 20, 12] are employed.

At the core of every ABC algorithm is simulation. To evaluate the quality of a parameter vector  $\theta$ , a simulation is run

---

\*Donald Bren School of Information and Computer Sciences  
University of California, Irvine, and Canadian Institute for Advanced Research.

using  $\theta$  as inputs and producing outputs  $\mathbf{x}$ . If the pseudo-data  $\mathbf{x}$  is “close” to observations  $\mathbf{y}$ , then  $\theta$  is kept as a sample from the approximate posterior. Parameters  $\theta$  are then adjusted, depending upon the algorithm, to obtain the next sample.

In ABC, there is a fundamental trade-off between the computation required to obtain independent samples and the approximation to the true posterior. If the parameter measuring closeness is too small, then samplers “mix” poorly; on the other hand, if it is too large, then the approximation is poor. As the dimension of the parameters grows, the problem worsens, just as it does for general Bayesian inference with probabilistic models, but it is more acute for ABC due to its simulation requirement. There is therefore a deep interest in improving the efficiency of ABC samplers (in terms of computation per independent sample). In this paper we address this issue directly by using Hamiltonian dynamics to approximately sample from likelihood-free models with high-dimensional parameters.

Hamiltonian Monte Carlo (HMC) [7, 16] is perhaps the only Bayesian inference algorithm that scales to high-dimensional parameter spaces. The core computation of HMC is the gradient of the log-likelihood. Two problems arise if we consider HMC for ABC: one, how can the gradients be computed for high-dimensional likelihood-free models, and two, given a stochastic approximation to the gradient, can a valid HMC algorithm be derived?

To answer the latter, we turn to recent developments in scaling Bayesian inference using HMC and stochastic gradients [25, 5, 6]. We call these *stochastic gradient Hamiltonian dynamics* (SGHD) algorithms. SGHD algorithms are computationally efficient for two reasons. First, they avoid computing the gradient of the log-likelihood over the entire data set, instead approximating it using small batches of data, i.e. computing stochastic gradients. Second, they can maintain reasonable approximations to the Hamiltonian dynamics and therefore avoid a Metropolis-Hastings correction step involving the full data set. Different strategies are employed to do this: small step-sizes combined with Langevin dynamics [25] (stochastic gradi-

ent Langevin dynamics—SGLD), using friction to prevent accumulation of errors in the Hamiltonian [5] (stochastic gradient HMC—SGHMC), and using a thermostat to control the temperature of the Hamiltonian [6] (stochastic gradient Nose-Hoover thermostats—SGNHT). Each of these strategies can be used by HABC.

In HABC, we use forward simulations to approximate the likelihood-free gradient. The key difference between SGHD methods and HABC is that the stochasticity of the gradient does not come from approximating the full data gradient with a mini-batch gradient, but by the stochasticity of the simulator. It is therefore not the expense of the simulator (though this could very well be the case for many interesting simulation-based models – see Section 7) that requires an approximation to the gradient, but the likelihood-free nature of the problem.

There are several difficulties in estimating gradients of likelihood-free models that we address with HABC. The first is due to the form of the ABC log-likelihood. As we show in Section 2, using a conditional model for  $\pi(\mathbf{x}|\theta)$  provides an estimate of the ABC likelihood that is less sensitive to  $\epsilon$  and therefore is more conducive to stochastic gradient computations. The second difficulty is that for high-dimensional parameter spaces, computing the gradients naively (i.e. by finite differences (FD) [9]) can squash the gains brought by the Hamiltonian dynamics. Fortunately, we can use existing stochastic approximation algorithms [21, 22] that can be used to compute unbiased estimators of the gradient with a small number of forward simulations that is *independent* of the parameter dimension. The *stochastic perturbation stochastic approximation* (SPSA) [21] is described in Section 4

A further innovation of this paper is the use of persistent random numbers (PRNs) to improve the efficiency of the Hamiltonian dynamics. The idea behind PRNs is to use the same set of random seeds for estimating a gradient by FD or SPSA, i.e. when simulating  $\pi(\mathbf{x}|\theta + d\theta)$  and  $\pi(\mathbf{x}|\theta - d\theta)$  use the same random seeds. This was applied successfully to SPSA [10] (and is analogous to using the same mini-batch in stochastic gradient methods). We extend and simplify this approach by including the random seeds  $\omega$  into the state of the Markov chain; by keeping the random seeds fixed for several consecutive steps, the second order gradient stochasticity is greatly reduced. We show that doing this produces a valid MCMC procedure. This approach is not exclusive to HABC; our experiments show it also helps random-walk ABC-MCMC.

We briefly review ABC in Section 2. In Section 3 we review three approaches to stochastic gradient inference using Hamiltonian dynamics: SGLD, SGHMC, and SGNHT. We then introduce Hamiltonian ABC in Section 4, where we will show how to improve the stability of the gradient estimates by using PRNs and local density estimators

of the simulator. Extensions to high-dimensional parameter spaces are also discussed. In Section 5 we show how HABC behaves on a simple one-dimensional problem, then in Section 6 we compare HABC with ABC-MCMC for two problems: a low-dimensional model of chaotic population dynamics and a high-dimensional problem.

## 2 APPROXIMATE BAYESIAN COMPUTATION

Consider the Bayesian inference task of either drawing samples from or learning an approximate model of the following (usually intractable) posterior distribution:

$$\pi(\theta|\mathbf{y}_1, \dots, \mathbf{y}_N) \propto \pi(\theta)\pi(\mathbf{y}_1, \dots, \mathbf{y}_N|\theta) \quad (1)$$

where  $\pi(\theta)$  is a prior distribution over parameters  $\theta \in \mathbb{R}^D$  and  $\pi(\mathbf{y}_1, \dots, \mathbf{y}_N|\theta)$  is the likelihood of  $N$  data observations, where  $\mathbf{y}_i \in \mathbb{R}^J$ . In ABC, the vector of  $J$  observations are typically informative statistics of the raw observations. It can be shown that if the statistics used in the likelihood function are sufficient, then these algorithms sample correctly from an approximation to the true posterior [12]. The simulator is treated as a generator of random pseudo-observations, i.e.  $\mathbf{x} \stackrel{\text{sim}}{\sim} \pi(\mathbf{x}|\theta)$  is a draw from the simulator. Discrepancies between the simulator outputs  $\mathbf{x}$  and the observations  $\mathbf{y}$  are scaled by a closeness parameter  $\epsilon$  and treated as likelihoods. This is the equivalent to putting an  $\epsilon$ -kernel around the observations, and using a Monte Carlo estimate of the likelihood using  $S$  draws of  $\mathbf{x}$ :

$$\pi_\epsilon(\mathbf{y}|\theta) = \int \pi_\epsilon(\mathbf{y}|\mathbf{x})\pi(\mathbf{x}|\theta)d\mathbf{x} \approx \frac{1}{S} \sum_{s=1}^S \pi_\epsilon(\mathbf{y}|\mathbf{x}^{(s)}) \quad (2)$$

In ABC Markov chain Monte Carlo (MCMC) [13, 26] the Metropolis-Hastings (MH) proposal distribution is composed of the product of the proposal for the parameters  $\theta$  and the proposal for the simulator outputs:

$$q(\theta', \mathbf{x}^{(1)'}, \dots, \mathbf{x}^{(S)' }|\theta) = q(\theta'|\theta) \prod_s \pi(\mathbf{x}^{(s)'}|\theta') \quad (3)$$

Using this form of the proposal distribution, and using the Monte Carlo approximation eq 2, we arrive at the following Metropolis-Hastings accept-reject probability,

$$\alpha = \min \left( 1, \frac{\pi(\theta') \sum_{s=1}^S \pi_\epsilon(\mathbf{y}|\mathbf{x}^{(s)'})q(\theta|\theta')}{\pi(\theta) \sum_{s=1}^S \pi_\epsilon(\mathbf{y}|\mathbf{x}^{(s)})q(\theta'|\theta)} \right) \quad (4)$$

If the simulations are part of the Markov chain, the algorithm corresponds to the pseudo-marginal (PM) sampler [2], otherwise it is a marginal sampler [13, 20]. For this paper we will be interested in the PM sampler because this is equivalent to having the random states that generated the simulation outputs in the state of the Markov chain, which

we will use within a valid ABC sampling algorithm in Section 4.

An alternative approach to computing the ABC likelihood is to estimate the parameters of a conditional model  $\pi(\mathbf{x}|\boldsymbol{\theta})$ , e.g. using kernel density estimate [24] or a Gaussian model [28]. While either approach should be adequate and both have their own limits and advantages, for this paper we will use a Gaussian model. In ABC, using a conditional Gaussian model for  $\pi(\mathbf{x}|\boldsymbol{\theta})$  is called a *synthetic likelihood* (SL) model [28]. For a SL log-likelihood model, we compute estimators of the first and second moments of  $\pi(\mathbf{x}|\boldsymbol{\theta})$ . The advantage is that for a Gaussian  $\epsilon$ -kernel, we can convolve the two densities

$$\begin{aligned}\pi_{\epsilon}(\mathbf{y}|\boldsymbol{\theta}) &= \int \mathcal{N}(\mathbf{y}|\mathbf{x}, \epsilon^2)\mathcal{N}(\mathbf{x}|\mu_{\boldsymbol{\theta}}, \sigma_{\boldsymbol{\theta}}^2)d\mathbf{x} \quad (5) \\ &= \mathcal{N}(\mathbf{y}|\mu_{\boldsymbol{\theta}}, \sigma_{\boldsymbol{\theta}}^2 + \epsilon^2) \quad (6)\end{aligned}$$

Of particular concern to this paper is the behavior of the log-likelihoods for different values of  $\epsilon$ . In the  $\epsilon$ -kernel case, the log-likelihood is very sensitive to small values of  $\epsilon$ :

$$\begin{aligned}\log \pi_{\epsilon}(\mathbf{y}|\boldsymbol{\theta}) &= \log \sum_s \mathcal{N}(\mathbf{y}|\mathbf{x}^{(s)}, \epsilon^2) \quad (7) \\ &= \log \mathcal{N}(\mathbf{y}|\mathbf{x}^{(s)}, \epsilon^2) + \log(1 + H) \quad (8) \\ &\approx -\log \epsilon - \frac{1}{2\epsilon^2}(\mathbf{y} - \mathbf{x}^{(m)})^2 \quad (9)\end{aligned}$$

where  $m$  is the simulation that is closest to  $\mathbf{y}$ ,  $H$  is a sum over terms close to 0. We can see that the log-likelihood can be set arbitrarily small by decreasing  $\epsilon$ . On the other hand, by using a model of the simulation at  $\boldsymbol{\theta}$

$$\log \pi_{\epsilon}(\mathbf{y}|\boldsymbol{\theta}) \approx -\frac{1}{2} \log(\sigma_{\boldsymbol{\theta}}^2 + \epsilon^2) - \frac{(\mathbf{y} - \mu_{\boldsymbol{\theta}})^2}{2(\sigma_{\boldsymbol{\theta}}^2 + \epsilon^2)} \quad (10)$$

For the SL model,  $\epsilon$  acts as a smoothing term and can be set to small values with little change to the log-likelihood, as long as the SL estimators are fit appropriately. This insensitivity to  $\epsilon$  will be used in Section 4 for estimating gradients of the ABC likelihood. Before describing HABC in full detail however, we now explain how scaling Hamiltonian dynamics in Bayesian learning can be accomplished using stochastic gradients from batched data.

### 3 SCALING BAYESIAN INFERENCE USING HAMILTONIAN DYNAMICS

Scaling Bayesian inference algorithms to massive datasets is necessary for their continuing relevance in the so-called *big data* era. We now review the role stochastic gradient methods combined with Hamiltonian dynamics have played in recent advances in scaling Bayesian inference. Most importantly, these methods have combined the ability of HMC to explore high-dimensional parameter spaces

with the computational efficiency of using stochastic gradients based on small mini-batches of the full dataset. After an overview of HMC, we will briefly describe stochastic gradient Hamiltonian dynamics (SGHD), starting with using Langevin dynamics [25], then HMC with friction [5], and finally HMC with thermostats [6]. We will then make the connection between SGHD and HABC in Section 4.

#### 3.1 Hamiltonian Monte Carlo

Hamiltonian dynamics are often necessary to adequately explore the target distribution of high-dimensional parameter spaces. By proposing parameters that are far from the current location and yet have high acceptance probability, Hamiltonian Monte Carlo [7, 16] can efficiently avoid random walk behavior that can render proposals in high-dimensions painfully slow to mix.

HMC simulates the trajectory of a particle along a frictionless surface, using random initial momentum  $\boldsymbol{\rho}$  and position  $\boldsymbol{\theta}$ . The Hamiltonian function computes the energy of the system and the dynamics govern how the momentum and position change over time. The continuous Hamiltonian dynamics can be simulated by discretizing time into small steps  $\eta$ . If  $\eta$  is small, the value of  $\boldsymbol{\theta}$  at the end of a simulation can be used as proposals within the Metropolis-Hastings algorithm. Hamiltonian dynamics should propose  $\boldsymbol{\theta}$  that are always accepted, but errors due to discretization may require a Metropolis-Hastings correction. It is this correction step that SGHD algorithms want to avoid as it requires computing the log-likelihood over the full data set.

More formally, the Hamiltonian  $H(\boldsymbol{\theta}, \boldsymbol{\rho}) = U(\boldsymbol{\theta}) + K(\boldsymbol{\rho})$  is a function of the current potential energy  $U(\boldsymbol{\theta})$  and kinetic energy  $K(\boldsymbol{\rho}) = \boldsymbol{\rho}^T \mathbf{M}^{-1} \boldsymbol{\rho} / 2$  ( $\mathbf{M}$  is a diagonal matrix of masses which for presentation are set to 1). The potential energy is defined by the negative log joint density of the data and prior:

$$U(\boldsymbol{\theta}) = -\log \pi(\boldsymbol{\theta}) - \sum_{i=1}^N \log \pi(\mathbf{y}_i|\boldsymbol{\theta}) \quad (11)$$

The Hamiltonian dynamics follow

$$d\boldsymbol{\theta} = \boldsymbol{\rho} dt \quad d\boldsymbol{\rho} = -\nabla U(\boldsymbol{\theta}) dt \quad (12)$$

in simulation  $dt = \eta$ .

#### 3.2 Stochastic Gradient Hamiltonian Dynamics

If the log-likelihood over the full data set is replaced with a mini-batch estimate, as is done for the following *stochastic gradient Hamiltonian dynamics* (SGHD) algorithms, then the error in simulating the Hamiltonian dynamics comes not only from the discretization, but from the variance of the stochastic gradient. As long as this error is controlled, either by using small steps  $\eta$  (SGLD), or adding friction

terms  $B$  (SGHMC), or using a thermostat  $\xi$  (SGNHT), the expensive MH correction step can be avoided and values of  $\theta$  from the Hamiltonian dynamics can be used as approximate samples from the posterior. SGHD algorithms belong to a larger class of *noisy Monte Carlo* methods that target intractable likelihoods; see [1] for an extensive overview of noisy Monte Carlo.

We develop SGHD from the large-scale data case, where the intractability is due to computing the full potential energy and its gradient; it is approximated using mini-batches:

$$\begin{aligned}\hat{U}(\theta) &= -\log \pi(\theta) - \frac{N}{n} \sum_{i=h_1}^{h_n} \log \pi(\mathbf{y}_i|\theta) \quad (13) \\ \nabla \hat{U}(\theta) &= -\nabla \log \pi(\theta) - \frac{N}{n} \sum_{i=h_1}^{h_n} \nabla \log \pi(\mathbf{y}_i|\theta) \quad (14)\end{aligned}$$

where  $n$  is the mini-batch size, and  $h_i$  are indices chosen randomly without replacement from  $[1, N]$  (i.e. it defined a random mini-batch). In likelihood-free settings, the stochasticity of the potential energy due to the mini-batches is instead caused by simulation noise; further likelihood assumptions, such as a Gaussian model, add another layer of approximation to our posterior. Below we describe three SGHD algorithms, originally developed for large-scale data applications, but for which we will apply directly to likelihood-free inference using gradient approximations in Section 4.

**Stochastic gradient Langevin dynamics** (SGLD) [25] performs one full leap-frog step of HMC. In doing so, SGLD avoids explicitly computing updates for momenta  $\rho$ ; the update for  $\theta$  is

$$\theta_{t+1} = \theta_t + \eta \mathcal{N}(0, \mathbf{I}_p) - \eta^2 \nabla \hat{U}(\theta_t)/2 \quad (15)$$

One of the potential drawbacks of SGLD is that the momentum term is *refreshed* (implicitly) for every update of the  $\theta$ , and since this means the parameter update only uses the current gradient approximation, it limits the benefits of using Hamiltonian dynamics. On the other hand, this also prevents SGLD from accumulating errors in the Hamiltonian dynamics. SGLD has been applied to another intractable likelihood model, Gibbs random fields [1], which closely resembles how SGLD is applied in this paper.

**Stochastic Gradient HMC** (SGHMC) [5] avoids  $\rho$  refreshment altogether. SGHMC makes the assumption  $\nabla \hat{U}(\theta) = \nabla U(\theta) + \mathcal{N}(0, \mathbf{V}_\theta)$ , where  $\mathbf{V}_\theta$  is the covariance of the gradient approximation. To avoid a MH correction step at the end of a trajectory, a friction term  $\mathbf{B}$  proportional to  $\mathbf{V}_\theta$  is added to  $\Delta \rho$ . In practice, since we can only approximate  $\mathbf{B}$ , a user defined friction term  $\mathbf{C}$  is used. In our experiments we compute an online estimate  $\hat{\mathbf{V}}$  and set  $\mathbf{C} = c\mathbf{I}_p + \hat{\mathbf{V}}$ .

**Stochastic Gradient thermostats** (SGNHT) [6] addresses the difficulty of estimating  $\mathbf{B}$  by introducing a scalar variable  $\xi$  who's addition to the Hamiltonian dynamics maintains the temperature of the system constant, i.e. it acts as a (Nose-Hoover) thermostat [11].

## 4 HAMILTONIAN ABC

The general approach of applying Hamiltonian dynamics to ABC requires choosing one of the SGHD algorithms and then plugging in the ABC gradient approximation  $\nabla \hat{U}(\theta)$ . With this in mind we leave the details of the Hamiltonian updates to previous work [25, 5, 6] and focus on the details of how stochastic gradients are computed in the likelihood-free setting. Note that in our implementation, we do not use a MH correction (except when switching seeds), though this can easily be added for any particular problem.

### 4.1 Deterministic Representations of Simulations

Implicit in each simulation run  $\mathbf{x} \stackrel{\text{sim}}{\sim} \pi(\mathbf{x}|\theta)$  is a sequence of internally generated random numbers that are used to produce random draws from  $\pi(\mathbf{x}|\theta)$ . These random numbers are important to HABC because we wish to control the stochasticity of the simulator when computing its gradient. Furthermore, we will control the random numbers over multiple time steps. Instead of keeping track of random numbers, we can equivalently keep a vector of  $S$  random seeds  $\omega$ . This allows HABC to treat the simulation function  $\pi(\mathbf{x}|\theta)$  as a blackbox, outside of which we can control the random number generator (RNG), and represent  $\mathbf{x}^{(s)}$  as the output of a deterministic function; i.e.  $\mathbf{x}^{(s)} = f(\theta, \omega_s)$  instead of  $\mathbf{x}^{(s)} \stackrel{\text{sim}}{\sim} \pi(\mathbf{x}|\theta)$ . We include  $\omega$  as part of the state of our Markov chain.

### 4.2 Kernel- $\epsilon$ versus Synthetic-likelihood -based Gradients

In Section 2 we showed that the synthetic-likelihood representation of  $\mathcal{L}_\epsilon(\theta)$  is less sensitive to small choices of  $\epsilon$ . This is particularly important to HABC as our gradient approximations are proportional to differences in  $\mathcal{L}_\epsilon(\theta)$ ; if the variance of the stochastic gradients is too high, then we must choose a very small step-size  $\eta$ , eliminating the usefulness of HMC for ABC. Under the deterministic representation of  $\mathbf{x}^{(s)}$ , we can write the log-likelihood as

$$\mathcal{L}_\epsilon(\theta) \propto \log \sum_s \mathcal{N}(\mathbf{y}|f(\theta, \omega_s), \epsilon^2) \quad (16)$$

$$\approx -\log \epsilon - \frac{1}{2\epsilon^2} (\mathbf{y} - f(\theta, \omega_m))^2 \quad (17)$$

In the second line we have assumed  $\epsilon$  is very small and  $m$  is the index of the random seed producing the closest simulation to  $\mathbf{y}$ . For a finite difference approximation,

---

**Algorithm 1**  $\nabla U$  SPSA-ABC
 

---

**inputs:**  $\theta, d_\theta, f, \omega, \mathcal{L}_\epsilon, \pi, R$   
 $\hat{g} \leftarrow \mathbf{0}$   
**for**  $r = 1 : R$  **do**  
 $\Delta \sim 2 \cdot \text{Bernoulli}(1/2, D) - 1$   
**for**  $s = 1 : S$  **do**  
 $\mathbf{x}_+^{(s)} \leftarrow f(\theta + d_\theta \Delta, \omega_s)$   
 $\mathbf{x}_-^{(s)} \leftarrow f(\theta - d_\theta \Delta, \omega_s)$   
**end for**  
 $\hat{g} \leftarrow \hat{g} + \left( \mathcal{L}_\epsilon(\{\mathbf{x}_+^{(s)}\}) - \mathcal{L}_\epsilon(\{\mathbf{x}_-^{(s)}\}) \right) \cdot \Delta^{-1}$   
**end for**  
 $\hat{g} \leftarrow \hat{g} / (2d_\theta R) + \nabla \log \pi(\theta)$   
**return**  $-\hat{g}$

---

$\partial \mathcal{L}_\epsilon(\theta) / \partial \theta$  is

$$\frac{1}{4d_\theta \epsilon^2} \left( (\mathbf{y} - f(\theta - d_\theta, \omega_m^-))^2 - (\mathbf{y} - f(\theta + d_\theta, \omega_m^+))^2 \right) \quad (18)$$

On the other hand, the synthetic-likelihood is stable; using a deterministic representation, we have

$$\mu_\theta = \frac{1}{S} \sum_s f(\theta, \omega_s) \quad \sigma_\theta^s = \frac{1}{S-1} \sum_s (\mu_\theta - f(\theta, \omega_s))^2 \quad (19)$$

the gradients (for a 1-dim problem) use  $\epsilon$  as a smoothness prior in  $\partial \mathcal{L}_\epsilon(\theta) / \partial \theta$ :

$$-\frac{1}{2} \log \left( \frac{\sigma_{\theta^+}^2 + \epsilon^2}{\sigma_{\theta^-}^2 + \epsilon^2} \right) - \frac{(\mathbf{y} - \mu_{\theta^+})^2}{2(\sigma_{\theta^+}^2 + \epsilon^2)} + \frac{(\mathbf{y} - \mu_{\theta^-})^2}{2(\sigma_{\theta^-}^2 + \epsilon^2)} \quad (20)$$

In Figure 2, as part of our demonstration of HABC, we compare the gradient approximations around the true  $\theta_{\text{MAP}}$  using SL versus kernel- $\epsilon$  for a simple problem. Although there is a small bias using SL due to its Gaussian assumption, it has much smaller variance, convergence to this (biased) posterior should be stable. Further, [19] showed that convergence for SGHD type algorithms depends on the tails of the log-posterior, which suggests that despite its bias, the non-heavy tails of the Gaussian may allow SL to produce a more efficient Markov chain.

### 4.3 From Finite Differences to Simultaneous Perturbations

If the dimension of  $\theta$  is small, then *finite difference stochastic approximation* (FDSA) [9] can be applied to  $\nabla U(\theta)$  (conditioned on random seeds  $\omega$ ). The number of simulations required for FDSA is  $2SD$ , which may be acceptable for some small ABC problems. Our main goal is to scale ABC to high-dimensions and for that we need an alternative stochastic approximation to  $\nabla U(\theta)$ .

In the gradient-free setting, Spall [21, 22] provides a stochastic approximate to the true gradient using only 2

Figure 1: A view of a simulator using persistent random numbers; in other contexts, these are called common random numbers [10]. The horizontal line represents  $\mathbf{y}$  and red shading  $\pm 2\epsilon$ . The shaded curved region represents  $2\sigma$  of  $\pi(\mathbf{x}|\theta)$ . The dashed lines are  $f(\theta, \omega_s)$  for several values of  $\omega$ . The blue circles are potential random samples from  $\pi(\mathbf{x}|\theta)$ . For a fixed value  $\omega_s$ , the simulator produces deterministic outputs that change smoothly, even though the simulator itself is quite noisy.

forward simulations for any dimension  $D$  (though the approximation can be improved by averaging  $R$  estimates). Spall's *simultaneous perturbation stochastic approximation* (SPSA) algorithm works as follows. Let  $L$  be the gradient-free function we wish to optimize. Each approximation randomly generates a *perturbation mask* (our name)  $\Delta$  of dimension  $D$  where entry  $\Delta_d \sim 2\text{Bernoulli}(1/2) - 1$  (i.e. all entries randomly set to  $\pm 1$ ). Then  $L$  is evaluated at  $\theta + d_\theta \Delta$  and  $\theta - d_\theta \Delta$ , giving the gradient approximation  $\hat{g}(\theta) \approx \partial L(\theta) / \partial \theta$ :

$$\hat{g}(\theta) = \frac{L(\theta + d_\theta \Delta) - L(\theta - d_\theta \Delta)}{2d_\theta} \begin{bmatrix} 1/\Delta_1 \\ 1/\Delta_2 \\ \vdots \\ 1/\Delta_D \end{bmatrix} \quad (21)$$

If we let  $\hat{g}_r(\theta)$  be the estimate using perturbation mask  $\Delta_r$ , the estimate  $\hat{g}(\theta)$  can be improved by averaging  $\hat{g}(\theta) = 1/R \sum_r \hat{g}_r(\theta)$ . Algorithm 1 shows SPSA to estimate  $\nabla U(\theta)$ . The number of simulations required for SPSA is  $2SR$ , where  $R \geq 1$ .

Variations of SPSA include *one-sided* SPSA [22] (we use what Spall calls 2SPSA) and an algorithm for estimating the Hessian based on the same principle as SPSA [23]. The one-sided version is attractive computationally, but for HABC, the updates for  $\theta$  require simulating two-sides anyway (once at  $\theta$ , after a step is taken, and once for the one-sided gradient). SPSA has also been used within a procedure for maximum-likelihood estimation for hidden Markov models using ABC [8].

### 4.4 Persistent Random Numbers

The usefulness of applying *persistent* random numbers (PRNs) in SPSA has been previously demonstrated [10]. In

that work, the same random numbers are used to simulate both sides of the optimization function within the SPSA gradient. This makes sense intuitively, as we would generally assume that the expected simulation function varies smoothly in  $d\theta$ ; by using PRNs, this smoothness is easily exploited (see Figure 1). If we were to apply SPSA to Bayesian learning, then using PRNs in the gradient step would be analogous to using the same mini-batch for both sides of the computation. In the case where the number of random numbers is unknown or is itself random, we can simply consider seeds of the random number generator instead of vectors of random numbers.

In addition to using PRNs in simulations for each gradient computation, we have found that using PRNs helps HABC explore the parameter landscape more easily for some algorithms and problems. Intuitively, for a gradient-based sampling algorithm, it means a particle can slide along a smooth Hamiltonian landscape because the additive noise is suppressed. This is very similar to using dependent random streams to drive MCMC [15, 17], the main difference we believe is that we are using the Hamiltonian dynamics to drive proposals for  $\theta$  and using persistent seeds  $\omega$  to suppress simulation noise. The full benefits of suppressing the noise may be limited, however. Recent work has shown that scaling HMC for large data applications may be fundamentally limited [4]: noise from mini-batches causes biases in trajectories, which require either increasing mini-batch sizes (in our case, running more simulations) or decreasing the step size.

Using random seeds (versus, say, a set of random numbers) allows us to treat the simulator as a black-box, setting the random seed of its RNG without knowing the internal mechanisms it uses to generate random numbers. In light of our arguments above, we propose including persistent random seeds  $\omega$  in the state of our Markov chain. We will now describe a simple Metropolis-Hastings transition operator that randomly proposes *flipping* each seed  $\omega_s$  at time  $t$  with some probability  $\gamma$ .

This Metropolis-Hastings transition conditions of the current parameter location  $\theta$  and proposes changing a single random seed  $\omega$  (it easily generalizes to  $S$  seeds). The procedure is as follows: 1) propose a new seed  $\omega' \sim q(\omega'|\omega) = \pi(\omega)$  (independent of the current seed and from its uniform prior); 2) simulate *deterministically*  $\mathbf{x}' = f(\theta, \omega')$ ; 3) compute the acceptance ratio (which reduces to the ratio of  $\pi(\mathbf{y}|\mathbf{x}')/\pi(\mathbf{y}|\mathbf{x})$ ). It is straightforward to show that this leaves the target distribution invariant. The probability of the proposal is  $q(\omega', \omega|\theta, \omega) = \pi(\omega')\delta(\mathbf{x}' - f(\theta, \omega'))$ , where  $\delta(a)$  is a delta function at  $a = 0$ . Because the  $q$  has this form, the acceptance ratio simplifies:

$$\frac{\pi_\epsilon(\mathbf{y}|\mathbf{x}')\pi(\omega')\pi(\mathbf{x}'|\theta, \omega')\pi(\omega)\delta(\mathbf{x} - f(\theta, \omega))}{\pi_\epsilon(\mathbf{y}|\mathbf{x})\pi(\omega)\pi(\mathbf{x}|\theta, \omega)\pi(\omega')\delta(\mathbf{x}' - f(\theta, \omega'))} = \frac{\pi_\epsilon(\mathbf{y}|\mathbf{x}')}{\pi_\epsilon(\mathbf{y}|\mathbf{x})} \quad (22)$$

In pseudo-marginal ABC-MCMC one could propose  $q(\mathbf{x}^{(s)}|\theta)$  (fixing  $\theta$ ) and still sample correctly from the distribution of simulations with high likelihood at  $\theta$ . What we propose is slightly different. By instead keeping the random seeds fixed, we can sample  $\theta$  using HABC and use  $\omega$  as PRNs within the gradient computation step and suppress gradient noise over time. In this way, random seeds carry over the same additive noise from one step to the next.

## 5 Demonstration

We use a simple  $D = 1$  problem to demonstrate HABC. Let  $y = \frac{1}{N} \sum_i e_i$ , where  $e_i \sim \text{Exp}(1/\theta^*)$ ;  $\theta^* = 0.15$ ,  $N = 20$ , and  $y = 7.74$  in our concrete example. Assuming  $\pi(\theta) = \text{Gamma}(\alpha, \beta)$ , the true posterior is a gamma distribution with shape  $\alpha + N$  and rate  $\beta + Ny$ . Our simulator therefore generates the average of  $N$  exponential random variates with rate  $\lambda = 1/\theta$ . Data  $x \stackrel{\text{sim}}{\sim} \pi(x|\theta)$  are shown in Figure 1. We have explicitly shown the smoothness of the simulator by generating data along trajectories of fixed seeds  $\omega_s$ ; i.e. for several  $\omega_s$  we vary  $\theta$  (dashed lines are function  $f(\theta, \omega_s)$ ) and randomly reveal simulation data (blue circles). The horizontal line with shading indicates  $y \pm 2\epsilon$ , where  $\epsilon = 0.37$  is used throughout the demonstration.

### 5.1 Bias and Variance of $\nabla \hat{U}(\theta)$

To test our assumption that the synthetic-likelihood model is better suited for HABC, we ran FDSA at the true  $\theta_{\text{MAP}}$ . Using  $S = 5$  and  $S = 50$  and fixing  $\epsilon = 0.37$ , we gather  $10K$  gradient samples using kernel- $\epsilon$  and SL likelihoods. These gradient estimate densities are shown in Figure 2. An unbiased estimate of the gradient should be centered at 0. There are two important results. First, the SL estimates have a small bias, even at  $S = 50$ . This is because it is estimating the true Gamma distribution of  $\pi(\mathbf{x}|\theta)$  with a Gaussian. We can analytically estimate this bias as  $S \rightarrow \infty$ ; for this example it is  $-7.8$  which is what SL estimates are centered around ( $-9.3$  for  $S = 5$  and  $7.3$  for  $S = 50$ ). The kernel- $\epsilon$  likelihood, on the other hand, exhibits low bias at  $S = 50$ . However, the second important result is the variances. SL variances decrease quickly with  $S$ :  $\sigma^2 = 43^2 \rightarrow 4.9^2$ , whereas kernel- $\epsilon$  starts very high and remains high:  $\sigma^2 = 147^2 \rightarrow 19^2$ . It is for this reason that we have chosen to use SL likelihoods for our gradient estimates, despite their small bias. As mentioned in Section 4.2 it is possible that other likelihood models, such as a kernel density estimate, might provide low bias and low variance gradient estimates. We leave this for future work.

### 5.2 Posterior Inference using HABC

We ran chains of length  $50K$  for SL-MCMC, SGLD, SGHMC, and SGNHT versions of HABC using SL gra-

Figure 2: Variance of gradient estimation using kernel- $\epsilon$  and SL for different values of  $S \in \{5, 50\}$  and fixed  $\epsilon = 0.37$  (the same used in the other results). When  $S = 5$ , the empirical estimates of  $\nabla \hat{U}(\theta_{MAP})$  are  $-12 \pm 147$  (kernel- $\epsilon$ ) and  $-9.3 \pm 43$  (SL). When  $S = 50$  they are  $-0.80 \pm 19$  (kernel- $\epsilon$ ) and  $-7.3 \pm 4.9$  (SL). Note the large discrepancy in variance. Note the limit of  $S \rightarrow \infty$ ,  $\nabla \hat{U}(\theta_{MAP}) = -7.8$ . The bias if SL gradients is due to its Gaussian approximation (smoothed by  $\epsilon$ ) of  $\pi(\mathbf{x}|\theta)$ , which is a heavy-tailed Gamma distribution (the sum of  $N$  exponentials).

dient estimates ( $S = 5$ ). SL-MCMC refers to pseudo-marginal ABC-MCMC. We note that SGHMC gave results nearly identical to SGNHT, so are not shown due to space limitations. In one set of experiments, the same random seeds were used for gradient computations but did not persist over time steps; these experiments are called *non-persistent*. In another set of runs, we resampled  $\omega_s$  at each time step with probability  $\gamma = 0.1$ ; these experiments are *persistent*. In Figure 3 we show the posterior distributions for these experiments; in Table 1 we report the *total variational distance* between the true posterior and the ABC posteriors using the first  $10K$  samples and after  $50K$  samples (averaged over 5 chains). Of note is the poor approximation of SG-Thermostats when the seeds are not persistent. By adding persistent seeds, SGNHT gives similar posteriors to the other methods.

In Figure 4 we show the trace plots of the last 1000 samples from a single chain for each algorithm. In the left column, traces for non-persistent random seeds are shown, and on the right, traces for persistent seeds. We can observe that persistent random seeds further reduces the random walk behavior of all three methods. We also observe small improvements in total variational distance for SL-MCMC and SGLD, while SGNHT improves significantly. We find this a compelling mystery. Is it because of the interaction between hyperparameters and stochastic gradients, or is this an artifact of this simple model?

## 6 Experiments

We present experimental results comparing HABC with standard ABC-MCMC for two challenging simulators. The first is the *blowfly* model which uses stochastic differential equations to model possibly chaotic population dynamics

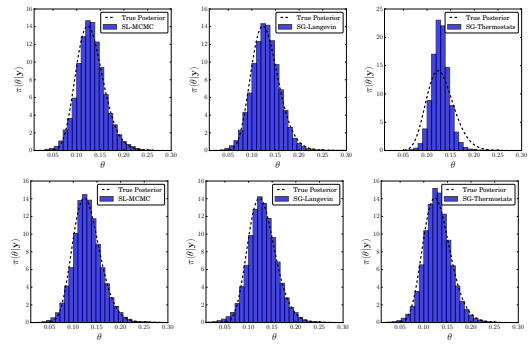

Figure 3: Posterior distributions for the demonstration problem; columns left to right: SL-MCMC, SGLD (SG-Langevin), SGNHT (SG-Thermostats). **Top row:** No persistent seeds. **Bottom row:** Persistent seeds with  $\gamma = 0.1$ . Histograms of the posterior estimates are overlaid with the true posterior (dashed line). All algorithms (except for SGNHT for non-persistent  $\omega$ ) give roughly the same posterior estimate. By adding persistent  $\omega$  SGNHT achieved similar posteriors to the other algorithms.

Table 1: Average total variational distance (tvd) for the demonstration problem. *Non-persistent* used no persistent random seeds, whereas *Persistent* randomly proposes a new  $\omega_s$  with  $\gamma = 0.1$ . Each algorithms' parameters were optimized for minimal tvd after  $10K$  samples. The results for SGHMC (not shown) and SGNHT are nearly identical.

| Algo    | Non-persistent |       | Persistent |       |
|---------|----------------|-------|------------|-------|
|         | 10K            | 50K   | 10K        | 50K   |
| SL-MCMC | 0.047          | 0.045 | 0.045      | 0.045 |
| SGLD    | 0.049          | 0.048 | 0.048      | 0.043 |
| SGNHT   | 0.232          | 0.239 | 0.055      | 0.051 |

[28]. Although it is a low-dimensional problem, the noise and chaotic behavior of the model make it challenging for gradient-based sampling. Our second experiment applies HABC to a Bayesian logistic regression model. Although we only use 2 classes (0's versus 1's), the dimensionality is very high ( $D = 1568$ ). We show that HABC can work well despite using SPSA gradients.

### 6.1 Blowfly

For these experiments, a simulator of adult sheep blowfly populations [28] is used with statistics set to those from [14]. The observational vector  $\mathbf{y}$  is a time-series of a fly population counted daily. The population dynamics are modeled using a stochastic differential equation<sup>1</sup>

$$N_{t+1} = PN_{t-\tau} \exp(-N_{t-\tau}/N_0)e_t + N_t \exp(-\delta\epsilon_t)$$

where  $e_t \sim \mathcal{G}(1/\sigma_p^2, 1/\sigma_p^2)$  and  $\epsilon_t \sim \mathcal{G}(1/\sigma_d^2, 1/\sigma_d^2)$  are sources of noise, and  $\tau$  is an integer. In total, there are  $D =$

<sup>1</sup>Equation 1 in Section 1.2.3 of the supplementary information in [28].

Figure 4: Trajectories of the last 1000  $\theta$  samples for the demonstration problem. **Top row:** Non-persistent random seeds. **Bottom row:** Persistent random seeds with  $\gamma = 0.1$ . Each algorithm’s parameters were optimized to minimize the total variational distance. With persistent seeds, each algorithm’s random walk behavior is suppressed. Without persistent seeds, the optimal step-size  $\eta$  for SGNHT is small, resulting in an under-dispersed estimate of the posterior; when the seeds are persistent, the gradients are more consistent, and the optimal step-size is larger and therefore there is larger injected noise. The resulting posteriors are shown in Figure 3.

6 parameters  $\theta = \{\log P, \log \delta, \log N_0, \log \sigma_d, \log \sigma_p, \tau\}$ . As [14] we place broad log-normal priors over  $\theta_{1..5}$  and a Poisson prior over  $\tau$ . This is considered a challenging problem because slight changes to some parameter settings can produce degenerate  $\mathbf{x}$ , while others settings can be very noisy due to the chaotic nature of the equations. The statistics from [14] are used ( $J = 10$ ): the log average of 4 quantiles of  $N/1000$ , the average of 4 quantiles of the first-order differences in  $N/1000$ , and the number of maximal population peaks under two different thresholds.

We compare difference HABC algorithms with ABC-MCMC for the blowfly population problem. We use  $\epsilon = \{1/2, 1/2, 1/2, 1/2, 1/4, 1/4, 1/4, 1/4, 3/4, 3/4\}$  (slightly different  $\epsilon$  from [14]) and  $S = 10$  for all experiments (this means that there are  $S$  random seeds). We use SPSA with  $R = 2$  using SL log-likelihoods for all HABC gradient estimates. Without persistent seeds, the number of simulations per time-step is  $2SR$  (about double marginal ABC-MCMC) and with it is  $2SR + 2S\gamma$ .

Figure 5 show the posterior distributions for three parameters for SL-MCMC, SGLD, and SGNHT using non-persistent seeds (persistent seeds, not shown, produced very similar posteriors). In the second row we show the trajectories of two parameters, clearly showing the suppressed random walk behavior of SGLD and SG-Thermostats relative to ABC-MCMC. In Figure 6 the scatter plots of trajectories are shown for two parameters. Though not shown due to space limitations, we have found that persistent seeds can improve convergence of the posterior predictive distribution. Further experiments with persistent seeds needs to be carried out to understand the extent to which the help and how to determine when they are necessary, if at all.

## 6.2 Bayesian Logistic Regression

We perform Bayesian inference on a logistic regression model using the digits 0 and 1 from MNIST. Although

Figure 6: Blowfly trajectories of two parameters over the last 1000 time-steps. **Top:** SGLD and **Bottom:** SGNHT (SG-Thermostats). Relative to SL-MCMC (not shown), the Hamiltonian dynamics clearly show persistent  $\theta$  trajectories.

not technically an ABC problem because we use the actual likelihoods, it still represents a high-dimensional problem ( $D = 1568$ ) and is therefore useful to evaluate the potential of SPSA-like gradients in actual HABC problems. We first ran stochastic gradient descent to determine  $\theta_{\text{MAP}}$  using the true gradient. We then ran SGLD and SGNHT starting  $\theta_{\text{MAP}}$  to discover how well the algorithms explore the posterior. We examine how SGLD and SGNHT trajectories are affected by using SPSA instead of the *true* gradients. We use  $n = 100$  sized mini-batches and  $R = 10$  perturbations for SPSA. Figure 7 shows samples randomly projected onto 2 dimensions (1000 evenly sub-sampled from

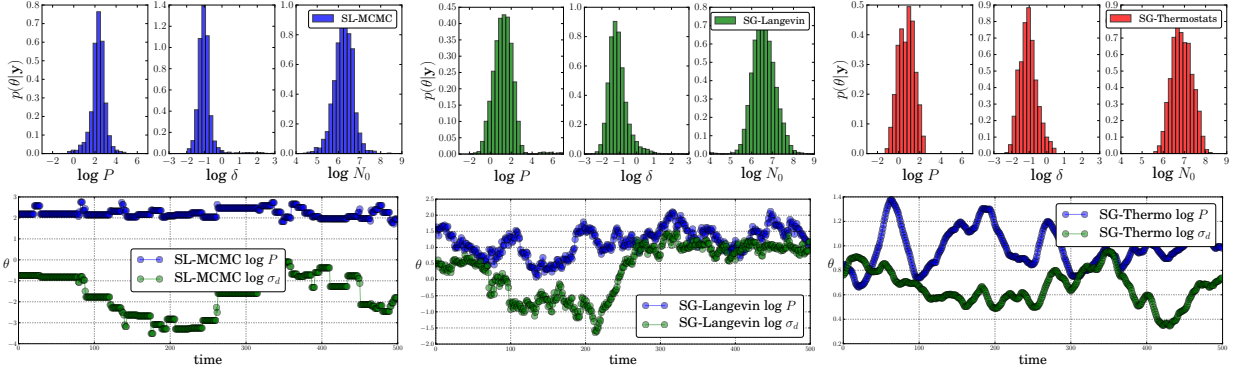

Figure 5: Blowfly posterior distributions (non-persistent seeds). **Top row:** Posteriors for three parameters for SL-MCMC (left set of three), SGLD (SG-Langevin) (middle), and SGNHT (SG-Thermostats) (right). **Bottom row:** Last trajectories of the last 1000 samples for two parameters for the same algorithms.

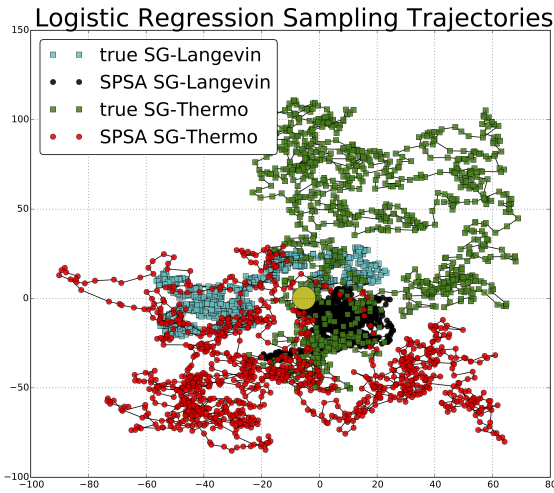

Figure 7: Bayesian logistic regression sampling trajectories randomly projected. The yellow circle is the projected MAP of  $\theta$ .

10K). We can clearly see that the trajectories using SPSA exhibit very similar behavior to Bayesian learning with the true gradients. This is very positive result that indicates HABC can successfully exploit the noisy and less informative gradients of SPSA.

## 7 DISCUSSION AND CONCLUSION

Hamiltonian ABC proposes a new set of algorithms for Bayesian inference of likelihood-free models. HABC builds upon the connections between Hamiltonian Monte Carlo with stochastic gradients and well-established gradient approximations based on a minimal number of forward simulations, even in high-dimensions. We have performed some preliminary experiments showing the feasibility of running HABC on both small and large problems, and we hope that the door has been opened for exploration of larger simulation-based models using HABC.

Another innovation we introduce is the use of persistent random seeds to suppress the simulator noise and therefore smooth the simulation landscape over a local region

of parameter space. For some algorithms run on certain models, improved performance has been observed. This is most likely to be the case for simulators with large additive noise and algorithms that benefit from long Hamiltonian trajectories (i.e. SGHMC and SGNHT). We feel that new classes of ABC algorithms could develop from using persistent random seeds, not just gradient-based samplers but traditional ABC-MCMC.

There are several unresolved and open questions regarding the application of stochastic gradients to ABC. The first issue is the importance of the bias-variance relationship for different ABC likelihood models. We found that using gradients based on the synthetic-likelihood greatly reduced their variance, but introduced a small bias, because of its Gaussian assumption. The second issue is setting algorithm parameters, in particular the step-sizes  $\eta$ , the injected noise  $C$  (for SGHMC/SGNHT), and the number of SPSA repetitions  $R$ . All of these parameters are highly interactive. Can we use statistical tests during the MCMC run to determine  $R$ ? Should  $\eta$  and  $C$  be set differently in the ABC setting? One final issue is monitoring or determining whether the correct amount of noise is being injected to ensure proper sampling. In SGLD [25], for example, we can always turn down  $\eta$  so that the injected noise term dominates, but when our goal is efficient exploration of the posterior, this is not a very satisfying solution.

Expensive simulators are an important class of models that we do not address in this work. However, previous work in Bayesian inference has shown the usefulness of HMC-based proposals based on Gaussian process of log-likelihood surfaces [18]. We could similarly use HABC with ABC surrogate models [14, 27] to minimize simulation calls, yet still benefit from Hamiltonian dynamics.

## Abstract

We study the problem of private stochastic multi-arm bandits. Our notion of privacy is the same as some of the earlier works in the general area of private online learning [13, 17, 24]. We design algorithms that are i) differentially private, and ii) have regret guarantees that (almost) match the regret guarantees for the best non-private algorithms (e.g., upper confidence bound sampling and Thompson sampling). Moreover, through our experiments, we empirically show the effectiveness of our algorithms.

## 1 INTRODUCTION

A general abstraction of bandit problems is the following: Given a set of  $k$  arms  $\mathcal{C} = \{a_1, \dots, a_k\}$ , at each time step one pulls an arm  $a_i \in \mathcal{C}$ , gets a reward corresponding to  $a_i$  and the objective of the algorithm is to obtain large cumulative reward over all time steps  $T$ . In a class of problems called the *adversarial bandits*, it is assumed that the reward can be adversarial, in the sense that the rewards for each of the arms in  $\mathcal{C}$  are arbitrarily chosen. The other class of problems is called the *stochastic bandits* where it is assumed that the reward for each of the arm in  $\mathcal{C}$  is from an unknown distribution. (See [5] for a detailed introduction to these classes.) In this paper we are interested in the stochastic bandit setting. We analyze two of the most common algorithms in this setting in the context of differential privacy, *upper confidence bound* (UCB) sampling by [4] and *Thompson sampling* by [2, 18]. We show that one can modify UCB sampling and Thompson sampling algorithms in such a way that ensures: i) differential privacy, and ii) regret guarantee which is only poly  $\log T$  factor worse compared to the regret for the non-private variants.

We now focus on the semantics of differential privacy in this setting where the data points (the rewards) arrive online in a stream at every time step. This setting was first studied by [13] and then followed by [17] and [24]. Let

$f_t = \langle f_t(a_1), \dots, f_t(a_k) \rangle$  be the vector of rewards for all the arms in  $\mathcal{C}$  at time step  $t$ . Privacy guarantee will ensure that from the output of the algorithm over all the  $T$  time steps the adversary will not be able to distinguish between the presence or absence of any single reward vector  $f_t$ . [16] studied differentially private online algorithms in the *full-information* setting, where at each time step  $t$  the algorithm can see the complete reward vector  $f_t$  as opposed to  $f_t(a)$  for the arm  $a$  pulled in the bandit setting. [24] extended this line of work to obtain tighter and nearly optimal regret guarantees for both full-information and adversarial bandit settings. Recall that in the non-private world, the full-information and the adversarial bandit settings both have optimal regret guarantee of  $\Omega(\sqrt{T})$  (see [23]). In contrast, stochastic bandit algorithms enjoy a regret of  $O(\log T)$ . In this work we obtain the *first* and *nearly optimal* regret guarantees for stochastic bandit problems. Since, stochastic bandit algorithms have a very different flavor than adversarial online algorithms, we needed to introduce new proof techniques tailored to our problem.

The stochastic multi-armed bandit algorithms usually run in the two implicit phases *exploration phase* and *exploitation phase*. During the exploration phase, the algorithm uses the pull of the arms in the initial rounds to get a sufficiently accurate estimate of the means of the arms, and then in the second phase uses this information to guide the decision of pulling of arms in the later rounds. However, in order to ensure differential privacy, we are required to introduce certain randomness in the observed rewards, but this tends to grossly corrupt the estimation of the means of the arms. At a high-level, for both UCB and Thompson sampling, we address this issue by increasing the number of rounds used by the algorithm to estimate these means. The exact details are very different for both the algorithms are discussed in the respective sections. One important point to keep in mind is that although we make stochastic assumptions on the data to ensure strong utility guarantees, we *do not* make any assumptions on the data while ensuring privacy for our algorithms. Using the distributional assumption on the data for any kind of privacy guarantee may be disastrous, since real world data may not fol-

low the assumed distribution. For our algorithms, privacy should hold in the worst case scenario but the utility guarantee holds under distributional assumptions on the data. Finally, to fortify our theoretical guarantees we show that they work well in experiments and often are competitive w.r.t. the non-private algorithms.

**Practical motivation.** In the past few years bandit algorithms have become extremely popular in both the theoretical and applied online learning community. Along with having strong theoretical guarantees, these algorithms have found wide applicability in Internet scale systems. A concrete usage scenario is in the online search advertisement industry. Companies like Google, Microsoft and Yahoo run multi-million dollar industry based on showing relevant advertisements for a web-queries. For a given search query by the user, the search engine displays a few advertisement which the user is most likely to click (commonly known as the *main-line advertisement*). After the advertisement gets displayed, the user chooses to either click or not click. If he/she clicks, then we say that the search engine gets a reward of one, and zero otherwise. To earn maximum revenue, the search engine strives to get high overall reward. One important feature of this setup (and generally in bandit learning) is that the search engine only gets to see the reward for the advertisements that were shown to the user, and gets no feedback about what the user would have done on other candidate advertisements. Bandit algorithms have been extremely successful in such settings and often enjoy strong theoretical guarantees for the overall reward. Settings like search advertisements immediately raise privacy concern for the users whose data get used in training the learning algorithms. Consider the example of a user who searches for a lawyer in Port Jefferson, NY and clicks on an advertisement of a divorce law firm. If the learning algorithm uses this feedback to show the same advertisement for similar query (e.g., finance lawyer in Port Jefferson, NY), then one can use such feedbacks to infer significant amount of information about a particular user. [19] on the Facebook advertisement recommendation system and [6] on the Amazon recommendation system, showed that one can leverage such side information to breach user privacy.

### 1.1 Our Contributions

Here, we provide an overview of our contributions.

- **Differentially private UCB sampling [Section 3].** We provide a differentially private variant of UCB sampling which enjoys the same utility guarantee as the non-private algorithm up to poly-logarithmic factors in the number of time steps  $T$ . The privacy guarantee follows via standard reduction to the *tree-based-aggregation scheme*, proposed by [14, 7]. Our utility analysis goes via carefully analyzing the *exploration phase* of the algorithm, where it estimates the means of the arms. Thus, we provide a version of UCB sampling algorithm which

is robust to noise.

- **Differentially private Thompson sampling [Section 4].** We also provide a differentially private variant of Thompson sampling which enjoys the same utility guarantee as the non-private algorithm up to poly-logarithmic factors in the number of time steps  $T$ . The privacy analysis is very similar to the UCB sampling. But, the utility analysis is much trickier. In fact even without privacy analyzing the *exploration phase* was considered extremely difficult and it took more than seventy years for the community to come up with a formal analysis (see [2, 18]). The main technical contribution of this section is to come up with a noise robust version of Thompson sampling. In order to obtain this robustness, the exploration phase of the original algorithm had to be modified significantly. A question that we leave open in this work is that if that is necessary.

## 2 BACKGROUND AND PROBLEM DEFINITION

### 2.1 Background on Differential privacy

In this section we provide a short overview of differential privacy.  $\mathcal{D} = \langle f_1, \dots, f_T \rangle$  be a data set of all the reward functions. We call a data set  $\mathcal{D}'$  neighbor of  $\mathcal{D}$  if it differs from  $\mathcal{D}$  in exactly one reward function. Let  $\mathcal{C}^T$  be the space of all  $T$  outputs of Algorithm  $\mathcal{A}$ .

**Definition 1** (Differential privacy [12]). *A randomized algorithm  $\mathcal{A}$  is  $\epsilon$ -differentially private if for any two neighboring data sets  $\mathcal{D}$  and  $\mathcal{D}'$ , and for all sets  $\mathcal{O} \subseteq \mathcal{C}^T$  the following holds:*

$$\Pr[\mathcal{A}(\mathcal{D}) \in \mathcal{O}] \leq e^\epsilon \Pr[\mathcal{A}(\mathcal{D}') \in \mathcal{O}].$$

As per the semantics of the definition, differential privacy ensures that an adversary gets to know “almost the same thing” about a reward function  $f_t$  irrespective of its presence or absence in the data set  $\mathcal{D}$ . This closeness is measured by the privacy parameter  $\epsilon$ . A typical choice of  $\epsilon$  is a small constant (e.g., 0.1). One important requirement of the definition is that the guarantee should hold for every pair of neighboring data sets. This directly implies that although for the regret analysis of our algorithm  $\mathcal{A}$  we can assume that the reward function comes from some underlying distribution, but we *cannot* use any stochastic assumption on the reward functions for privacy guarantee. Next, we discuss some of the basic tools for designing differentially private algorithms.

**Laplace and Gamma mechanism.** Laplace [12] and Gamma mechanism [10] are sensitivity based methods to achieve differential privacy. The best way to introduce Laplace mechanism is via the following setting. Consider a domain of data entries  $\mathcal{U}$  and a function  $f : \mathcal{U}^* \rightarrow \mathbb{R}$ . For the domain of data sets  $\mathcal{U}^n$ , we define the sensitivity of the

function  $f$  as below.

$$s = \text{Sensitivity}(f) = \max_{\text{Neighbors } \mathcal{D}, \mathcal{D}' \in \mathcal{U}^*} |f(\mathcal{D}) - f(\mathcal{D}')|$$

Let  $\text{Lap}(\lambda)$  be the Laplace distribution with scaling parameter  $\lambda$ , *i.e.*, the density function of this distribution is given by  $\frac{1}{2\lambda} e^{-|x|/\lambda}$ . Laplace mechanism states that for a given data set  $\mathcal{D}$  and noise  $N \sim \text{Lap}(\frac{s}{\epsilon})$ ,  $f(\mathcal{D}) + N$  is  $\epsilon$ -differentially private. The proof of this claim directly follows from the density function for Laplace distribution and triangle inequality. [12]

Gamma mechanism is also very similar to Laplace mechanism. The only difference being that we are now working with a vector valued function  $f : \mathcal{U}^* \rightarrow \mathbb{R}^p$ . Analogous to Laplace mechanism, let us define the  $L_2$ -sensitivity of the function  $f$  as below.

$$s = \text{Sensitivity}(f) = \max_{\text{Neighbors } \mathcal{D}, \mathcal{D}' \in \mathcal{U}^*} \|f(\mathcal{D}) - f(\mathcal{D}')\|_2$$

Gamma mechanism states that if we sample the noise vector  $N \in \mathbb{R}^p$  from the noise distribution with kernel  $e^{-\epsilon \|N\|_2/s}$ , then  $f(\mathcal{D}) + N$  is  $\epsilon$ -differentially private. (See [10] for the proof.)

**Tree based aggregation.** Initially proposed by [14, 7], this aggregation scheme is extremely effective in releasing private continual statistics over a data stream. To define the scheme formally, consider a data set  $\mathcal{D} = \langle f_1, \dots, f_T \rangle$ , where each entry  $f_t \in [0, 1]$ , and these entries arrive in a stream, *i.e.*, at every time step  $t \in [T]$ , one entry  $f_t$  arrives.

At every time step  $t$ , the task is to output  $v_t = \sum_{\tau=1}^t f_t$  while ensuring that the complete output sequence  $\langle v_1, \dots, v_T \rangle$  is  $\epsilon$ -differentially private. One can design an algorithm (using a binary tree based aggregation), which assures an additive error of  $O\left(\frac{\log^{1.5} T}{\epsilon}\right)$  per query. Moreover, it is simple to extend this scheme to the case where  $f_t \in \mathbb{R}^p$  and  $\|f_t\|_2 \leq 1$  for all  $t \in [T]$ . Since, the noise used in this scheme is exponential in nature, a high-probability guarantee is also immediate. We defer the details of the scheme to Appendix A. Suppose at every time step  $t \in [T]$ , one entry from dataset  $\mathcal{D}$ ,  $f_t \in [0, 1]$  arrives and the task is to output  $v_t = \sum_{\tau=1}^t f_t$  while ensuring that the complete output sequence  $\langle v_1, \dots, v_T \rangle$  is  $\epsilon$ -differentially private. This algorithm uses a binary tree based aggregation scheme, which assures an additive error of  $O\left(\frac{\log^{1.5} T}{\epsilon}\right)$  per query. We defer the details of the scheme to Appendix A. Moreover, it can be extended to the case where  $f_t \in \mathbb{R}^p$  and  $\|f_t\|_2 \leq 1$  for all  $t \in [T]$ .

## 2.2 Background on Stochastic Multi-arm Bandits

A typical setup for an online learning problem is as follows: There is a sequence of *reward functions*  $f_1, \dots, f_T$

arriving in a stream (*i.e.*, one at every time step  $t \in [T]$ ), where each  $f_t$  maps from some fixed set  $\mathcal{C}$  to  $\mathbb{R}$ . At every time step  $t$ , an online learning algorithm  $\mathcal{A}$  is expected to produce an element  $x_t \in \mathcal{C}$  before  $f_t$  is revealed to it. Once  $f_t$  gets revealed to  $\mathcal{A}$ , the algorithm pays a reward of  $f_t(x_t)$ . The objective of  $\mathcal{A}$  is to be competitive with the best choice of  $x \in \mathcal{C}$  in the hindsight, *i.e.*, be competitive with  $\max_{x \in \mathcal{C}} \sum_{t=1}^T f_t(x)$ . A natural measure of the utility of  $\mathcal{A}$  is

$$\text{regret, defined: } \text{Regret}_{\mathcal{A}}(T) = \max_{x \in \mathcal{C}} \sum_{t=1}^T f_t(x) - \sum_{t=1}^T f_t(x_t).$$

(For a detailed discussion, see [23])

There are two popular settings under which these problems are studied, namely, i) *online learning under complete feedback or the full-information setting*, and ii) *online learning under partial feedback or the bandit setting*. In the first setting, it is assumed that at time step  $t$  after the algorithm  $\mathcal{A}$  has produced  $x_t$ , it gets to see the complete reward function  $f_t$ . In the second setting, the algorithm gets much lesser information from the environment and just sees the evaluation of  $f_t$  at  $x_t$ .

## 2.3 Problem Definition

Let us assume that for all  $t \in [T]$  we have  $f_t : \mathcal{C} \rightarrow [0, 1]$ , where  $\mathcal{C}$  is the set of  $k$ -arms. Additionally we assume that for each arm  $a \in \mathcal{C}$ , each  $f_t(a)$  is an independent sample from a distribution with mean  $\mu_a$ . The objective is to design differentially private algorithms, whose regret (defined in (1)) depends poly-logarithmically in the number of reward functions  $T$ .

$$\mathbb{E} [\text{Regret}_{\mathcal{A}}(T)] = T \max_{a \in \mathcal{C}} \mu_a - \mathbb{E} \left[ \sum_{t=1}^T f_t(a(t)) \right]. \quad (1)$$

Here,  $a(t) \in \mathcal{C}$  is the arm played in the  $t$ -th time step.

## 3 PRIVATE UCB SAMPLING

Upper Confidence Bound (UCB) sampling by [4] is a heuristic for stochastic multi-arm bandit (MAB) problems, which despite being very simple gives strong utility guarantees. The regret for UCB  $O^*(\log T)$  in fact matches the asymptotic lower given by [20] upto a problem dependent constant. This is in sharp contrast with the algorithms for adversarial multi-arm bandit problems where the regret depends polynomially on the time horizon  $T$  (see [1, 15]). Recently [24] provided differentially private algorithms for adversarial bandit problems, which are almost optimal in the parameter  $T$ . In this section, for the UCB algorithm for stochastic MAB, we provide a differentially private algorithm whose expected regret is only poly-logarithmically worse in  $T$ . Before we move on to the differentially private UCB algorithm, we provide a brief overview of the non-private version of the algorithm.

**Background on UCB sampling.** Recall that in the MAB problem there are  $k$ -arms denoted by the set  $\mathcal{C}$ , and at each time step  $t$  each arm  $a \in \mathcal{C}$  produces either 0 or 1 from some unknown but fixed distribution on  $[0, 1]$  with mean  $\mu_a$ . The objective is to minimize the regret defined in (1). For each arm  $a$ , the UCB algorithm records the number of times it got pulled  $n_a(t)$  and the average reward  $\frac{r_a(t)}{n_a(t)}$  aggregated so far upto time  $t$ . Upon initialization, the algorithm pulls each arm exactly once. Later, the algorithm picks the arm with the highest upper confidence bound, i.e.,  $\arg \max_{a \in \mathcal{C}} \frac{r_a(t)}{n_a(t)} + \sqrt{\frac{2 \log t}{n_a(t)}}$ .

**Theorem 2** (Regret for non-private UCB Sampling [4]). *Let  $\mu^* = \max_{a \in \mathcal{C}} \mu_a$ . For each arm  $a \in \mathcal{C}$ , let  $\Delta_a = \mu^* - \mu_a$ . The expected regret of UCB sampling algorithm is as follows:*

$$\mathbb{E}[\text{Regret}_{\text{UCB}}(T)] = O\left(\sum_{a \in \mathcal{C}: \mu_a < \mu^*} \frac{\log T}{\Delta_a} + \Delta_a\right).$$

The expectation is over the randomness of the data.

### 3.1 Private UCB Sampling: Algorithm and Analysis

In Algorithm 1 we modify the UCB sampling algorithm to obtain an  $\epsilon$ -differentially private variant. Notice that for each arm  $a \in \mathcal{C}$  the average reward  $r_a(t)$ , is the only term that depends directly on the data set whose privacy we want to protect. So, if we can ensure that this sequence,  $r_a(t)$ ,  $t \in [T]$  is  $\epsilon/k$ -differentially private for each arm  $a$ , then immediately we have  $\epsilon$ -differential privacy for the complete algorithm. We invoke the tree based aggregation algorithm from Section 2.1 to make these sequences private. Additionally, to counter the noise added to the empirical mean, we loosen the confidence interval for the biases of each arm.

#### 3.1.1 Privacy Analysis

**Theorem 3** (Privacy guarantee). *Algorithm 1 is  $\epsilon$ -differentially private.*

*Proof.* The algorithm only accesses the reward for its computation via the tree based aggregation scheme (see Section 2). Since, there are  $k$ -arms, we maintain  $k$  separate trees, each of which is guaranteed to be  $\epsilon_0 = \frac{\epsilon}{k}$  differentially private. Using the composition property of differential privacy, we immediately conclude that Algorithm 1 is  $\epsilon$ -differentially private.  $\square$

#### 3.1.2 Regret Analysis

The expected regret of the algorithm is given by  $\mathbb{E}[\sum_{a \in \mathcal{C}: \mu_a < \mu_{a^*}} \Delta_a n_a(T)]$ . Hence, if our algorithm limits the pulls of the bad arms, we are done. Our regret analysis proceeds as follows, first we bound the amount of noise that

---

### Algorithm 1 Differentially Private UCB Sampling

---

- Input:** Time horizon:  $T$ , arms:  $\mathcal{C} = \{a_1, \dots, a_k\}$ , privacy parameter:  $\epsilon$ , failure probability:  $\gamma$ .
- 1: Create an empty tree  $\text{Tree}_{a_i}$  with  $T$ -leaves for each arm  $a_i$ . Set  $\epsilon_0 \leftarrow \epsilon/k$ .
  - 2: **for**  $t \leftarrow 1$  to  $k$  **do**
  - 3: Pull arm  $a_t$  and observe reward  $f_t(a_t)$ .
  - 4: Insert  $f_t(a_t)$  into  $\text{Tree}_{a_t}$  via *tree based aggregation* (see Section 2.1) with privacy parameter  $\epsilon_0$ .
  - 5: **Number of pulls:**  $n_{a_t} = 1$ .
  - 6: **end for**
  - 7: Confidence relaxation:  $\Gamma \leftarrow \frac{k \log^2 T \log((kT \log T)/\gamma)}{\epsilon}$ .
  - 8: **for**  $t \leftarrow k + 1$  to  $T$  **do**
  - 9: **Total reward:**  $r_a(t) \leftarrow$  Total reward computed using  $\text{Tree}_a$ , for all  $a \in \mathcal{C}$ .
  - 10: Pull arm  $a^* = \arg \max_{a \in \mathcal{C}} \left(\frac{r_a(t)}{n_a} + \sqrt{\frac{2 \log t}{n_a}} + \frac{\Gamma}{n_a}\right)$  and observe  $f_t(a^*)$ .
  - 11: **Number of pulls:**  $n_{a^*} \leftarrow n_{a^*} + 1$ .
  - 12: Insert  $f_t(a^*)$  into  $\text{Tree}_{a^*}$  using *tree based aggregation* and privacy parameter  $\epsilon_0$ .
  - 13: **end for**
- 

can be present in any of the total rewards  $r_a(t)$ . And later using this bound, we show that the number of times the suboptimal arms get pulled is small. We bifurcate the analysis of the each of the suboptimal arms into exploration and exploitation phase. We argue that in case of bad arms, after getting pulled for  $O\left(\frac{k \log^2 T \log(kT)}{\epsilon \Delta_a^2}\right)$  rounds the arm is not selected again with high probability. The main arguments in this analysis follow the general sequence of arguments in the analysis for non-private UCB sampling. (See [9] for a comparison.)

**Theorem 4** (Utility guarantee). *Let  $\{\mu_a : a \in \mathcal{C}\}$  be the biases of the  $k$ -arms in the set  $\mathcal{C}$ . Let  $\mu^* = \max_{a \in \mathcal{C}} \mu_a$  and for each arm  $a \in \mathcal{C}$ ,  $\Delta_a = \mu^* - \mu_a$ . With probability at least  $1 - \gamma$  (over the randomness of the algorithm), the expected regret (over the randomness of the data) is as follows:*

$$\mathbb{E}[\text{Regret}_{\text{Priv-UCB}}(T)] = O\left(\sum_{a \in \mathcal{C}: \mu_a < \mu^*} \frac{k \log^2 T \log(kT/\gamma)}{\epsilon \Delta_a} + \Delta_a\right).$$

In the following lemma, we bound the error in the computation of the total reward in Line 9 in Algorithm 1, introduced due to privacy.

**Lemma 5.** *For all arms  $a \in \mathcal{C}$  and all time step  $t \in [T]$ , w.p.  $\geq 1 - \gamma$  (over the randomness of the algorithm), the error in the computation of the total reward for a till time  $t$  is at most  $\frac{k \log^2 T \log((kT \log T)/\gamma)}{\epsilon}$ .*

The proof of this lemma is given in Appendix B.

**Lemma 6.** For a given arm  $a \in \mathcal{C}$ , if the mean  $\mu_a < \mu^*$  and  $\Delta_a = \mu^* - \mu_a$ , then w.p.  $\geq 1 - \gamma$  (over the randomness of the algorithm)  $\mathbb{E}[n_a(T)] = O\left(\frac{\log^2 T \log(kT/\gamma)}{\epsilon \Delta_a^2}\right) + \zeta$ . Here  $\zeta$  is a fixed positive constant independent of the problem parameters. The expectation is over the randomness of the data and  $O(\cdot)$  only hides multiplicative constants.

*Proof.* This lemma provides us with an upper limit on the expected number of pulls of the suboptimal arms. For each arm we partition the analysis into two phases (exploration phase and exploitation phase). For an arm  $a$ , such that  $\mu_a < \mu^*$ , we show that the exploration phase lasts for  $s_a = \frac{8k \log^2 T \log((kT \log T)/\gamma)}{\epsilon \Delta_a^2}$  many pulls. Once exploration phase is over, the exploitation phase starts. If  $n_a(T) \leq s_a$ , then we are done, since it means the arm was never finished the exploration phase. Otherwise, we show that the probability of pulling an arm after its exploration phase is very low. In principle, what we show that for the bad arms, the expected number of pulls for those arms is bounded during its exploration phase.

Let  $X_a(t)$  be the true total reward and  $\text{Noise}_a(t) = r_a(t) - X_a(t)$  for an arm  $a$ . For the ease of notation, let  $\Gamma = \frac{k \log^2 T \log((kT \log T)/\gamma)}{\epsilon}$ . At time step  $t \in [T - 1]$ , an arm  $a$  is pulled over  $a^*$  if the following is true.

$$\begin{aligned} & \frac{r_{a^*}(t)}{n_{a^*}(t)} + \sqrt{\frac{2 \log t}{n_{a^*}(t)}} + \frac{\Gamma}{n_{a^*}(t)} \\ & \leq \frac{r_a(t)}{n_a(t)} + \sqrt{\frac{2 \log t}{n_a(t)}} + \frac{\Gamma}{n_a(t)} \\ & \Leftrightarrow \frac{X_{a^*}}{n_{a^*}(t)} + \sqrt{\frac{2 \log t}{n_{a^*}(t)}} + \frac{\Gamma}{n_{a^*}(t)} + \frac{\text{Noise}_{a^*}(t)}{n_{a^*}(t)} \\ & \leq \frac{X_a}{n_a(t)} + \sqrt{\frac{2 \log t}{n_a(t)}} + \frac{\Gamma}{n_a(t)} + \frac{\text{Noise}_a(t)}{n_a(t)} \end{aligned} \quad (2)$$

It can be easily shown that (2) is true, only if at least one of the following equations hold.

$$\frac{X_{a^*}}{n_{a^*}(t)} \leq \mu^* - \sqrt{\frac{2 \log t}{n_{a^*}(t)}} \quad (3)$$

$$\frac{X_a}{n_a(t)} \geq \mu_a + \sqrt{\frac{2 \log t}{n_a(t)}} \quad (4)$$

$$\begin{aligned} & \mu^* + \frac{\Gamma}{n_{a^*}(t)} + \frac{\text{Noise}_{a^*}(t)}{n_{a^*}(t)} \\ & < \mu_a + \frac{\Gamma}{n_a(t)} + 2\sqrt{\frac{2 \log t}{n_a(t)}} + \frac{\text{Noise}_a(t)}{n_a(t)} \end{aligned} \quad (5)$$

Directly by the use of Chernoff bound, we can show that with probability at least  $1 - 2t^{-4}$ , (3) and (4) are false. To ensure that (5) does not hold, it suffices to ensure the

following.

$$\begin{aligned} & \frac{\Gamma}{n_a(t)} + 2\sqrt{\frac{2 \log t}{n_a(t)}} + \frac{\text{Noise}_a(t)}{n_a(t)} \leq \frac{\Gamma}{n_{a^*}(t)} + \frac{\text{Noise}_{a^*}(t)}{n_{a^*}(t)} + \Delta_a \\ & \Leftrightarrow 2\sqrt{\frac{2 \log t}{n_a(t)}} + \frac{\Gamma + \text{Noise}_a(t)}{n_a(t)} - \left(\frac{\Gamma + \text{Noise}_{a^*}(t)}{n_{a^*}(t)}\right) \leq \Delta_a \end{aligned} \quad (6)$$

From Lemma 5 we know that during the execution of the algorithm, w.p.  $\geq 1 - \gamma$ ,  $|\text{Noise}_{a^*}(t)|$  and  $|\text{Noise}_a(t)|$  are at most  $\Gamma$ . Therefore, to ensure (6) it suffices to ensure the following.

$$2\sqrt{\frac{2 \log t}{n_a(t)}} + \frac{\Gamma + \text{Noise}_a(t)}{n_a(t)} \leq \Delta_a \quad (7)$$

If for some  $0 < \nu < 1$  we have,  $2\sqrt{\frac{2 \log t}{n_a(t)}} \leq \nu \Delta_a$  and  $\frac{\Gamma + \text{Noise}_a(t)}{n_a(t)} \leq (1 - \nu)\Delta_a$ , then we can claim (7). Hence

to ensure (7), by setting  $y = \sqrt{\frac{\log(t)}{\Gamma}}$  (assume  $T > 3$ ) it suffices to have  $n_a(t) \geq \frac{8\Gamma}{\Delta_a^2}$  since  $\Delta_a < 1$ . Recall that this is the exactly the threshold for the exploration phase for the arm  $a$ . We now focus our attention to the term  $\mathbb{E}[n_a(T)]$  we initially intended to bound. It is easy to see the following.

$$\begin{aligned} \mathbb{E}[n_a(T)] & \leq \left\lceil \frac{8\Gamma}{\Delta_a^2} \right\rceil + \sum_{t=\frac{8\Gamma}{\Delta_a^2}}^T \Pr[\text{Pulling arm } a \text{ at time } t] \\ & \leq \left\lceil \frac{8\Gamma}{\Delta_a^2} \right\rceil + \sum_{t=\frac{8\Gamma}{\Delta_a^2}}^T \Pr[\exists n_a(t), n_{a^*}(t) \text{ s.t. (2) holds}] \\ & \leq \left\lceil \frac{8\Gamma}{\Delta_a^2} \right\rceil + \sum_{t=\frac{8\Gamma}{\Delta_a^2}}^T \sum_{n_{a^*}=1}^t \sum_{n_a=\frac{8\Gamma}{\Delta_a^2}}^t 2t^{-4} \\ & \leq \left\lceil \frac{8\Gamma}{\Delta_a^2} \right\rceil + \sum_{t=1}^T 2t^{-2} \leq \frac{8\Gamma}{\Delta_a^2} + \zeta \end{aligned} \quad (8)$$

This completes the proof Lemma 6.  $\square$

*Proof of Theorem 4.* In order to obtain the final regret guarantee of Theorem 4 and conclude the proof, we notice that,  $\mathbb{E}[\text{Regret}_{\text{Priv-UCB}}(T)] = \mathbb{E}\left[\sum_{a \in \mathcal{C}: \mu_a < \mu_{a^*}} \Delta_a n_a(T)\right]$ . Using Lemma 6 in the expression above concludes the proof.  $\square$

## 4 PRIVATE THOMPSON SAMPLING

In this section we study a different flavor of bandit learning algorithms called *Thompson sampling*. Historically,

Thompson sampling [25] is much older than UCB sampling style algorithms, dating back to early 20<sup>th</sup> century. Although Thompson sampling is a very powerful heuristic and often outperforms UCB sampling in experimental setups, until recently little was known about its regret guarantees. [2] provided the first regret analysis for Thompson sampling and they showed that it has regret logarithmic in the time horizon  $T$ . We provide a differentially private variant of the Thompson sampling algorithm. One reason for studying private Thompson sampling along with private UCB sampling is because it is known that in the non-private world the experimental performance of Thompson sampling is much better than UCB sampling. Moreover it demonstrates properties like stability to delayed feedback. (See [8] for details.) The question we want to answer is whether we can obtain a differentially private variant of Thompson sampling which preserves the asymptotic regret guarantee of as the same order as the non-private algorithm and also demonstrate similar experimental properties.

**Background on Thompson sampling.** The basic Thompson sampling heuristic is extremely simple. Suppose there are  $k$ -arms  $\mathcal{C} = \{a_1, \dots, a_k\}$  which give Bernoulli rewards (i.e.,  $\{0,1\}$  rewards) and have biases  $\mu_{a_1}, \dots, \mu_{a_k}$ . Let  $r_{a_1}(t), \dots, r_{a_k}(t)$  be the number of ones and  $n_{a_1}(t), \dots, n_{a_k}(t)$  be the total number of arm pulls, upto time  $t$ . The rule to pick the arm for each round is: Sample  $\theta_i \sim \text{Beta}(r_{a_i}(t) + 1, n_{a_i}(t) - r_{a_i}(t) + 1)$  for  $i \in [k]$  for  $i \in [k]$  and pull the arm corresponding to the highest  $\theta_i$ . Based on the result of the arm pull, the posterior distribution for that particular arm gets updated.[2] showed that the expected regret for this algorithm (over the randomness of the algorithm and the data) is  $O\left(\sum_{a \in \mathcal{C} - a^*} \left(\frac{1}{\Delta_a^*}\right)^2 \log T\right)$ , where  $a^*$  be the optimal arm and  $\Delta_a = \mu_{a^*} - \mu_a$ .

#### 4.1 Private Thompson Sampling: Algorithm and Analysis

In this section we modify this generic Thompson sampling algorithm to obtain an  $\epsilon$ -differentially private variant (Algorithm 2). We show that even with the privacy constraint our algorithm has almost the same regret as non-private algorithm with only poly  $\log T$  overhead. This is the same setting in which [2] also proved their results. One interesting observation in the MAB problems is that all the sequential algorithms would encourage a downward bias, which means that if an arm does not give good results initially then it will not be pulled again, therefore it's empirical mean would be much lower than its true mean. UCB algorithm overcomes this problem by adding a monotonically decreasing function of the number of pulls ( $n_a(t)$ ) to the empirical mean, thus in some sense balancing out this downward bias. But in case of Thompson sampling, we are randomizing our decision hence the bias correction mech-

anism is different, it is due to randomization. In Thompson sampling, the biggest challenge is to bound the number of mistakes in the initial rounds. Moreover to ensure differential privacy, we introduce additional randomness to the original Thompson sampling algorithm, it becomes even harder for us to analyze the number of mistakes in the initial rounds. So, we take a slightly different approach. We segregate the algorithm into *explicit exploration phase* and a *combined exploration and exploitation* phase. The idea in the exploration phase is to estimate the biases of the two arms (within sufficient confidence) without bothering about the number of mistakes made. In the joint exploration and exploitation phase, we use the standard Thompson sampling, except we make sure the algorithm only has differentially private access to the rewards. Similar to the private UCB algorithm (Algorithm 1), we use the *private tree based aggregation* (from Section 2.1) to ensure differential privacy. In the following section, for the convenience of notation we assume that  $\mu^* = \mu_{a_1} > \mu_{a_2} \geq \dots \geq \mu_{a_k}$ .

##### 4.1.1 Privacy Analysis

**Theorem 7** (Privacy guarantee). *Algorithm 2 is  $\epsilon$ -differentially private.*

*Proof.* The proof of privacy is segregated into two parts. In the first part we argue that the *gap estimation* section is  $\epsilon/2$ -differentially private. In the second part we argue that the rest of the sections of the algorithm are combined  $\epsilon/2$ -differentially private. Using these two arguments and the composition property of differential privacy we argue that Algorithm 2 is  $\epsilon$ -differentially private. Notice that in the first part, each arm  $i, i \in [k]$  is pulled in batches of  $m$ -pulls, till the condition in Line 8 in Algorithm 2 is satisfied. If each of this batch is made  $\frac{\epsilon}{2k}$ -differentially private, then by *parallel composition* property of differential privacy, the first phase is  $\epsilon/2$ -differentially private. To guarantee  $\frac{\epsilon}{2k}$ -differential privacy for a given batch, we use Laplace mechanism from Section 2.1. The  $\epsilon/2$ -privacy guarantee for the second phase follows directly from the analysis of tree based aggregation scheme described in Section 2.1.  $\square$

##### 4.1.2 Regret Analysis

In this section, we provide the regret analysis for our private Thompson sampling algorithm (Algorithm 2). The high-level structure of the analysis is as follows. First we establish that in the gap estimation phase, the estimated gap  $\hat{\Delta}$  is within constant factor of the true gap  $\Delta = |\mu_{a_{(1)}} - \mu_{a_{(2)}}|$  (i.e. the mean difference of the best arm and the second best arm). Moreover, we argue that the gap estimation runs for at most poly  $\log T$  number of rounds. Second, assuming our estimation  $\hat{\Delta}$  is reasonably accurate, we pull all the arms randomly for certain number of steps to ensure sufficient concentration of the empirical means around the true means. In the third and final stage, we analyze the noisy version of the classic Thompson sampling with *beta* prior. The analysis of this part resembles the analysis of [2]

---

**Algorithm 2** Differentially Private Thompson Sampling

- Input:** Time horizon:  $T$ , arms:  $\mathcal{C} = \{a_1, a_2, \dots, a_k\}$ , privacy parameter:  $\epsilon$ .
- 1: **Gap** ( $\Delta = |\mu_{a_1} - \mu_{a_2}|$ ) **estimation**
  - 2: **Initialize:** Time counter:  $\tau \leftarrow 0$ , estimated gap:  $\hat{\Delta} \leftarrow 1$ , total pulls:  $n_{a_1}, n_{a_2}, \dots, n_{a_k}$ .
  - 3: **repeat**
  - 4: Pull each arm  $a_i$   $m = \frac{192k \log T}{\epsilon \hat{\Delta}^2}$  times to obtain average rewards  $\tilde{\mu}_{a_i} \forall a_i \in \mathcal{C}$ . Increment  $n_{a_i} \leftarrow n_{a_i} + m \forall a_i \in \mathcal{C}$ .
  - 5: **Differentially private means:**  $\hat{\mu}_{a_i} \leftarrow \tilde{\mu}_{a_i} + \text{Lap}\left(\frac{2k}{\epsilon m}\right), \forall a_i \in \mathcal{C}$ .
  - 6: Set  $\hat{\Delta} \leftarrow \hat{\Delta}/2$  and  $\tau \leftarrow \tau + km$ .
  - 7: Find the best and second best arms as,  $a(1) = \operatorname{argmax}_{a_i \in \mathcal{C}} \mu_{a_i}$  and  $a(2) = \operatorname{argmax}_{a_i \in \mathcal{C}, a_i \neq a(1)} \mu_{a_i}$
  - 8: **until**  $|\hat{\mu}_{a(1)} - \hat{\mu}_{a(2)}| > \hat{\Delta}$
  - 9: Create empty trees  $\text{Tree}_{a_i}$  with  $(T - \tau)$ -leaves  $\forall a_i \in \mathcal{C}$ . Set  $\epsilon_0 \leftarrow \epsilon/2k$ .
  - 10: **Random pullings of arms to build confidence**
  - 11: **Confidence parameter:**  $\Gamma \leftarrow \frac{192 \log^3 T}{\epsilon}$ .
  - 12: Pull each arm  $a_i$ ,  $\frac{\Gamma}{\hat{\Delta}^2}$  times. Record the total rewards  $r_i \forall a_i \in \mathcal{C}$ . Insert  $r_i$  in  $\text{Tree}_{a_i}$  with privacy parameter  $\epsilon_0, \forall a_i \in \mathcal{C}$ . Increment  $n_{a_i} \leftarrow n_{a_i} + \frac{\Gamma}{\hat{\Delta}^2}$  and  $\tau \leftarrow \tau + \frac{k\Gamma}{\hat{\Delta}^2}$ .
  - 13: **Combined explore-exploit phase of Thompson sampling**
  - 14: **for**  $t \leftarrow \tau + 1$  to  $T$  **do**
  - 15: **Total reward:**  $r_a(t) \leftarrow$  Total reward computed using  $\text{Tree}_{a_i}, \forall a_i \in \mathcal{C}$ .  $\theta_a(t) \sim \text{Beta}(r_a(t) + 1, n_a(t) - r_a(t) + 1), \forall a_i \in \mathcal{C}$ . Pull arm  $a^* = \operatorname{argmax}_{a_i \in \mathcal{C}} (\theta_a(t))$  and observe reward  $f_t(a^*)$ , Insert  $f_t(a^*)$  into  $\text{Tree}_{a^*}$  using *tree based aggregation* and privacy parameter  $\epsilon_0$ ,
  - 16: **Number of pulls:**  $n_{a^*}(t) \leftarrow n_{a^*}(t) + 1$ .
  - 17: **end for**
- 

closely. The overall regret guarantee is given in Theorem 8 below.

**Theorem 8** (Utility guarantee). *Let  $\mu_{a_1}, \mu_{a_2}, \dots, \mu_{a_k}$  be the biases of the  $k$  arms. Let  $\Delta = |\mu_{a(1)} - \mu_{a(2)}|$ , where  $a(1) = \operatorname{argmax}_{a_i \in \mathcal{C}} \mu_{a_i}$  and  $a(2) = \operatorname{argmax}_{a_i \in \mathcal{C}, a_i \neq a(1)} \mu_{a_i}$ .*

*Then, for  $T \geq 8 \max\{\log_2 \frac{1}{\Delta}, 1\}$  and  $\epsilon < 1$  expected regret of Algorithm 2 (over the randomness of the data and the algorithm) is as follows:*

$$\mathbb{E} [\text{Regret}_{\text{Priv-Thompson}}(T)] = O\left(k \frac{\log^3 T}{\Delta^2 \epsilon^2}\right)$$

Let  $N_1, N_2$  and  $N_3$  denote the number of times the wrong arm is pulled in the *gap estimation phase*, *random pullings phase* and *combined explore and exploit phase* of Algorithm 2 respectively. We would bound the expected values of  $N_1, N_2$  and  $N_3$  using the following lemmas which would allow us to prove Theorem 8.

**Lemma 9** (Bound on gap estimation phase). *Following the notation of Theorem 8, then with probability at least  $1 - 1/T^4$  (over the randomness of the algorithm and the data distribution), for  $T \geq 8k \max\{\log_2 \frac{1}{\Delta}, 1\}$  and  $\epsilon < 1$  the estimated gap  $\hat{\Delta}$  in Algorithm 2 is in  $[\Delta/3, 2\Delta]$ , the expected number of times incorrect arm is pulled is,  $\mathbb{E}[N_1] = O\left(\frac{k \log_2 T}{\epsilon}\right)$ .*

The proof of this Lemma is provided in Appendix C.

**Lemma 10** (Bound on geometric random variables (Lemma 3 [2])). *Let  $s_j$  be a random variable, index by  $j \in \mathbb{Z}^+$  s.t. for fixed parameters  $T \in \mathbb{Z}^+$  and  $\mu \in [0, 1]$ , with probability at least  $1 - T^{-2}$ ,  $\frac{s_j}{j} > \frac{\mu + y}{2}$ . Let  $y \in [0, \mu]$  be a predefined threshold and let  $X(s_j, y)$  be the random variable that counts the number samples  $w \sim \text{Beta}(s_j + 1, j - (s_j + 1))$  that need to be drawn i.i.d. before  $w$  exceeds  $y$ . Using  $T$  as the fixed upper bound on  $X(s_j, y)$ , if  $j \geq \frac{4 \log_2 T}{(\mu - y)^2}$ , then  $\mathbb{E}_s [\mathbb{E}_w [\min\{X(s_j, y), T\}]] = O\left(\frac{1}{T}\right)$ .*

**Lemma 11** (Bound on Beta random variable [Lemma 7 [2]]). *Let us define event  $E(t)$  as,  $E(t) : \theta_a(t) \in [\mu_a - \frac{\Delta_a}{2}, \mu_a + \frac{\Delta_a}{2}], \forall a \in \mathcal{C}, a \neq a(1)$ . Then  $\Pr(E(t), n_a(t) \geq \frac{32 \log_2 T}{\Delta^2}) \geq 1 - \frac{4(k-1)}{T^3}, \forall t$ .*

**Lemma 12** (Regret bound in the combined explore and exploit phase). *Suppose  $N_3$  is a random variable which counts the number of times the suboptimal arms are pulled in Algorithm 2. Then, over the randomness of the algorithm and the data,  $\mathbb{E}[N_3] = O(1)$ .*

*Proof.* In order to calculate the regret we count the number of times the sub-optimal arms get pulled since it upper bounds the regret. The main idea behind the proof of this lemma is that via random pulling of the arms in Algorithm 2, the arm  $a_1$  is well separated from the other sub-optimal arms. Hence, in the combined explore and exploit phase, with high probability the optimal arm gets pulled almost always. We will use the proof technique from [2] for analyzing the number of pulls of the suboptimal arms.

We denote the set of suboptimal arms by  $\mathbb{S}$  and  $\mathbb{S} = a_2, \dots, a_k$ . We count the number of pulling of sub-optimal arm  $a_s$ , by the following scheme: count the number of pulls of arm  $a_s$  in between two successive pulls of arm  $a_1$ . First, recall that with probability at least  $1 - T^{-4}$  (from Lemma 9),  $\hat{\Delta}$  (the estimated gap) is within  $[\Delta/3, 2\Delta]$ . By the property of the tree based aggregation discussed earlier, the difference between the true total reward at time  $t(j)$  and  $r_a(t(j))$  is at most  $\frac{\log_2^3 T}{\epsilon}$ , with probability  $1 - \text{negl}(T)$ . Since by the beginning of combined explore and exploit phase, we have pulled arm  $a_1$  at least  $\frac{\Gamma}{\hat{\Delta}^2}$ -times, it follows that with probability at least  $1 - 2T^{-4}$ , difference between the true total reward at time  $t(j)$  and  $r_{a_1}(t(j))$  is at most  $\frac{\Delta}{4}$ . Using Lemma 11 and the fact that we pulled all the arms for  $\Gamma/\Delta^2 > \frac{32 \log_2 T}{\Delta^2}$ , we observe that with probability atleast

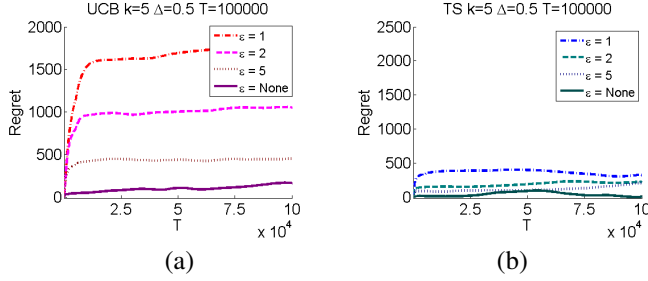

Figure 1: Simulation results for our differentially private algorithms UCB sampling (Algorithm 1) and Thompson sampling (Algorithm 2) for the number of arms  $k = 5$  and  $\Delta = 0.5$ . Smaller  $\epsilon$  indicates more privacy.

$1 - \frac{4k-2}{T^3}$ ,  $\theta_a < \mu_a + \Delta_a/2$ . Hence bundled up failure probabilities obtained so far for  $\theta_{a_1} < \theta_{a_s}$  using union bound is  $1 - \frac{4}{T^2}$ . Let  $j$  and  $j+1$  be any two successive pulls of arm  $a_1$ , let  $t(j)$  and  $t(j+1)$  be the respective time epochs and denote  $\Delta_s = \mu_{a_s} - \mu_{a_1}$ . The Beta distribution for the sample  $\theta_a$  from arm  $a$  in between these pulls (not including the  $(j+1)$ -th pull) is  $\text{Beta}(r_a(t(j))+1, n_a(t(j))-r_a(t(j))+1)$ . Now a suboptimal arm  $a_s$  is pulled during round  $j$  and  $j+1$  pull of arm  $a_1$  if  $\theta_{a_1} < \mu_{a_1} - \min_{a_s \in \mathbb{S}} \Delta_{a_s}$ . In order to use Lemma 10 above, we set the threshold  $y = \mu_{a_2} + \frac{\Delta}{2}$ . Moreover, if we set  $s_j = r_{a_1}(t(j))$ , then we know that with probability at least  $1 - 4T^{-2}$ ,  $\frac{s_j}{j} > \mu_{a_1} - \frac{\Delta}{4}$ . Hence, the conditions of Lemma 10 holds and summing over all  $T$  rounds, we complete the proof.  $\square$

*Proof of Theorem 8.* The expected regret of multi-armed bandit algorithms can be upper bounded by the number of times the suboptimal arm is pulled. We defined  $N_1$ ,  $N_2$  and  $N_3$  to denote the number of times the wrong arm is pulled in the *gap estimation* phase, *random pullings* phase of Algorithm 2 and *combined explore and exploit* phase of Algorithm 2 respectively. Thus we have,

$$\mathbb{E}[\text{Regret}_{\text{Priv-Thompson}}(T)] = \mathbb{E}[N_1] + \mathbb{E}[N_2] + \mathbb{E}[N_3]$$

From Lemma 9 we know that  $\mathbb{E}[N_1] = O\left(k \frac{\log T}{\epsilon^2}\right)$ . From Lemma 9 and Algorithm 2, we know that  $\mathbb{E}[N_2] = O\left(k \frac{\Gamma}{\Delta^2}\right)$ , where  $\Gamma = O\left(\frac{\log^3 T}{\epsilon}\right)$ . Finally from Lemma 12, we know that  $\mathbb{E}[N_3] = O(1)$ . Combining these bounds, we get the bound on the expected regret.  $\square$

## 5 EXPERIMENTAL EVALUATION

In this section, we support the theoretical regret bounds for our algorithms (Algorithm 1 and 2) with empirical results. The experimental results show that there is a smooth trade-off between privacy and accuracy. As we increase our privacy parameter  $\epsilon$ , the regret improves. We perform the simulation experiments on for stochastic multi-arm bandits, with rewards in  $\{0, 1\}$ . The  $k$ -arm private UCB sampling algorithm is described in Section 3. The 2-arm private Thompson sampling and its extension to  $k$ -arm private

Figure 2: Comparison of differentially private and non-private multi-armed bandit algorithms on Yahoo! front page News article recommender system. The click-through rates for each algorithm is normalized with respect a random algorithm.

Thompson sampling are given in Section 4.1. The true underlying distribution of the arms are chosen as follows. The mean for the best arm is 0.9 and the other arms have biases of  $0.9 - \Delta$  each, where  $\Delta = 0.5$ . We tune the parameters of our private algorithms, the *confidence parameter* (see Line 9 in Algorithm 1) for UCB and the number of *random pullings* (see Line 12 in Algorithm 1) for Thompson to enhance accuracy. Note, the parameter tuning does not violate privacy, since the access to the aggregated rewards is still based the on tree based aggregation scheme. All the UCB type sampling algorithms have a common parameter, the confidence interval; same as Line 9 in Algorithm 1. For our experiment on private UCB sampling (Algorithm 1), we use a particular confidence interval, given in [8], which seems to perform the best. The confidence interval is given as,  $\frac{\sqrt{r_a(t) \log t}}{n_a(t)} + \frac{\log t}{n_a(t)}$ , where  $r_a(t)$  and  $n_a(t)$  are the reward and number of pulls for arm  $a \in \mathcal{C}$  up to time  $t$  respectively. For our experiments on private Thompson sampling (see Algorithm 2) we do not implement the *gap estimation* phase and for the second phase that involves *random pullings* (Line 10 of 2), use a smaller value for  $m$ .

**Conclusions drawn from simulations.** We observe in the plots that the regret for the private algorithms saturates after certain time, similar to that of their non-private counterparts (see Figure 1). Also notice that in the simulations, Thompson sampling tends to perform much better than UCB sampling.

### 5.1 Yahoo! Front Page Data set

In this section, we describe our results on *Yahoo! front page news article recommendation* data set. The data set contains 45,811,883 user visits to the *Today module* during first 10 days in May 2009. Each user click on a news article shown corresponds to a reward of one for that article. This data set has also been used by [21], [11] for bandit experiments. One property of this data set is that the displayed article is chosen uniformly at random from the candidate article pool allowing us to use an *unbiased offline* evalua-

tion method [21, 22]. The pool of articles is small (around 20 articles), but it is dynamic which means that the articles may be added or removed from this pool. For each visit, both the user and each of the candidate articles are associated with a feature vector of dimension 6. The feature vector acts as a context for the news article recommender and based on this context the most suited article can be chosen using a bandit algorithm. This is the contextual bandit setting. In this setting, in each of  $T$  rounds, a learner is presented with the context vector:  $z_a \in \mathbb{R}^d$  for each arm  $a \in \mathcal{C}$  and based on his previous observations and this new context vector, the learner needs to select one out of  $k$  actions. The learner’s aim is to learn the relation between the reward and the context vector in an online fashion.

***Differentially private contextual sampling (Algorithm 3 and Algorithm 4 in Appendix D.2 and D.3.)*** The private contextual UCB algorithm is adapted from the *LinUCB* algorithm in [21] and is similar to the basic UCB sampling algorithm, as it computes the expected reward of each arm and then chooses the arm with the highest upper confidence bound. The expected reward is given as  $z_t^T \theta_t$ , where  $\theta_t$  is estimated using ridge regression and the confidence bound is given as  $\sqrt{z_a(t)^T A_t z_a(t)}$ , which is the Mahalanobis distance of the context vector with covariance matrix  $A$ . On the other hand, the private contextual Thompson sampling algorithm is a differentially private version for the algorithm provided by [3]. In regular Thompson sampling, for each round we choose an arm according to its posterior probability of having the best parameter. A natural generalization of Thompson Sampling for contextual bandits is to use Gaussian prior and Gaussian likelihood function. The extension of these algorithms to private algorithms is straightforward. In both the private algorithms, we restrict our access to the parameters which aggregate over each time stamp and use *tree based aggregation* scheme to retrieve those parameters. We give the details of these algorithms in Appendix D.2 and D.3.

***Conclusions on experiments with Yahoo! front page data set.*** The results for this experiment are summarized in Figure 2. We find that the private algorithms do not perform much worse than the non-private algorithms. Since, the feature vector is of length 6 by setting the privacy  $\epsilon_0$  of each parameter as 0.1, the total privacy measured in terms of the total privacy parameter  $\epsilon = 2.7$ . We also investigate the performance of the algorithms with respect to delays. We have considered the delay values in  $\{0, 100, 1000\}$ . When the input data does not have any delay in the feedback, the private algorithms perform slightly worse than the non-private counter parts and as the delay increases the performance of the non-private algorithms is hurt more than the private algorithms.

## Abstract

Significant progress has recently been made towards formalizing symmetry-aware variational inference approaches into a coherent framework. With the exception of TRW for marginal inference, however, this framework resulted in approximate MAP algorithms only, based on equitable and orbit partitions of the graphical model. Here, we deepen our understanding of it for marginal inference. We show that a large class of concave free energies admits equitable partitions, of which orbit partitions are a special case, that can be exploited for lifting. Although already interesting on its own, we go one step further. We demonstrate that concave free energies of pairwise models can be reparametrized so that existing convergent algorithms for lifted marginal inference can be used without modification.

## 1 INTRODUCTION

Computing likelihoods and marginals using graphical models [24] is an important task for many applications in biology, information retrieval, and computer vision, among other fields. If the graphical models are defined over trees, marginals can be efficiently computed using belief propagation. For models with cycles, however, exact inference is generally intractable. This motivates approximate inference algorithms, favoring algorithms which are as accurate as possible while being guaranteed to converge. One prominent example are variational inference approaches [24, 7, 14], where one aims to approximate a given distribution by a simpler one, i.e., one whose marginals are easier to read off. If a good fit is found, the marginals of the approximating distribution can be used as approximations to the marginals of the original one. Such approaches are typically obtained in two steps: (1) one selects an approximation criterion (a free energy), which is a function of the

approximating marginals, and (2) designs optimization algorithms to minimize that free energy efficiently.

A recent development in probabilistic inference has been the use of symmetry [18, 1, 19, 23] as a basis for efficient algorithms. Detecting and utilizing symmetry is establishing itself as an important component of inference. On one hand, there are classes of models where symmetry provides the only means for tractable inference [4]. On the other, in approximate inference algorithms (which tend to be tractable by design) symmetry usually translates to significant improvements in running time as a result of reducing the number of variables of the problem. Symmetry-aware inference approaches are often referred to as lifted inference approaches [20, 9], and one of the first lifted variational inference approaches was lifted loopy belief propagation [8, 22, 10]. These works, however, are largely of algorithmic nature and specific to loopy belief propagation. More recently, Bui et al. [1] proposed a general, algebraic framework for lifted variational inference. It formalizes the notion of symmetry in graphical models via lifting partitions and shows how to exploit them within corresponding variational optimization problems. With the exception of lifted TRW via Frank-Wolfe optimization [2], however, the framework resulted in approximate MAP inference algorithms only, based on equitable and orbit partitions of the graphical model [1, 17, 16].

Our goal in this paper is to deepen our understanding of the lifted variational framework for marginal inference. We do so by extending the notion of equitable partitions — a formalization of symmetry — of models to equitable partitions of energies. We show that within a well-known class of concave energies, **a**) given a concave energy that admits an equitable partition, the number of variables in the resulting optimization problem can be reduced in a way that an exact solution can still be found. Moreover, **b**) given a model that admits an equitable partition, a concave energy that admits the same equitable partition can always be constructed. In combination, these two results allow us to perform concave inference without breaking the symmetry of the model. Although already interesting on its

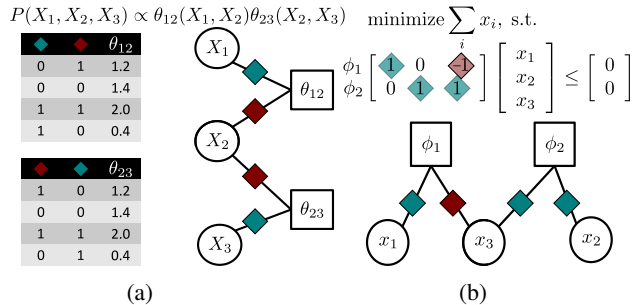

Figure 1: Representations. (a) An MRF and its factor graph. (b) An LP and its factor graph. (Best viewed in color)

own, we go one step further. We demonstrate that for the case of pairwise models, “lifted” concave free energies can be reparametrized to “ground” energies of smaller models. That is, for any pair  $(G, c)$  of pairwise model and energy parameters as well as an appropriate partition, we can find a pair  $(G', c')$  of smaller size such that the resulting energies are equivalent, regardless of the solver. This enables us to use existing highly efficient and distributed convergent message passing algorithms for lifted marginal inference such as ([21]) without modification. Furthermore, we provide a novel angle on the open question raised by Bui et al. regarding the applicability equitable partitions within lifted variational inference. While they point out that partitions coarser than an orbit partition of the model generally cannot lift the TRW energy [2] faithfully, we show that a large class of other energies in the same class do admit any equitable partition of the model.

To achieve the above goal(s) we start off by reviewing the required tools from (lifted) variational inference. Section 3 then introduces the notion of an equitable partition of a convex energy and shows that this partition is a lifting partition. In Section 4, we show to reparametrize energies and models modulo equitable partitions in order to eliminate the necessity of a lifted solver. Before concluding, we illustrate our theoretical results empirically.

## 2 BACKGROUND

We will start with reviewing variational inference in Markov random fields (MRF). Then we will touch upon the basics of the lifting framework for variational problems.

**Variational Inference in MRFs.** Let  $\mathbf{X} = (X_1, X_2, \dots, X_n)$  be a set of  $n$  discrete-valued random variables and let  $x_\alpha$  represent the possible realizations of a subset  $\alpha$  of these random variables. Markov random fields (MRFs) compactly represent a joint distribution over  $\mathbf{X}$  as a factorization  $P(\mathbf{X} = \mathbf{x}) = Z^{-1} \exp[\sum_\alpha \theta_\alpha(x_\alpha) + \sum_i \theta_i(x_i)]$ , see [24] for more details.

It is often convenient to represent MRFs by their factor

graphs. In this paper, however, we will slightly modify the standard definition of a factor graph. For our purposes, a **factor graph**  $G$  is a colored tri-partite graph, whose nodes represent the variables, factors and the positions of variables in factors within an MRF. In contrast to standard factor graphs and as illustrated in Fig. 1a, we connect a variable  $X_i$  to factor  $\theta_\alpha$  via a dummy position node  $\diamond_{i\alpha}$ , which we color according to the symmetry of  $\theta_\alpha$ . More precisely, if the positions of  $X_i$  and  $X_j$  are compatible, that is,  $\theta_\alpha(\dots, x_i, \dots, x_j, \dots) = \theta_\alpha(\dots, x_j, \dots, x_i, \dots)$  for all realizations  $x_i, x_j$ , we color  $\diamond_{i\alpha}$  and  $\diamond_{j\alpha}$  with the same color. If the positions are not compatible, they receive different colors. Moreover, we assume that factors, variables and positions use different color spaces, e.g. a position and factor node cannot share the same color. While this is not the most compact representation, it will allow us to use a common graphical representation across various kinds of partitions and optimization problems.

Inference in MRFs is generally intractable, hence, inference tasks are often addressed via approximations. One prominent class of approximate inference algorithms arises from the following optimization problem:

$$\boldsymbol{\mu}^* = \operatorname{argmax}_{\boldsymbol{\mu} \in \mathcal{L}(G)} \underbrace{\left[ \boldsymbol{\theta}^T \boldsymbol{\mu} + T \cdot \hat{H}(\boldsymbol{\mu}) \right]}_{=: F(\boldsymbol{\mu})}, \quad (1)$$

where  $F$  is the free energy and the set  $\mathcal{L}(G)$ , defined as

$$\mathcal{L}(G) = \left\{ \boldsymbol{\mu} \geq 0 \mid \begin{array}{l} \sum_{x_i} \mu_i(x_i) = 1 \\ \sum_{x_\alpha \setminus x_i} \mu_\alpha(x_\alpha) = \mu_i(x_i) \end{array} \right\}, \quad (2)$$

is known as the local polytope [24]. The problem in Eq. 1 is at the heart of many message-passing inference algorithms. For instance, if we set  $T = 0$  (or sufficiently small in the sense of [13]),  $\boldsymbol{\mu}^*$  in Eq. 1 yields a linear programming approximation of the Maximum a-Posteriori (MAP) problem and prominent MAP algorithms such as MPLP and MSD are typically derived as specialized solvers for the latter. If, on the other hand, we choose  $T$  to be 1 and  $\hat{H}$  to be an approximation of the entropy function,  $\boldsymbol{\mu}^*$  approximates the vector of single-node and factor marginals of the distribution  $P$ . For example, we can choose  $\hat{H} = \hat{H}_c$  as

$$\hat{H}_c(\boldsymbol{\mu}) = \sum_i c_i H_i(\mu_i) + \sum_\alpha c_\alpha H_\alpha(\mu_\alpha), \quad (3)$$

where  $H_i$  and  $H_\alpha$  are local entropies. For  $c_i = 1 - |\text{nb}(i)|$  and  $c_\alpha = 1$ ,  $F$  becomes the Bethe energy,  $F_{\text{Bethe}}$ . In this case, solving the set of saddle-point equations of Eq. 1 by means of fixed-point iteration yields the popular Loopy Belief Propagation algorithm. The Bethe Energy often gives surprisingly good approximations to the true marginals, however, it is rather difficult to optimize over. Thus, one may prefer to consider instances of  $\hat{H}_c$ , where maximization is efficient.

Naturally, a class of such energies results from  $\hat{H}$  being concave. In particular, we are interested in values of  $c$  that

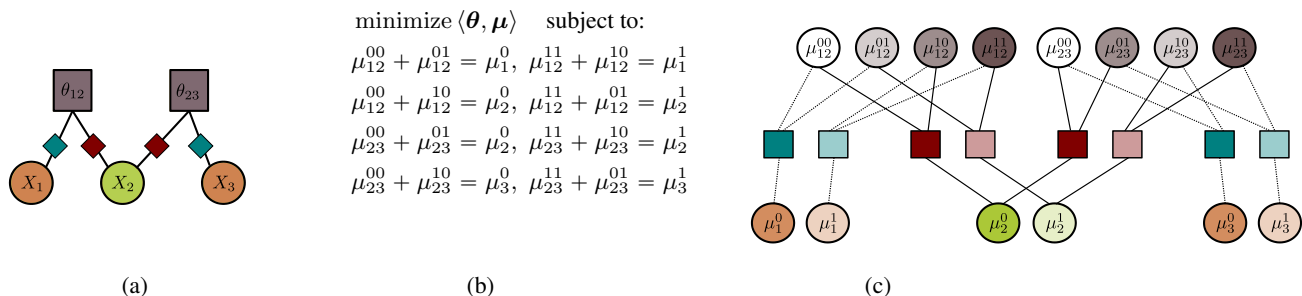

Figure 2: Model symmetry of  $G$  propagates to its MAP-LP. (a)  $G$  – colored by the classes of the CEP. (b) The MAP-LP of  $G$  (nonnegativity and normalization constraints as well as position nodes have been omitted for clarity). (c) The factor graph of the MAP-LP of  $G$  colored by its CEP. The colors indicate that the classes can be deduced from the CEP of  $G$ . Note that the darker and lighter version of each color are not grouped together. (Best viewed in color)

make  $\hat{H}_c$  in Eq. 3 concave, as the structure of these energies gives rise to message-passing algorithms with desirable theoretical properties, cf. [14, 6]. A sufficient condition for  $\hat{H}_c$  to be concave is that nonnegative auxiliary numbers  $c_{\alpha\alpha}$ ,  $c_{ii}$ , and  $c_{i\alpha}$  exist, called **counting numbers**, obeying to

$$C(G) = \left\{ c_\alpha, c_i \mid \begin{array}{l} \exists c_{\alpha\alpha}, c_{ii}, c_{i\alpha} \geq 0, \\ c_\alpha = c_{\alpha\alpha} + \sum_{i \in \alpha} c_{i\alpha}, \\ c_i = c_{ii} - \sum_{\alpha: i \in \alpha} c_{i\alpha} \end{array} \right\}. \quad (4)$$

Finally, note that for  $T = 0$ , Eq. 1 becomes a linear program (LP), called the MAP-LP of  $G$ . An LP is an optimization problem of the form maximize  $c^T x$  subject to  $Ax \leq b$ . While LPs are not the focus of this paper, they will be an important tool in the analysis of variational inference problems. Note that linear programs, like MRFs, can be represented by factor graphs. We represent a constraint  $\alpha$  (row  $\alpha$  of  $A$ ) as a factor node  $\phi_\alpha$ , LP variable  $i$  as a variable node  $x_i$  and the coefficient  $A_{\alpha i}$  as position node  $\diamond_{\alpha i}$ . Our notion of compatibility of positions here is that  $\diamond_{\alpha i}$  is colored with the same color as  $\diamond_{\beta j}$  if  $A_{\alpha i} = A_{\beta j}$ . Additionally,  $x_i$  and  $x_j$  are colored with the same color if  $c_i = c_j$ , while  $\phi_\alpha$  and  $\phi_\beta$  are colored the same if  $b_\alpha = b_\beta$ . An example is given in Fig. 1b. Having set-up the variational inference problem, we now give a short review of lifted variational inference.

**Lifted Variational Inference via Lifting Partitions.** Lifted inference approaches essentially amount to reducing the size a model by grouping together indistinguishable variables and factors. In other words, they exploit symmetries. To formalize the notion of symmetry more concisely, we follow [1].

Consider the linearly constrained concave program

$$x^* = \operatorname{argmax}_{Ax \leq b} J(x). \quad (\clubsuit)$$

We are interested in partitioning the variables of the program by a partition  $\mathcal{P} = \{P_1, \dots, P_p\}$ ,  $P_i \cap P_j = \emptyset$ ,

$\bigcup_i P_i = [x_1, \dots, x_n]$ , such that there exists at least one solution that **respects** the partition. More formally,  $\mathcal{P}$  is a **lifting partition** of  $(\clubsuit)$  if  $(\clubsuit)$  admits a solution with  $x_i = x_j$  whenever  $x_i$  and  $x_j$  are in the same class in  $\mathcal{P}$ . We call the linear subspace defined by the latter condition  $\mathbb{R}_{\mathcal{P}}$ .

Having obtained a lifting partition of the ground variational problem, we can now restrict the solution space to  $\{x : Ax \leq b\} \cap \mathbb{R}_{\mathcal{P}}$ . That is, we constrain equivalent variables to be equal, knowing that at least one solution will be preserved in this space of lower dimension. Since ground variables of the same class are now equal, they can be replaced with a single aggregated (lifted) variable. The resulting lifted problem has one variable per equivalence class, thus, if the lifting partition is coarse enough, significant compression and in turn run-time savings can be achieved. To recover a ground solution from the lifted solution, one assigns the value of the lifted variable to every ground variable in the class.

For linear programs, Mladenov et al. [15, 17, 16, 5] have shown that equitable partitions [3] act as lifting partitions. An **equitable partition of a graph** is a partition  $\mathcal{P}$  of the vertex set such that for any pair of vertices  $u$  and  $v$  in the same class  $P_n$  and any other class  $P_m$ ,  $|\text{nb}(u) \cap P_m| = |\text{nb}(v) \cap P_m|$ <sup>1</sup>. For colored graphs, we additionally require that the color vector respects the partition. We call the quantity  $|\text{nb}(v) \cap P_m|$  the degree of  $P_n$  to  $P_m$ ,  $\text{deg}(P_n, P_m)$ . For notational convenience, we will introduce equitable partitions of factor graphs as  $\mathcal{P} = \{P_1, \dots, P_p, Q_1, \dots, Q_q, D_1, \dots, D_d\}$ , where the  $P$ -classes refer to the variable classes, the  $Q$ -classes to factor classes and the  $D$ -classes to position classes.

For the purposes of our discussion, an **equitable partition of a linear program** is an equitable partition of its factor graph. The existence of an equitable partition of a linear program implies the existence of certain doubly-stochastic

<sup>1</sup>The orbit partitions discussed in [1, 2] are a special kind of equitable partitions.

matrices  $(\Sigma, \Pi)$  such that  $\mathbf{c}^T \Pi = \mathbf{c}^T$ ,  $\Sigma \mathbf{b} = \mathbf{b}$  and  $\Sigma \mathbf{A} = \mathbf{A} \Pi$  [5].

Recall that a concave energy inference problem as defined here is essentially a linear program (the MAP-LP) plus a linear combination of local entropies in the objective. The symmetries of the MAP-LP have already received attention [1, 17, 16], and it is understood that the MAP-LP preserves the symmetries present in the model. We will use this understanding as a starting point for our discussion of concave energies. We briefly formalize the claim.

**Lemma 1.** *Any equitable partition  $\mathcal{P}$  of an MRF  $G$  induces an equitable partition  $\mathcal{P}'$  of the resulting MAP-LP.*

Let us briefly sketch how this works. Suppose we are given an equitable partition  $\mathcal{P}$  of  $G$ . To obtain an equitable partition  $\mathcal{P}'$  on  $\mathcal{L}(G)$ , we group together  $\mu_i(0)$  with  $\mu_j(0)$ , resp.  $\mu_i(1)$  with  $\mu_j(1)$  if  $X_i$  is grouped with  $X_j$  in  $\mathcal{P}$ . To partition the joint state pseudomarginals, we use the following rule. Let  $\theta_\alpha$  and  $\theta_\beta$  be two factors grouped together in  $\mathcal{P}$  ( $\alpha = \beta$  is also allowed). Then, for all permutations  $\pi : \alpha \rightarrow \beta$  such that  $\pi(i) = j$  only if  $\diamond_{i\alpha}$  is grouped together with  $\diamond_{j\beta}$  in  $\mathcal{P}$ , we group together  $\mu_\alpha(\mathbf{x})$  with  $\mu_\beta(\pi(\mathbf{x}))$  for every joint configuration  $\mathbf{x}$ . This grouping of the LP variables also induces a grouping of the constraints and positions that completes the partition.

Due to lack of space, we will not prove this here. Instead, we give an example of how model symmetry propagates to MAP-LP symmetry. Fig. 2 shows an MRF  $G$  colored by its CEP (a) and the resulting MAP-LP (b) (some constraints and the position nodes have been omitted for clarity). In Fig. 2c, we see the correspondence between the CEP of  $G$  and the CEP of the MAP-LP as indicated by the colors.

### 3 EQUITABLE PARTITIONS OF CONCAVE FREE ENERGIES

With the basics of lifted variational inference at hand, we can now begin our main discussion. We proceed as follows. We start off by defining an equitable partition of a concave energy. Then, as the first main result of this section, we show that any concave energy that admits an equitable partition has a solution that **respects** that partition. This establishes that equitable partitions of concave energies are lifting partitions. Next, we show that given an equitable partition of an MRF, concave energies that admit this partition are guaranteed to exist. That is, if we want to do convergent inference on a model with symmetries, we can always find a suitable energy that does not break the symmetries. Finally, we will look at some heuristics used for selecting concave energies and examine their relationship to equitable partitions.

**Definition 2.** *An equitable partition of a concave energy  $\hat{H}_c$  (as in Eq. 3) with  $\mathbf{c} \in \mathcal{C}(G)$  is an equitable partition of  $G$  such that  $X_i$  and  $X_j$  are grouped together only if  $c_i = c_j$*

and  $\theta_\alpha, \theta_\beta$  are grouped together only if  $c_\alpha = c_\beta$ .

We will shortly show that equitable partitions of concave energies preserve optimal solutions of the variational problem. Before we do so, however, we will formalize what we consider to be the symmetries of  $\hat{H}_c$ .

If we set aside the constraints and ignore semantics of  $\mu$ ,  $\hat{H}_c$  is just a linear combination of  $x \log x$  terms, i.e.  $\hat{H}_c(\mathbf{x}) = \sum_k c_k x_k \log x_k$ . Observe that if we permute any two variables whose  $c$ 's are the same, we do not change  $\hat{H}_c$ . In other words, any permutation  $\Pi$  with  $\Pi \mathbf{c} = \mathbf{c}$  is an automorphism of  $\hat{H}_c$ , i.e.,  $\hat{H}_c(\Pi \mathbf{x}) = \hat{H}_c(\mathbf{x})$ . Moreover, switching any pair of variables can be done independently of other pairs. We now restate the above in formal terms. If we introduce  $\mathcal{R} = \{R_1, \dots, R_r\}$  that partitions the variables into classes having equal  $c$ , then the following holds:

**Observation 3.** *The group  $\Gamma = \bigotimes_{R \in \mathcal{R}} \mathbb{S}_{|R|}$  is isomorphic to a subgroup of  $\mathbb{AUT}(\hat{H})$ .*

Here  $\bigotimes$  denotes the group product and  $\mathbb{S}_n$  is the symmetric group over  $n$  elements. Now, let us “switch on” the semantics of the argument and interpret the automorphism group of  $\hat{H}_c$  in terms of pseudomarginals. We can see that the following operations are automorphisms of  $\hat{H}_c$ : we can exchange the pseudomarginals of any two variables with the same  $c$ 's, e.g.,  $(\mu_i(0), \mu_i(1)) \mapsto (\mu_j(0), \mu_j(1))$ ; similarly, we can exchange any two sets of factor beliefs; we could also exchange states within a set of beliefs:  $\mu_i(0) \mapsto \mu_i(1)$ , or even exchange states across variables,  $\mu_i(0) \mapsto \mu_j(1)$  (given that the  $c$ 's are compatible). All of these operations can be done independently of each other. Of course, many symmetries of  $\hat{H}_c$  are not symmetries of Eq. 1, as they are not symmetries of the constraints. For example, Eq. 1 would generally not admit, say the reordering of states of a variable without reordering the states of its neighbors as a symmetry, since marginalization constraints tie adjacent nodes in the factor graph.

In summary,  $\hat{H}_c$  is a highly symmetric object given that we have equal  $c$ 's. Hence, what we really have to be careful about are the symmetries of the constraints. However, as we will discuss now, equitability takes care of the constraints and we end up with lifting partitions for Eq. 1.

**Theorem 4** (EPs of Concave Energies are Lifting Partitions). *Let  $G$  be an MRF and  $\mathbf{c} \in \mathcal{C}(G)$  a vector of counting numbers. If  $\mathcal{P}$  is an equitable partition of  $\hat{H}_c$ , then  $\mathcal{P}'$  obtained from  $\mathcal{P}$  via Lemma 1 is a lifting partition of Eq. 1.*

*Proof.* To prove that  $\mathcal{P}'$  is a lifting partition of Eq. 1, we need to prove that Eq. 1 admits a solution, where equivalent variables take on equal values. We will establish this in the following way. Given any feasible vector  $\mu$  of Eq. 1, we will produce a vector  $\mu'$  by replacing each variable by the average of its class. E.g., if the variable  $\mu_i(x)$  is in some class  $P$ , then  $\mu'_i(x) = 1/|P| \sum_{j \in P} \mu_j(x)$ . Thus averaged,

the vector  $\mu'$  respects  $\mathcal{P}'$ . Then, we need that **a)**  $\mu'$  is feasible as well and that **b)**  $F(\mu') \geq F(\mu)$ . Having established **a)** and **b)**, the rest is simple: we take any optimal solution of Eq. 1 and average over the classes. By **a)** we know the average is feasible. By **b)** we know that it will not decrease the objective value. Since we started with something that was already optimal, it must be that averaged vector is of equal objective value, as improvement over the optimum is not possible by definition. Thus we have found a new optimum that respects the partition. It now only remains to verify that **a)** and **b)** indeed hold.

**Proof of a).** The averaging operation over the partition classes can be represented in a linear algebraic way, as multiplying  $\mu$  with the doubly stochastic matrix  $X$  defined as:

$$X_{ij} = \begin{cases} 1/|C| & \text{if } (\mu)_i, (\mu)_j \text{ are both in some } C \in \mathcal{P}', \\ 0 & \text{otherwise.} \end{cases}$$

The brackets in the equation indicate that the indices above are used in a generic sense (not bound to factors, variables or particular states). The theory of equitable partitions of LPs tells us that if  $\mathcal{P}'$  is equitable, then  $\mu$  being feasible implies  $\mu' = X\mu$  is feasible as well, as  $X$  is a fractional automorphism of the LP [5].

**Proof of b).** The Birkhoff-von-Neumann Theorem [12] allows one to decompose the doubly stochastic  $X$  as a convex combination of permutation matrices  $\sum_i \lambda_i \Pi_i$ . Note that any of these permutation matrices will exchange only variables that had been grouped together in  $\mathcal{P}'$ . This follows from the fact that the  $\lambda$ 's form a convex combination. If  $\Pi_k$  has a nonzero element, then  $\sum_k \lambda_k (\Pi_k)_{ij} = X_{ij}$  has to be strictly greater than 0 as well, as the convex combination has at least one nonzero element. By definition  $c$  respects  $\mathcal{P}'$ , hence all  $\Pi$ 's are automorphisms of  $\hat{H}_c$ . Moreover,  $\theta$  also respects  $\mathcal{P}'$  due to our definition of equitable partitions, hence the  $\Pi$ 's are automorphisms of  $\theta^T$  as well. Taken together, we establish that all  $\Pi_i$ 's are automorphisms of  $F$ ,  $F(\mu) = F(\Pi_i \mu)$ . With this in mind, the concavity of  $F$  gives us the result:  $F(\mu') = F(\sum_i \lambda_i \Pi_i \mu) \geq \sum_i \lambda_i F(\Pi_i \mu) = F(\mu)$ .  $\square$

Thus, we have established that equitable partitions of concave energies are lifting partitions for the variational problem of interest. However, an important question that remains is: do they actually exist? That is, if we want to do inference, can we find counting numbers that permit lifting at all? As we will show now, not only do such numbers exist, but also most heuristics presented in literature for finding counting numbers will yield  $c$  that respect equitable partitions of  $G$ . Let us first show the existence of liftable counting numbers.

**Lemma 5** (Existence of liftable counting numbers). *Let  $\mathcal{P}$  be an equitable partition of the MRF  $G$ . If  $\mathcal{C}(G)$  is not empty, then there exists a  $c$ -vector that respects  $\mathcal{P}$ . In other words,  $\mathcal{P}$  is an equitable partition of  $\hat{H}_c$  for at least one  $c$ .*

Figure 3: (a) Illustration of Lemma 5. (b) Commutative diagram underlying the “lifted inference by reparametrization” paradigm. (Best viewed in color)

*Proof (sketch).* Observe that the set of counting numbers is defined by a linear program, as Eq. 4 consists of linear constraints. Thus, we can again rely on the fact that equitable partitions of linear programs act as lifting partitions, given that we manage to translate  $\mathcal{P}$  into an equitable partition  $\mathcal{P}'$  of  $\mathcal{C}(G)$ . Let us show the translation in question. We group together  $c_i$  with  $c_j$ ,  $c_{ii}$  with  $c_{jj}$ , and  $\phi_i$  (the constraint generated by  $X_i$ ) with  $\phi_j$  in  $\mathcal{P}'$  if  $X_i$  and  $X_j$  are grouped together in  $\mathcal{P}$ . Similarly, if  $\mathcal{P}$  groups  $\theta_\alpha$  and  $\theta_\beta$ , we group  $c_\alpha$  with  $c_\beta$ ,  $c_{\alpha\alpha}$  with  $c_{\beta\beta}$ , and  $\phi_\alpha$  (the constraint generated by  $\theta_\alpha$ ) with  $\phi_\beta$ . Finally,  $c_{i\alpha}$  and  $c_{j\beta}$  are grouped together if  $\diamond_{i\alpha}$  and  $\diamond_{j\beta}$  are grouped together in  $\mathcal{P}$ . Now let us argue that  $\mathcal{P}'$  is indeed equitable on  $\mathcal{C}(G)$ . The main idea is as follows: we will show that the factor graph of  $G$  is isomorphic to a “skeleton” subgraph of the factor graph of  $\mathcal{C}(G)$ . As such, any equitable partition of  $G$  is also equitable on the skeleton of  $\mathcal{C}(G)$ . Then, we will complete the partition on the remaining elements of  $\mathcal{C}(G)$  in a way that preserves equitability.

To obtain the skeleton, we temporarily ignore the variables  $c_i$ ,  $c_{ii}$ ,  $c_\alpha$ ,  $c_{\alpha\alpha}$ . Then, the map  $M : G \rightarrow \mathcal{C}(G)$ , which maps the position node  $\diamond_{\alpha i}$  to the LP variable  $c_{i\alpha}$ , the factor  $\theta_\alpha$  to the constraint of the factor and the variable  $X_i$  to the constraint of the variable, is an isomorphism. This follows directly from Eq. 4. An LP variable  $c_{i\alpha}$  appears in the factor constraint of  $\theta_\alpha$  if and only if  $\theta_\alpha$  is connected to position node  $\diamond_{\alpha i}$  (in other words variable  $i$  participates in factor  $\theta_\alpha$ ). Moreover a variable  $c_{i\alpha}$  appears in the variable constraint of  $X_i$  if and only if  $X_i$  is connected to position node  $\diamond_{\alpha i}$ . Thus, an equitable partition of  $G$  yields an equitable partition of the constraints and the variables  $c_{i\alpha}$ . If we reintroduce now  $c_i$ ,  $c_{ii}$ ,  $c_\alpha$ ,  $c_{\alpha\alpha}$ , we see that each appears in exactly one constraint, so they can be partitioned in a way to preserve equitability. Fig. 3a provides an illustration. Note that we have so far ignored the position nodes in the FG of  $\mathcal{C}(G)$ . It can be verified that they can be partitioned without breaking the equitability of the partition obtained thus far.  $\square$

We have established that if  $G$  admits an equitable parti-

tion, then there will be at least one energy that admits the same equitable partition. The question now is, how do we compute the appropriate counting numbers? Naturally, as in Thm 4, we can take any vector of counting numbers, any equitable partition of  $G$  and simply average  $c$  over the classes. However, as  $\mathcal{C}(G)$  is a polyhedron, there are infinitely many vectors of counting numbers and the usefulness of the resulting energies in terms of the approximate inference problem will vary. In the following, we show that several heuristics for picking counting numbers naturally yield counting numbers that allow nice equitable partitions of the energy. The heuristics that we will discuss first are the following two: **(a)** [6] following the principle of insufficient reason one tries to make  $c$ 's as uniform as possible by minimizing either  $\sum_{\alpha}(c_{\alpha} - 1)^2$  or  $\sum_{\alpha} c_{\alpha} \log c_{\alpha}$  over  $\mathcal{C}(G)$ ; **(b)** [14] finding the least-squares projection of the  $c$ 's of the Bethe energy onto  $\mathcal{C}(G)$ , i.e.  $c^* = \operatorname{argmin}_{c \in \mathcal{C}(G)} \sum_{\alpha}(c_{\alpha} - 1)^2 + \sum_i (c_i - |\operatorname{nb}(X_i)| + 1)^2$ . Both of them lead to liftable energies.

**Proposition 6** (Finding lifted counting numbers). *Let  $\mathcal{P}$  be an EP of  $G$  and  $\mathcal{P}'$  is an EP of  $\mathcal{C}(G)$  obtained as in Thm. 5. Then  $\mathcal{P}'$  is a lifting partition of both (a) and (b).*

*Proof.* The proof is identical to the proof of Thm. 4. As, Lemma 5 already established, given any  $c \in \mathcal{C}(G)$ , we obtain a new  $c' \in \mathcal{C}(G)$  by assigning to any  $c'_{\alpha}$  or  $c'_i$  the average of  $c$  over the respective class. Now we need to show that this averaging does not increase the respective objective values. We argue in the same way as in Thm. 4. For both cases in **(a)**, the automorphism group consists of the product of two symmetric groups - we can exchange any two  $c_i, c_j$  and any two  $c_{\alpha}, c_{\beta}$  independently. Thus averaging over  $\mathcal{P}'$  is equivalent to averaging over automorphisms of the objectives, which by convexity does not increase the value. For the case of **(b)**, the automorphism group is smaller. We are allowed to exchange any two  $c_{\alpha}, c_{\beta}$  independently, but we can exchange  $c_i, c_j$  only if  $|\operatorname{nb}(X_i)| = |\operatorname{nb}(X_j)|$ . Recall however, that in any equitable partition, for any class  $Q$ , we group  $X_i$  and  $X_j$  if  $\deg(X_i, Q) = \deg(X_j, Q)$ . This implies  $|\operatorname{nb}(X_i)| = |\operatorname{nb}(X_j)|$ . Thus, the averaging matrix  $X$  as in Thm. 4 will have a non-zero value only if  $|\operatorname{nb}(X_i)| = |\operatorname{nb}(X_j)|$ , and the resulting Birkhoff-von-Neumann decomposition will consist of automorphisms of the objective.  $\square$

In essence, this proposition tells us that optimal numbers (w.r.t. **(a)** and **(b)**) can be found that turn any equitable partition of  $G$  into an equitable partition of the energy. Could this be the case for all heuristics? As it turns out, some heuristics can impose restrictions on what partitions can be EPs of their respective energies.

To see this, consider for example as a further option **(c)** Tree-Reweighted BP (in pairwise models). We obtain  $c \in \mathcal{C}(G)$  by setting  $c_{\alpha}$  to be the number of spanning trees passing through  $\theta_{\alpha}$  divided by the number of all spanning trees in  $G$ . If we translate the result of Bui et al. [2] in the lan-

guage of the present paper, it states that the equitable partition of  $G$  coarser than its orbit partition may generally not be turned into an equitable partition of the TRW energy. However, for the orbit partition, they give an efficient algorithm to produce the appropriate  $c$ .

Finally, one could also follow Meshi et al. [14] as option **(d)**: instead of approximating the numbers of  $F_{\text{Bethe}}$ , we project  $F_{\text{Bethe}}$  itself onto the set of concave energies  $F_{c \in \mathcal{C}(G)}$ . More precisely, we take  $c^* = \operatorname{argmin}_{c \in \mathcal{C}(G)} \int_{\mu \in \mathcal{L}(G)} (F_{\text{Bethe}}(\mu) - F_c(\mu))^2 d\mu$ . As a matter of fact, it is even an open question whether  $F_{\text{Bethe}}$  admits stationary points that respect<sup>2</sup> any  $\mathcal{P}$ . It should be noted that if we want a coarser partition than what **(c)** or **(d)** permit, we could still take the counting numbers and average them over a coarser equitable partition of  $G$ . However, the question of whether this operation preserves the quality of approximation remains open.

## 4 LIFTING AS REPARAMETRIZATION

One issue that arises with the above approach is that in certain cases, compression changes the structure of the optimization problem. For example, given an equitable partition  $\mathcal{P} = \{Q_1, \dots, Q_q, P_1, \dots, P_p, D_1, \dots, D_d\}$  of  $G$ , the compressed inference problem will take on the following form:  $\mu^* =$

$$\operatorname{argmax}_{\mu \in \mathcal{L}(G)'} E'(\mu) + \sum_{P \in \mathcal{P}} |P| c_P H_P(\mu_P) + \sum_{Q \in \mathcal{P}} |Q| c_Q H_Q(\mu_Q),$$

where

$$E'(\mu) = \sum_{P \in \mathcal{P}} |P| \theta_P \mu_P + \sum_{Q \in \mathcal{P}} |Q| \theta_Q \mu_Q \quad \text{and}$$

$$\mathcal{L}(G)' = \left\{ \mu \geq 0 \left| \begin{array}{l} \mu_P^0 + \mu_{P'}^1 = 1 \\ \mu_Q^{00} + \mu_D^{01} = \mu_P^0 \\ \mu_Q^{11} + \mu_{D'}^{01} = \mu_{P'}^1 \\ \mu_Q^{00} + \mu_{D'}^{01} = \mu_P^0 \\ \mu_Q^{11} + \mu_D^{01} = \mu_{P'}^1 \end{array} \right. \right\}. \quad (5)$$

Here,  $Q$  is the representative of a factor class,  $P$  and  $P'$  are the representatives of its neighboring variable classes and  $D$  and  $D'$  are the representatives of the position classes that connect variables in  $P$  and  $P'$  to factors in  $Q$ . Note that our notation treats the beliefs of factor  $Q$  being in state 00 or 11 differently from the beliefs of factor  $Q$  being in state 01 or 01. This becomes important in the following situation: in an equitable partition, it could happen that  $P = P'$ . That is, for any ground factor in the class  $Q$ , both participating variables are in the same class of the lifting partition. For the variational problem, this means that we need to unify the

<sup>2</sup>Works on lifted loopy belief propagation [8, 22, 10] do indeed show that BP admits such solutions. However, the question of whether this is due to  $F_{\text{Bethe}}$  or an artifact of the way BP optimizes it is unclear.

variables  $\mu_{D'}^{01}$  and  $\mu_D^{01}$ , ending up with a peculiar-looking set of constraints such as:

$$\mu_Q^{00} + \mu_D^{01} = \mu_P^0 \text{ and } \mu_Q^{11} + \mu_D^{01} = \mu_P^1 \quad .$$

This example illustrates why we cannot simply view the lifted inference problem as a standard inference problem on a smaller “proper” factor graph. We have a binary factor that has the same variable in both positions (which is, unfortunately, not equivalent to a unary factor). Now, in terms of message-passing, to send a message to  $P$ ,  $Q$  would have to first eliminate  $P$  – an operation which is not supported by standard message-passing frameworks.

To circumvent the problem, at least for the case of  $T = 0$  in Eq. 1, we can follow the “lifted inference as reparametrization” paradigm recently advocated by Mladenov et al. [16]. The main idea is based on the fact that equitable partitions allow one to not only recover a solution of the ground variational problem from the lifted one, but also a solution of the ground problem can be projected onto  $\mathbb{R}_{\mathcal{P}}$  by averaging the variables within each equivalence class. Thus, what we do is the following: given an  $G$  and an equitable partition  $\mathcal{P}$ , we find a smaller  $G'$  and a partition  $\mathcal{P}'$  such that the variational problem of  $G$  lifted with  $\mathcal{P}$  is identical to the variational problem of  $G'$  lifted with  $\mathcal{P}'$ . So, we solve the smaller  $G'$  with a ground solver, average over  $\mathcal{P}'$  to obtain a solution to the lifted problem of  $G'$ , transfer that to the lifted variational problem of  $G$ , since they are identical, and then finally unlift according to  $\mathcal{P}$ . The idea is illustrated in Fig. 3. The work of [16] shows how to find  $G'$  and  $\mathcal{P}$  and then reparametrize the factors of  $G'$  such that its lifted MAP-LPs are same the one of  $G$ . Our goal here is to show that if in addition we reparametrize the  $c$ 's, their lifted concave energies will also be the same. Thus, in essence, we can make use of any ground concave energy solver that allows manually setting  $c$ 's for lifted inference.

As we would like to avoid introducing again the technical arguments of [16], we will introduce a notion of weak partition equivalence, which subsumes the equivalence in [16], and build upon that. We will show that reparametrization of  $\hat{H}_c$  is possible among partition-equivalent pairs. Since the pairs produced by the algorithm of [16] are partition-equivalent, the result applies.

**Definition 7.** Let  $G$  and  $G'$  be MRFs. We call  $G$  and  $G'$  **weakly partition-equivalent** if they admit equitable partitions  $\mathcal{P} = \{P_1, \dots, P_p, Q_1, \dots, Q_q, D_1, \dots, D_d\}$  resp.  $\mathcal{P}' = \{P'_1, \dots, P'_p, Q'_1, \dots, Q'_q, D'_1, \dots, D'_d\}$  having the same number of variable, factor and position classes. Moreover, for any two classes  $X, Y \in \mathcal{P}$ , we have  $\deg(X, Y) \neq 0$  if and only if  $\deg(X', Y') \neq 0$  ( $\spadesuit$ ).

Note that the actual number of nodes in the class may very well be different, we do not require  $|Q| = |Q'|$ .

**Lemma 8.** If  $G$  and  $G'$  are weakly partition equivalent w.r.t.  $\mathcal{P}$  and  $\mathcal{P}'$ , then  $\deg(Q, D) \neq 0$  implies

$$\frac{|Q|}{|Q'|} \deg(Q, D) = \frac{|D|}{|D'|} \deg(Q', D'), \text{ resp. } \deg(P, D) \neq 0 \text{ implies } \frac{|P|}{|P'|} \deg(P, D) = \frac{|D|}{|D'|} \deg(P', D').$$

*Proof.* For any equitable partition it will hold that  $|Q| \deg(Q, D) = |D| \deg(D, Q)$ , resp.  $|Q'| \deg(Q', D') = |D'| \deg(D, Q)$ . Since  $D$  consists of only position nodes, and every position node can be connected to exactly one factor (and one variable),  $\deg(D, Q) = \deg(D', Q') = 1$ . With this in mind, we take the quotient of both equations and obtain  $\frac{|Q| \deg(Q, D)}{|Q'| \deg(Q', D')} = \frac{|D|}{|D'|}$ . Multiplying both sides by  $\deg(Q', D')$  yields the result. The reasoning for the variable classes is identical.  $\square$

Now, suppose counting numbers for  $G$  which respect  $\mathcal{P}$  have been found, that is, for every  $\theta_\alpha$  in the class  $Q$ ,  $c_\alpha = c_Q$  and so on, as in Thm. 5. Then, we can construct a vector of counting numbers for  $G'$  by the following procedure: for every vertex in  $G'$  (regardless of whether it is a variable, factor, or position), we take the size of its class,  $|X'|$ , the size of the corresponding class in  $\mathcal{P}$ ,  $|X|$  and then normalize the counting number  $c_X$  (from  $G$ ) by their ratio. That is,  $c'_k = (|X|/|X'|)c_X$ .

**Theorem 9.** Suppose  $G$  and  $G'$  are weakly partition equivalent with respect to  $\mathcal{P}$  and  $\mathcal{P}'$  and  $c \in \mathcal{C}(G)$  respects  $\mathcal{P}$ . Then, the vector  $c'$  having  $c'_k = c_{X'} = \frac{|X|}{|X'|}c_X$  consists of counting numbers for  $G'$ . I.e.  $c' \in \mathcal{C}(G')$ .

*Proof.* We have assumed  $c$  respects  $\mathcal{P}$ . This allows us to rewrite the conditions of Eq. 4 as

$$C_Q = C_{QQ} + \sum_D \deg(Q, D)c_D \quad \text{and,} \\ C_P = C_{PP} + \sum_D \deg(P, D)c_D .$$

The above describes the lifted LP of  $\mathcal{C}(G)$  after unification of all equivalent variables. Now, observe that

$$C_{Q'} = \frac{|Q|}{|Q'|} C_Q = \frac{|Q|}{|Q'|} \left[ C_{QQ} + \sum_D \deg(Q, D)c_D \right] \\ = \frac{|Q|}{|Q'|} C_{QQ} + \sum_{D: \deg(Q, D) \neq 0} \frac{|Q|}{|Q'|} \deg(Q, D)c_D \\ = C_{Q'Q'} + \sum_{D: \deg(Q, D) \neq 0} \deg(Q', D') \frac{|D|}{|D'|} c_D \\ = C_{Q'Q'} + \sum_{D': \deg(Q', D') \neq 0} \deg(Q', D') c_{D'} .$$

Note, we were allowed to switch the index in the last line due to ( $\spadesuit$ ). Similarly,

$$C_{P'} = \frac{|P|}{|P'|} C_P = \frac{|P|}{|P'|} \left[ C_{PP} - \sum_D \deg(P, D)c_D \right] \\ = \frac{|P|}{|P'|} C_{PP} - \sum_{D: \deg(P, D) \neq 0} \frac{|P|}{|P'|} \deg(P, D)c_D \\ = C_{P'P'} - \sum_{D: \deg(P, D) \neq 0} \deg(P', D') \frac{|D|}{|D'|} c_D \\ = C_{P'P'} - \sum_{D': \deg(P', D') \neq 0} \deg(P', D') c_{D'} .$$

| Complete Graph                                     | Friends-Smokers   | Clique-Cycle   |

Table 1: The Markov Logic Network models used to illustrate our theoretical results. Details are given in the main text.

What this tells us is that  $c'$  is a solution of  $\mathcal{C}(G')$  lifted according to  $\mathcal{P}'$ . This implies that we can recover a vector of ground counting numbers by assigning to  $c'_k$  the corresponding  $c'_X$ .  $\square$

So now, given  $c$  obtained as above, let us examine the lifted entropy of  $G'$  with respect to  $\mathcal{P}'$ ,

$$\begin{aligned} \hat{H}' &= \sum_{P' \in \mathcal{P}'} |P'| c_{P'} H_{P'} + \sum_{Q' \in \mathcal{P}'} |Q'| c_{Q'} H_{Q'} \\ &= \sum_{P' \in \mathcal{P}'} |P'| \frac{|P|}{|P'|} c_P H_{P'} + \sum_{Q' \in \mathcal{P}'} |Q'| \frac{|Q|}{|Q'|} c_Q H_{Q'} \\ &= \sum_{P \in \mathcal{P}} |P| c_P H_P + \sum_{Q \in \mathcal{P}} |Q| c_Q H_Q = \hat{H}. \end{aligned}$$

As we see, this is exactly the lifted entropy of  $G$  with respect to  $\mathcal{P}$ . To conclude the argument, we note that the algorithm of [16] takes care that the linear  $E'(\cdot)$  part and the constraints of the lifted variational problems are the same. Thus, with the addition of the reparametrized  $c$ 's, we achieve full equivalence of both lifted variational problems.

## 5 EMPIRICAL ILLUSTRATION

We will now illustrate our theoretical results by demonstrating that the “lifting by reparametrization” paradigm allows one to lift Schwing et al.’s distributed message-passing algorithm<sup>3</sup> for marginal inference [21] without any overhead. As far as we know, this presents the first lifted convergent variational marginal inference that can handle problems efficiently by distributing and parallelizing the inference computation and the memory requirements. The convergence and optimality guarantees are preserved by consistency messages, sent between the distributed cores, that our lifted variant directly inherits from Schwing et al.’s original version. Together with parallelizable lifting approaches [11], this shows for the first time that each step of the lifted inference pipeline is readily parallelizable.

The experimental protocol is inspired by [2] and uses three of their test models in Markov Logic Network syntax, cf. Tab. 1: complete graph, friends-smokers, and clique-cycle.

We focus on the repulsive case, i.e. the weight of interaction clauses is set to a negative values. The parameter  $W$  denotes the weight that will be varying across the experiments. As Bui et al. [2] point out, in all models except clique-cycle,  $W$  acts like the “local field” potential in an Ising model; a positive value of  $W$  means that variables tend to be in the 1 state, whereas a negative value favors the 0 state. The complete graph model is an Ising model over the complete graph over  $n$  nodes (the domain size); all parameters are the same. The weight of the interaction clause is repulsive with  $-0.1$ . The friends-smokers is a pairwise version of the one negated one used by Bui et al., where we also used a repulsive interaction between smokers: Here the domain size is the number of people. Finally, the clique-cycle model encodes a model with 3 cliques, each consisting of  $n$  nodes (the domain size), and 3 bipartite graphs between them. For more details we refer to [2].

Since we reparametrize an existing variational approach, we will not report on the accuracy of the marginals and the quality of the objective as they have been investigated already in the corresponding literature. Rather, we perform a “within model” comparison of the objectives achieved, the size of the models, and the running times for inference since they are what our theoretical results are about. Specifically, we evaluated the lifted and the ground version on several instances of the three test models, varying the parameter  $W$  and the domain size. We assume no evidence has been observed, which results in a large amount of symmetries. As Bui et al. [2] argue this is a sensible setting since performing marginal inference in relational probabilistic models can be very useful for maximum-likelihood parameter estimation.

The experimental results are summarized in Fig. 4. As one can see the lifted inference can be orders of magnitude faster than its ground version. We also ran a single-core lifted loopy belief propagation. However, due to its lack of convergence, it is difficult to have a meaningful comparison of running times. Nevertheless, we observed cases where it did not converge but actually started to oscillate.

<sup>3</sup><http://alexander-schwing.de/projects.php>

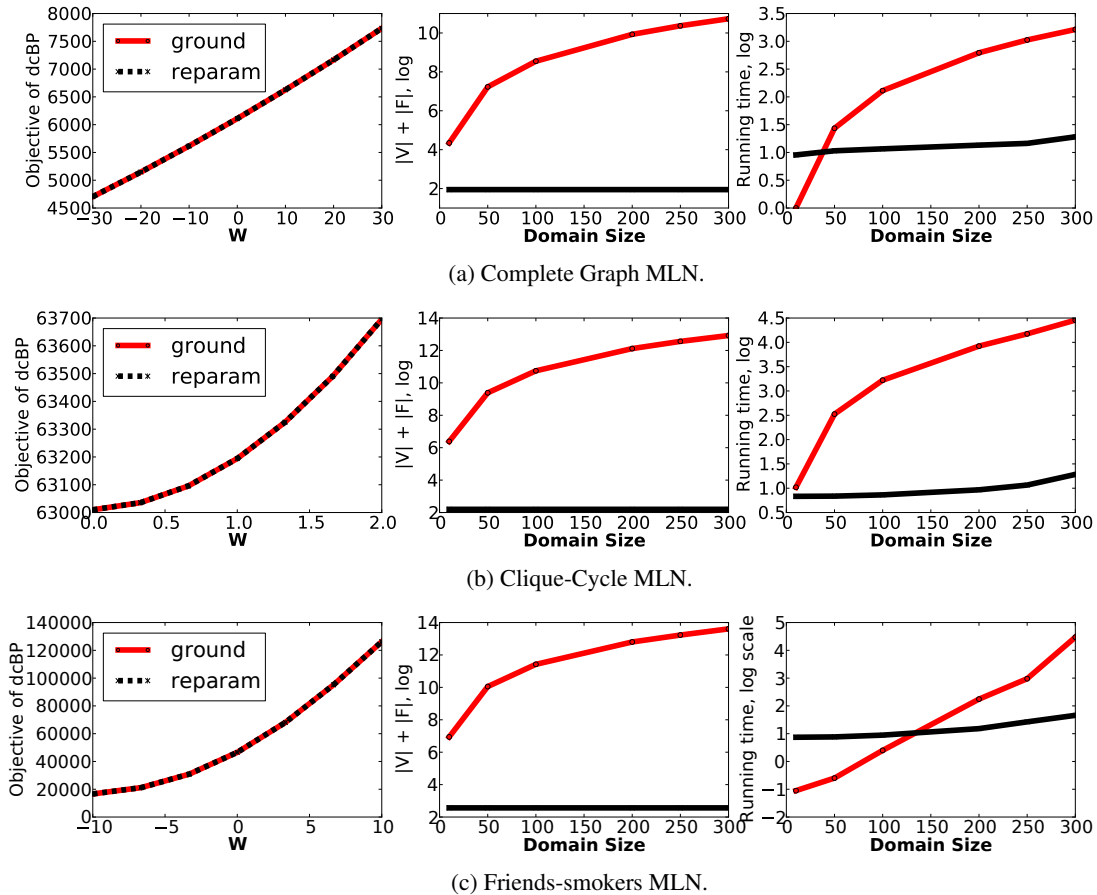

Figure 4: Experimental results on the test models from Tab. 1. Each row shows from left to right the objective for different weights, the size (number of nodes and factors) in log-space and the running time in seconds in log-space for ground (red) versus lifted (black). As one case see, lifted variational marginal inference can be orders of magnitude faster than it ground version without sacrificing the objective. (best viewed in color)

## 6 CONCLUSIONS

We have established a “lifted inference by reparametrization” paradigm for variational marginal inference. More precisely, we have introduced the notion of equitable partitions of concave free energies and shown how to use them to reparameterize the corresponding variational optimization problems. In turn, a large class of existing variational marginal inference algorithms can directly be made aware of symmetries without modifications. We illustrated this by lifting Schwing et al.’s distributed message-passing algorithm for marginal inference, resulting in the first lifted, distributed, convergent message passing algorithms for marginal inference. Moreover, the paradigm of reparametrization allows us to address the observation of Bui et al. [2] about their Frank-Wolfe TRW solver running slower than BP. At least in the case where no extra tightening is required, one can just compute the TRW counting numbers with lifted Kruskal, reparametrize and apply a generic convergent message-passing algorithm.

Our work provides several avenues for future work. For instance, one should explore what other constraints we can pose on counting numbers to enforce exactness while we can still optimize over the set in a lifted fashion. Since the dimensionality reduction changes the geometry of the variational optimization problem, one should also investigate its interaction with the solvers. It is interesting to explore features of relational languages to speed up lifted variational marginal inference even more. One of the most interesting open question raised by our work is whether non-trivial reparametrizations of  $F_{\text{Bethe}}$  and of energies in general exists and are exploitable for speeding up optimization, at least in an approximate sense. An affirmative answer would have deep implications not only for probabilistic inference but for many tasks in computer vision, machine learning, and AI in general.

## Abstract

We present an extensive analysis of the key problem of learning optimal reserve prices for generalized second price auctions. We describe two algorithms for this task: one based on density estimation, and a novel algorithm benefiting from solid theoretical guarantees and with a very favorable running-time complexity of  $O(nS \log(nS))$ , where  $n$  is the sample size and  $S$  the number of slots. Our theoretical guarantees are more favorable than those previously presented in the literature. Additionally, we show that even if bidders do not play at an equilibrium, our second algorithm is still well defined and minimizes a quantity of interest. To our knowledge, this is the first attempt to apply learning algorithms to the problem of reserve price optimization in GSP auctions. Finally, we present the first convergence analysis of empirical equilibrium bidding functions to the unique symmetric Bayesian-Nash equilibrium of a GSP.

## 1 INTRODUCTION

The Generalized Second-Price (GSP) auction is currently the standard mechanism used for selling sponsored search advertisement. As suggested by the name, this mechanism generalizes the standard second-price auction of [Vickrey \(1961\)](#) to multiple items. In the case of sponsored search advertisement, these items correspond to ad slots which have been ranked by their position. Given this ranking, the GSP auction works as follows: first, each advertiser places a bid; next, the seller, based on the bids placed, assigns a score to each bidder. The highest scored advertiser is assigned to the slot in the best position, that is, the one with the highest likelihood of being clicked on. The second highest score obtains the second best item and so on, until all slots have been allocated or all advertisers have been assigned to a slot. As with second-price auctions, the bidder's payment is independent of his bid. Instead, it depends

solely on the bid of the advertiser assigned to the position below.

In spite of its similarity with second-price auctions, the GSP auction is not an incentive-compatible mechanism, that is, bidders have an incentive to lie about their valuations. This is in stark contrast with second-price auctions where truth revealing is in fact a dominant strategy. It is for this reason that predicting the behavior of bidders in a GSP auction is challenging. This is further worsened by the fact that these auctions are repeated multiple times a day. The study of all possible equilibria of this repeated game is at the very least difficult. While incentive compatible generalizations of the second-price auction exist, namely the Vickrey-Clark-Gloves (VCG) mechanism, the simplicity of the payment rule for GSP auctions as well as the large revenue generated by them has made the adoption of VCG mechanisms unlikely.

Since its introduction by Google, GSP auctions have generated billions of dollars across different online advertisement companies. It is therefore not surprising that it has become a topic of great interest for diverse fields such as Economics, Algorithmic Game Theory and more recently Machine Learning.

The first analysis of GSP auctions was carried out independently by [Edelman et al. \(2005\)](#) and [Varian \(2007\)](#). Both publications considered a full information scenario, that is one where the advertisers' valuations are publicly known. This assumption is weakly supported by the fact that repeated interactions allow advertisers to infer their adversaries' valuations. [Varian \(2007\)](#) studied the so-called Symmetric Nash Equilibria (SNE) which is a subset of the Nash equilibria with several favorable properties. In particular, Varian showed that any SNE induces an efficient allocation, that is an allocation where the highest positions are assigned to advertisers with high values. Furthermore, the revenue earned by the seller when advertisers play an SNE is always at least as much as the one obtained by VCG. The authors also presented some empirical results showing that some bidders indeed play by using an SNE. However, no theoretical justification can be given for the choice of

this subset of equilibria (Börger et al., 2013; Edelman and Schwarz, 2010). A finer analysis of the full information scenario was given by Lucier et al. (2012). The authors proved that, excluding the payment of the highest bidder, the revenue achieved at any Nash equilibrium is at least one half that of the VCG auction.

Since the assumption of full information can be unrealistic, a more modern line of research has instead considered a Bayesian scenario for this auction. In a Bayesian setting, it is assumed that advertisers’ valuations are i.i.d. samples drawn from a common distribution. Gomes and Sweeney (2014) characterized all symmetric Bayes-Nash equilibria and showed that any symmetric equilibrium must be efficient. This work was later extended by Sun et al. (2014) to account for the quality score of each advertiser. The main contribution of this work was the design of an algorithm for the crucial problem of revenue optimization for the GSP auction. Lahaie and Pennock (2007) studied different *squashing* ranking rules for advertisers commonly used in practice and showed that none of these rules are necessarily optimal in equilibrium. This work is complemented by the simulation analysis of Vorobeychik (2009) who quantified the distance from equilibrium of bidding truthfully. Lucier et al. (2012) showed that the GSP auction with an optimal reserve price achieves at least 1/6 of the optimal revenue (of any auction) in a Bayesian equilibrium. More recently, Thompson and Leyton-Brown (2013) compared different allocation rules and showed that an *anchoring* allocation rule is optimal when valuations are sampled i.i.d. from a uniform distribution. With the exception of Sun et al. (2014), none of these authors have proposed an algorithm for revenue optimization using historical data.

Zhu et al. (2009) introduced a ranking algorithm to learn an optimal allocation rule. The proposed ranking is a convex combination of a quality score based on the features of the advertisement as well as a revenue score which depends on the value of the bids. This work was later extended in (He et al., 2014) where, in addition to the ranking function, a behavioral model of the advertisers is learned by the authors.

The rest of this paper is organized as follows. In Section 2, we give a learning formulation of the problem of selecting reserve prices in a GSP auction. In Section 3, we discuss previous work related to this problem. Next, we present and analyze two learning algorithms for this problem in Section 4, one based on density estimation extending to this setting an algorithm of Guerre et al. (2000), and a novel discriminative algorithm taking into account the loss function and benefiting from favorable learning guarantees. Section 5 provides a convergence analysis of the empirical equilibrium bidding function to the true equilibrium bidding function in a GSP. On its own, this result is of great interest as it justifies the common assumption of buyers playing a symmetric Bayes-Nash equilibrium. Finally, in

Section 6, we report the results of experiments comparing our algorithms and demonstrating in particular the benefits of the second algorithm.

## 2 MODEL

For the most part, we will use the model defined by Sun et al. (2014) for GSP auctions with incomplete information. We consider  $N$  bidders competing for  $S$  slots with  $N \geq S$ . Let  $v_i \in [0, 1]$  and  $b_i \in [0, 1]$  denote the per-click valuation of bidder  $i$  and his bid respectively. Let the position factor  $c_s \in [0, 1]$  represent the probability of a user noticing an ad in position  $s$  and let  $e_i \in [0, 1]$  denote the expected click-through rate of advertiser  $i$ . That is  $e_i$  is the probability of ad  $i$  being clicked on given that it was noticed by the user. We will adopt the common assumption that  $c_s > c_{s+1}$  (Gomes and Sweeney, 2014; Lahaie and Pennock, 2007; Sun et al., 2014; Thompson and Leyton-Brown, 2013). Define the score of bidder  $i$  to be  $s_i = e_i v_i$ . Following Sun et al. (2014), we assume that  $s_i$  is an i.i.d. realization of a random variable with distribution  $F$  and density function  $f$ . Finally, we assume that advertisers bid in an efficient symmetric Bayes-Nash equilibrium. This is motivated by the fact that even though advertisers may not infer what the valuation of their adversaries is from repeated interactions, they can certainly estimate the distribution  $F$ .

Define  $\pi: s \mapsto \pi(s)$  as the function mapping slots to advertisers, i.e.  $\pi(s) = i$  if advertiser  $i$  is allocated to position  $s$ . For a vector  $\mathbf{x} = (x_1, \dots, x_N) \in \mathbb{R}^N$ , we use the notation  $x^{(s)} := x_{\pi(s)}$ . Finally, denote by  $r_i$  the reserve price for advertiser  $i$ . An advertiser may participate in the auction only if  $b_i \geq r_i$ . In this paper we present an analysis of the two most common ranking rules (Qin et al., 2014):

1. Rank-by-bid. Advertisers who bid above their reserve price are ranked in descending order of their bids and the payment of advertiser  $\pi(s)$  is equal to  $\max(r^{(s)}, b^{(s+1)})$ .
2. Rank-by-revenue. Each advertiser is assigned a quality score  $q_i := q_i(b_i) = e_i b_i \mathbb{1}_{b_i \geq r_i}$  and the ranking is done by sorting these scores in descending order. The payment of advertiser  $\pi(s)$  is given by  $\max(r^{(s)}, \frac{q^{(s+1)}}{e^{(s)}})$ .

In both setups, only advertisers bidding above their reserve price are considered. Notice that rank-by-bid is a particular case of rank-by-revenue where all quality scores are equal to 1. Given a vector of reserve prices  $\mathbf{r}$  and a bid vector  $\mathbf{b}$ , we define the revenue function to be

$$\begin{aligned} \text{Rev}(\mathbf{r}, \mathbf{b}) &= \sum_{s=1}^S c_s \left( \frac{q^{(s+1)}}{e^{(s)}} \mathbb{1}_{q^{(s+1)} \geq e^{(s)} r^{(s)}} + r^{(s)} \mathbb{1}_{q^{(s+1)} < e^{(s)} r^{(s)}} \right) \end{aligned}$$

Using the notation of [Mohri and Medina \(2014\)](#), we define the loss function

$$L(\mathbf{r}, \mathbf{b}) = -\text{Rev}(\mathbf{r}, \mathbf{b}).$$

Given an i.i.d. sample  $\mathcal{S} = (\mathbf{b}_1, \dots, \mathbf{b}_n)$  of realizations of an auction, our objective will be to find a reserve price vector  $\mathbf{r}^*$  that maximizes the expected revenue. Equivalently,  $\mathbf{r}^*$  should be a solution of the following optimization problem:

$$\min_{\mathbf{r} \in [0,1]^N} \mathbb{E}_{\mathbf{b}}[L(\mathbf{r}, \mathbf{b})]. \quad (1)$$

### 3 PREVIOUS WORK

It has been shown, both theoretically and empirically, that reserve prices can increase the revenue of an auction ([Myerson, 1981](#); [Ostrovsky and Schwarz, 2011](#)). The choice of an appropriate reserve price therefore becomes crucial. If it is chosen too low, the seller might lose some revenue. On the other hand, if it is set too high, then the advertisers may not wish to bid above that value and the seller will not obtain any revenue from the auction.

[Mohri and Medina \(2014\)](#), [Pardoe et al. \(2005\)](#), and [Cesa-Bianchi et al. \(2013\)](#) have given learning algorithms that estimate the optimal reserve price for a second-price auction in different information scenarios. The scenario we consider is most closely related to that of [Mohri and Medina \(2014\)](#). An extension of this work to the GSP auction, however, is not straightforward. Indeed, as we will show later, the optimal reserve price vector depends on the distribution of the advertisers' valuation. In a second-price auction, these valuations are observed since the corresponding mechanism is an incentive-compatible. This does not hold for GSP auctions. Moreover, for second-price auctions, only one reserve price had to be estimated. In contrast, our model requires the estimation of up to  $N$  parameters with intricate dependencies between them.

The problem of estimating valuations from observed bids in a non-incentive compatible mechanism has been previously analyzed. [Guerre et al. \(2000\)](#) described a way of estimating valuations from observed bids in a first-price auction. We will show that this method can be extended to the GSP auction. The rate of convergence of this algorithm, however, in general will be worse than the standard learning rate of  $O(\frac{1}{\sqrt{n}})$ .

[Sun et al. \(2014\)](#) showed that, for advertisers playing an efficient equilibrium, the optimal reserve price is given by  $r_i = \frac{\bar{r}}{e_i}$  where  $\bar{r}$  satisfies

$$\bar{r} = \frac{1 - F(\bar{r})}{f(\bar{r})}.$$

The authors suggest learning  $\bar{r}$  via a maximum likelihood technique over some parametric family to estimate  $f$  and

$F$ , and to use these estimates in the above expression. There are two main drawbacks for this algorithm. The first is a standard problem of parametric statistics: there are no guarantees on the convergence of their estimation procedure when the density function  $f$  is not part of the parametric family considered. While this problem can be addressed by the use of a non-parametric estimation algorithm such as kernel density estimation, the fact remains that the function  $f$  is the density for the unobservable scores  $s_i$  and therefore cannot be properly estimated. The solution proposed by the authors assumes that the bids in fact form a perfect SNE and so advertisers' valuations can be recovered using the process described by [Varian \(2007\)](#). There is however no justification for this assumption and, in fact, we show in [Section 6](#) that bids played in a Bayes-Nash equilibrium do not in general form a SNE.

### 4 LEARNING ALGORITHMS

Here, we present and analyze two algorithms for learning the optimal reserve price for a GSP auction when advertisers play a symmetric equilibrium.

#### 4.1 DENSITY ESTIMATION ALGORITHM

First, we derive an extension of the algorithm of [Guerre et al. \(2000\)](#) to GSP auctions. To do so, we first derive a formula for the bidding strategy at equilibrium. Let  $z_s(v)$  denote the probability of winning position  $s$  given that the advertiser's valuation is  $v$ . It is not hard to verify that

$$z_s(v) = \binom{N-1}{s-1} (1 - F(v))^{s-1} F^p(v),$$

where  $p = N - s$ . Indeed, in an efficient equilibrium, the bidder with the  $s$ -th highest valuation must be assigned to the  $s$ -th highest position. Therefore an advertiser with valuation  $v$  is assigned to position  $s$  if and only if  $s-1$  bidders have a higher valuation and  $p$  have a lower valuation.

For a rank-by-bid auction, [Gomes and Sweeney \(2014\)](#) showed the following results.

**Theorem 1** ([Gomes and Sweeney \(2014\)](#)). *A GSP auction has a unique efficient symmetric Bayes-Nash equilibrium with bidding strategy  $\beta$  if and only if  $\beta$  is strictly increasing and satisfies the following integral equation:*

$$\begin{aligned} & \sum_{s=1}^S c_s \int_0^v \frac{dz_s(t)}{dt} t dt \\ &= \sum_{s=1}^S c_s \binom{N-1}{s-1} (1 - F(v))^{s-1} \int_0^v \beta(t) p F^{p-1}(t) f(t) dt. \end{aligned} \quad (2)$$

Furthermore, the optimal reserve price  $r^*$  satisfies

$$r^* = \frac{1 - F(r^*)}{f(r^*)}. \quad (3)$$

The authors show that, if the click probabilities  $c_s$  are sufficiently diverse, then,  $\beta$  is guaranteed to be strictly increasing. When ranking is done by revenue, Sun et al. (2014) gave the following theorem.

**Theorem 2** (Sun et al. (2014)). *Let  $\beta$  be defined by the previous theorem. If advertisers bid in a Bayes-Nash equilibrium then  $b_i = \frac{\beta(v_i)}{e_i}$ . Moreover, the optimal reserve price vector  $\mathbf{r}^*$  is given by  $r_i^* = \frac{\bar{r}}{e_i}$  where  $\bar{r}$  satisfies equation (3).*

We are now able to present the foundation of our first algorithm. Instead of assuming that the bids constitute an SNE as in (Sun et al., 2014), we follow the ideas of Guerre et al. (2000) and infer the scores  $s_i$  only from observables  $b_i$ . Our result is presented for the rank-by-bid GSP auction but an extension to the rank-by-revenue mechanism is trivial.

**Lemma 1.** *Let  $v_1, \dots, v_n$  be an i.i.d. sample of valuations from distribution  $F$  and let  $b_i = \beta(v_i)$  be the bid played at equilibrium. Then the random variables  $b_i$  are i.i.d. with distribution  $G(b) = F(\beta^{-1}(b))$  and density  $g(b) = \frac{f(\beta^{-1}(b))}{\beta'(\beta^{-1}(b))}$ . Furthermore,*

$$\begin{aligned} v_i &= \beta^{-1}(b_i) \\ &= \frac{\sum_{s=1}^S c_s \binom{N-1}{s-1} (1-G(b_i))^{s-1} b_i p G(b_i)^{p-1} g(b_i)}{\sum_{s=1}^S c_s \binom{N-1}{s-1} \frac{d\bar{z}}{db}(b_i)} \\ &\quad - \frac{\sum_{s=1}^S c_s (s-1) (1-G(b_i))^{s-2} g(b_i) \int_0^{b_i} p G(u)^{p-1} u g(u) du}{\sum_{s=1}^S c_s \binom{N-1}{s-1} \frac{d\bar{z}}{db}(b_i)}, \end{aligned} \quad (4)$$

where  $\bar{z}_s(b) := z_s(\beta^{-1}(b))$  and is given by  $\binom{N-1}{s-1} (1-G(b))^{s-1} G(b)^{p-1}$ .

*Proof.* By definition,  $b_i = \beta(v_i)$  is a function of only  $v_i$ . Since  $\beta$  does not depend on the other samples either, it follows that  $(b_i)_{i=1}^N$  must be an i.i.d. sample. Using the fact that  $\beta$  is a strictly increasing function we also have  $G(b) = P(b_i \leq b) = P(v_i \leq \beta^{-1}(b)) = F(\beta^{-1}(b))$  and a simple application of the chain rule gives us the expression for the density  $g(b)$ . To prove the second statement observe that by the change of variable  $v = \beta^{-1}(b)$ , the right-hand side of (2) is equal to

$$\begin{aligned} &\sum_{s=1}^S \binom{N-1}{s-1} (1-G(b))^{s-1} \int_0^{\beta^{-1}(b)} p \beta(t) F^{p-1}(t) f(t) dt \\ &= \sum_{s=1}^S \binom{N-1}{s-1} (1-G(b))^{s-1} \int_0^b p u G(u)^{p-1} g(u) du. \end{aligned}$$

The last equality follows by the change of variable  $t = \beta(u)$  and from the fact that  $g(b) = \frac{f(\beta^{-1}(b))}{\beta'(\beta^{-1}(b))}$ . The same change of variables applied to the left-hand side of (2)

yields the following integral equation:

$$\begin{aligned} &\sum_{s=1}^S \binom{N-1}{s-1} \int_0^b \beta^{-1}(u) \frac{d\bar{z}}{du}(u) du \\ &= \sum_{s=1}^S \binom{N-1}{s-1} (1-G(b))^{s-1} \int_0^b u p G(u)^{p-1} g(u) du. \end{aligned}$$

Taking the derivative with respect to  $b$  of both sides of this equation and rearranging terms lead to the desired expression.  $\square$

The previous Lemma shows that we can recover the valuation of an advertiser from its bid. We therefore propose the following algorithm for estimating the value of  $\bar{r}$ .

1. Use the sample  $\mathcal{S}$  to estimate  $G$  and  $g$ .
2. Plug this estimates in (4) to obtain approximate samples from the distribution  $F$ .
3. Use the approximate samples to find estimates  $\hat{f}$  and  $\hat{F}$  of the valuations density and cumulative distribution functions respectively.
4. Use  $\hat{F}$  and  $\hat{f}$  to estimate  $\bar{r}$ .

In order to avoid the use of parametric methods, a kernel density estimation algorithm can be used to estimate  $g$  and  $f$ . While this algorithm addresses both drawbacks of the algorithm proposed by Sun et al. (2014), it can be shown (Guerre et al., 2000)[Theorem 2] that if  $f$  is  $R$  times continuously differentiable, then, after seeing  $n$  samples,  $\|f - \hat{f}\|_\infty$  is in  $\Omega\left(\frac{1}{n^{R/(2R+3)}}\right)$  independently of the algorithm used to estimate  $f$ . In particular, note that for  $R = 1$  the rate is in  $\Omega\left(\frac{1}{n^{1/4}}\right)$ . This unfavorable rate of convergence can be attributed to the fact that a two-step estimation algorithm is being used (estimation of  $g$  and  $f$ ). But, even with access to bidder valuations, the rate can only be improved to  $\Omega\left(\frac{1}{n^{R/(2R+1)}}\right)$  (Guerre et al., 2000). Furthermore, a small error in the estimation of  $f$  affects the denominator of the equation defining  $\bar{r}$  and can result in a large error on the estimate of  $\bar{r}$ .

## 4.2 DISCRIMINATIVE ALGORITHM

In view of the problems associated with density estimation, we propose to use empirical risk minimization to find an approximation to the optimal reserve price. In particular, we are interested in solving the following optimization problem:

$$\min_{\mathbf{r} \in [0,1]^N} \sum_{i=1}^n L(\mathbf{r}, \mathbf{b}_i). \quad (5)$$

We first show that, when bidders play in equilibrium, the optimization problem (1) can be considerably simplified.

**Proposition 1.** *If advertisers play a symmetric Bayes-Nash equilibrium then*

$$\min_{\mathbf{r} \in [0,1]^N} \mathbb{E}_{\mathbf{b}}[L(\mathbf{r}, \mathbf{b})] = \min_{r \in [0,1]} \mathbb{E}_{\mathbf{b}}[\tilde{L}(r, \mathbf{b})],$$

Figure 1: Plot of the loss function  $L_{i,s}$ . Notice that the loss in fact resembles a broken “V”.

where  $\tilde{q}_i := \tilde{q}_i(b_i) = e_i b_i$  and

$$\tilde{L}(r, \mathbf{b}) = - \sum_{s=1}^S \frac{c_s}{e^{(s)}} \left( \tilde{q}^{(s+1)} \mathbb{1}_{\tilde{q}^{(s+1)} \geq r} + r \mathbb{1}_{\tilde{q}^{(s+1)} < r \leq \tilde{q}^{(s)}} \right).$$

*Proof.* Since advertisers play a symmetric Bayes-Nash equilibrium, the optimal reserve price vector  $\mathbf{r}^*$  is of the form  $r_i^* = \frac{r}{e_i}$ . Therefore, letting  $D = \{\mathbf{r} | r_i = \frac{r}{e_i}, r \in [0, 1]\}$  we have  $\min_{\mathbf{r} \in [0, 1]^N} \mathbb{E}_{\mathbf{b}}[L(\mathbf{r}, \mathbf{b})] = \min_{\mathbf{r} \in D} \mathbb{E}_{\mathbf{b}}[L(\mathbf{r}, \mathbf{b})]$ . Furthermore, when restricted to  $D$ , the objective function  $L$  is given by

$$- \sum_{s=1}^S \frac{c_s}{e^{(s)}} \left( q^{(s+1)} \mathbb{1}_{q^{(s+1)} \geq r} + r \mathbb{1}_{q^{(s+1)} < r \leq q^{(s)}} \right).$$

Thus, we are left with showing that replacing  $q^{(s)}$  with  $\tilde{q}^{(s)}$  in this expression does not affect its value. Let  $r \geq 0$ , since  $q_i = \tilde{q}_i \mathbb{1}_{\tilde{q}_i \geq r}$ , in general the equality  $q^{(s)} = \tilde{q}^{(s)}$  does not hold. Nevertheless, if  $s_0$  denotes the largest index less than or equal to  $S$  satisfying  $q^{(s_0)} > 0$ , then  $\tilde{q}^{(s)} \geq r$  for all  $s \leq s_0$  and  $q^{(s)} = \tilde{q}^{(s)}$ . On the other hand, for  $S \geq s > s_0$ ,  $\mathbb{1}_{q^{(s)} \geq r} = \mathbb{1}_{\tilde{q}^{(s)} \geq r} = 0$ . Thus,

$$\begin{aligned} & \sum_{s=1}^S \frac{c_s}{e^{(s)}} \left( q^{(s+1)} \mathbb{1}_{q^{(s+1)} \geq r} + r \mathbb{1}_{q^{(s+1)} < r \leq q^{(s)}} \right) \\ &= \sum_{s=1}^{s_0} \frac{c_s}{e^{(s)}} \left( q^{(s+1)} \mathbb{1}_{q^{(s+1)} \geq r} + r \mathbb{1}_{q^{(s+1)} < r \leq q^{(s)}} \right) \\ &= \sum_{s=1}^{s_0} \frac{c_s}{e^{(s)}} \left( \tilde{q}^{(s+1)} \mathbb{1}_{\tilde{q}^{(s+1)} \geq r} + r \mathbb{1}_{\tilde{q}^{(s+1)} < r \leq \tilde{q}^{(s)}} \right) \\ &= -\tilde{L}(r, \mathbf{b}), \end{aligned}$$

which completes the proof.  $\square$

In view of this proposition, we can replace the challenging problem of solving an optimization problem in  $\mathbb{R}^N$  with solving the following simpler empirical risk minimization problem

$$\min_{r \in [0, 1]} \sum_{i=1}^n \tilde{L}(r, \mathbf{b}_i) = \min_{r \in [0, 1]} \sum_{i=1}^n \sum_{s=1}^S L_{s,i}(r, \tilde{q}^{(s)}, \tilde{q}^{(s+1)}), \quad (6)$$

---

### Algorithm 1 Minimization algorithm

---

**Require:** Scores  $(\tilde{q}_i^{(s)})$ ,  $1 \leq n, 1 \leq s \leq S$ .

- 1: Define  $(p_{is}^{(1)}, p_{is}^{(2)}) = (\tilde{q}_i^{(s)}, \tilde{q}_i^{(s+1)})$ ;  $m = nS$ ;
  - 2:  $\mathcal{N} := \bigcup_{i=1}^n \bigcup_{s=1}^S \{p_{is}^{(1)}, p_{is}^{(2)}\}$ ;
  - 3:  $(n_1, \dots, n_{2m}) = \mathbf{Sort}(\mathcal{N})$ ;
  - 4: Set  $\mathbf{d}_i := (d_1, d_2) = \mathbf{0}$
  - 5: Set  $d_1 = - \sum_{i=1}^n \sum_{s=1}^S \frac{c_s}{e_i} p_{is}^{(2)}$ ;
  - 6: Set  $r^* = -1$  and  $L^* = \infty$
  - 7: **for**  $j = 2, \dots, 2m$  **do**
  - 8:   **if**  $n_{j-1} = p_{is}^{(2)}$  **then**
  - 9:      $d_1 = d_1 + \frac{c_s}{e_i} p_{is}^{(2)}$ ;  $d_2 = d_2 - \frac{c_s}{e_i}$ ;
  - 10:   **else if**  $n_{j-1} = p_{is}^{(1)}$  **then**
  - 11:      $d_2 = d_2 + \frac{c_s}{e_s}$
  - 12:   **end if**
  - 13:    $L = d_1 - n_j d_2$ ;
  - 14:   **if**  $L < L^*$  **then**
  - 15:      $L^* = L$ ;  $r^* = n_j$ ;
  - 16:   **end if**
  - 17: **end for**
  - 18: **return**  $r^*$ ;
- 

where  $L_{s,i}(r, \tilde{q}^{(s)}, \tilde{q}^{(s+1)}) := - \frac{c_s}{e^{(s)}} (\tilde{q}_i^{(s+1)} \mathbb{1}_{\tilde{q}_i^{(s+1)} \geq r} - r \mathbb{1}_{\tilde{q}_i^{(s+1)} < r \leq \tilde{q}_i^{(s)}})$ . In order to efficiently minimize this highly non-convex function, we draw upon the work of [Mohri and Medina \(2014\)](#) on minimization of sums of  $v$ -functions.

**Definition 1.** A function  $V: \mathbb{R}^3 \rightarrow \mathbb{R}$  is a  $v$ -function if it admits the following form:

$$\begin{aligned} & V(r, q_1, q_2) \\ &= -a^{(1)} \mathbb{1}_{r \leq q_2} - a^{(2)} r \mathbb{1}_{q_2 < r \leq q_1} + \left[ \frac{r}{\eta} - a^{(3)} \right] \mathbb{1}_{q_1 < r < (1+\eta)q_1}, \end{aligned}$$

with  $0 \leq a^{(1)}, a^{(2)}, a^{(3)}, \eta \leq \infty$  constants satisfying  $a^{(1)} = a^{(2)} q_2$ ,  $-a^{(2)} q_1 \mathbb{1}_{\eta > 0} = \left( \frac{1}{\eta} q_1 - a^{(3)} \right) \mathbb{1}_{\eta > 0}$ . Under the convention that  $0 \cdot \infty = 0$ .

As suggested by their name, these functions admit a characteristic “V shape”. It is clear from Figure 1 that  $L_{s,i}$  is a  $v$ -function with  $a^{(1)} = \frac{c_s}{e^{(s)}} \tilde{q}_i^{(s+1)}$ ,  $a^{(2)} = \frac{c_s}{e^{(s)}}$  and  $\eta = 0$ . Thus, we can apply the optimization algorithm given by [Mohri and Medina \(2014\)](#) to minimize (6) in  $O(nS \log nS)$  time. Algorithm 1 gives the pseudocode of that the adaptation of this general algorithm to our problem. A proof of the correctness of this algorithm can be found in [\(Mohri and Medina, 2014\)](#).

We conclude this section by presenting learning guarantees for our algorithm. Our bounds are given in terms of the Rademacher complexity and the VC-dimension.

**Definition 2.** Let  $\mathcal{X}$  be a set and let  $G := \{g: \mathcal{X} \rightarrow \mathbb{R}\}$  be a family of functions. Given a sample  $\mathcal{S} = (x_1, \dots, x_n) \in$

$\mathcal{X}$ , the empirical Rademacher complexity of  $G$  is defined by

$$\widehat{\mathfrak{R}}_S(G) = \frac{1}{n} \mathbb{E}_\sigma \left[ \sup_{g \in G} \frac{1}{n} \sum_{i=1}^n \sigma_i g(x_i) \right],$$

where  $\sigma_i$ s are independent random variables distributed uniformly over the set  $\{-1, 1\}$ .

**Proposition 2.** Let  $m = \min_i e_i > 0$  and  $\mathfrak{M} = \sum_{s=1}^S c_s$ . Then, for any  $\delta > 0$ , with probability at least  $1 - \delta$  over the draw of a sample  $\mathcal{S}$  of size  $n$ , each of the following inequalities holds for all  $r \in [0, 1]$ :

$$\mathbb{E}[\widetilde{L}(r, \mathbf{b})] \leq \frac{1}{n} \sum_{i=1}^n \widetilde{L}(r, \mathbf{b}_i) + C(\mathfrak{M}, m, n, \delta) \quad (7)$$

$$\frac{1}{n} \sum_{i=1}^n \widetilde{L}(r, \mathbf{b}_i) \leq \mathbb{E}[\widetilde{L}(r, \mathbf{b})] + C(\mathfrak{M}, m, n, \delta), \quad (8)$$

where  $C(\mathfrak{M}, m, n, \delta) = \frac{1}{\sqrt{n}} + \sqrt{\frac{\log(en)}{n}} + \sqrt{\frac{\mathfrak{M} \log(1/\delta)}{2mn}}$ .

*Proof.* Let  $\Psi: S \mapsto \sup_{r \in [0,1]} \frac{1}{n} \sum_{i=1}^n \widetilde{L}(r, \mathbf{b}_i) - \mathbb{E}[\widetilde{L}(r, \mathbf{b})]$ . Let  $\mathcal{S}^i$  be a sample obtained from  $\mathcal{S}$  by replacing  $\mathbf{b}_i$  with  $\mathbf{b}'_i$ . It is not hard to verify that  $|\Psi(\mathcal{S}) - \Psi(\mathcal{S}^i)| \leq \frac{\mathfrak{M}}{nm}$ . Thus, it follows from a standard learning bound that, with probability at least  $1 - \delta$ ,

$$\mathbb{E}[\widetilde{L}(r, \mathbf{b})] \leq \frac{1}{n} \sum_{i=1}^n \widetilde{L}(r, \mathbf{b}_i) + \widehat{\mathfrak{R}}_S(\mathcal{R}) + \sqrt{\frac{\mathfrak{M} \log(1/\delta)}{2mn}},$$

where  $\mathcal{R} = \{\bar{L}_r : \mathbf{b} \mapsto \widetilde{L}(r, \mathbf{b}) | r \in [0, 1]\}$ . We proceed to bound the empirical Rademacher complexity of the class  $\mathcal{R}$ . For  $q_1 > q_2 \geq 0$  let  $\bar{L}(r, q_1, q_2) = q_2 \mathbb{1}_{q_2 > r} + r \mathbb{1}_{q_1 \geq r \geq q_2}$ . By definition of the Rademacher complexity we can write

$$\begin{aligned} \widehat{\mathfrak{R}}_S(\mathcal{R}) &= \frac{1}{n} \mathbb{E}_\sigma \left[ \sup_{r \in [0,1]} \sum_{i=1}^n \sigma_i \bar{L}_r(\mathbf{b}_i) \right] \\ &= \frac{1}{n} \mathbb{E}_\sigma \left[ \sup_{r \in [0,1]} \sum_{i=1}^n \sigma_i \sum_{s=1}^S \frac{c_s}{e_s} \bar{L}(r, \tilde{q}_i^{(s)}, \tilde{q}_i^{(s+1)}) \right] \\ &\leq \frac{1}{n} \mathbb{E}_\sigma \left[ \sum_{s=1}^S \sup_{r \in [0,1]} \sum_{i=1}^n \sigma_i \psi_s(\bar{L}(r, \tilde{q}_i^{(s)}, \tilde{q}_i^{(s+1)})) \right], \end{aligned}$$

where  $\psi_s$  is the  $\frac{c_s}{m}$ -Lipschitz function mapping  $x \mapsto \frac{c_s}{e^{(s)}} x$ . Therefore, by Talagrand's contraction lemma (Ledoux and Talagrand, 2011), the last term is bounded by

$$\sum_{s=1}^S \frac{c_s}{nm} \mathbb{E}_\sigma \sup_{r \in [0,1]} \sum_{i=1}^n \sigma_i \bar{L}(r, \tilde{q}_i^{(s)}, \tilde{q}_i^{(s+1)}) = \sum_{s=1}^S \frac{c_s}{m} \widehat{\mathfrak{R}}_{\mathcal{S}_s}(\widetilde{\mathcal{R}}),$$

where  $\mathcal{S}_s = ((\tilde{q}_1^{(s)}, \tilde{q}_1^{(s+1)}), \dots, (\tilde{q}_n^{(s)}, \tilde{q}_n^{(s+1)}))$  and  $\widetilde{\mathcal{R}} := \{\bar{L}(r, \cdot, \cdot) | r \in [0, 1]\}$ . The loss  $\bar{L}(r, \tilde{q}^{(s)}, \tilde{q}^{(s+1)})$  in fact evaluates to the negative revenue of a second-price auction

with highest bid  $\tilde{q}^{(s)}$  and second highest bid  $\tilde{q}^{(s+1)}$  (Mohri and Medina, 2014). Therefore, by Propositions 9 and 10 of Mohri and Medina (2014) we can write

$$\begin{aligned} \widehat{\mathfrak{R}}_{\mathcal{S}_s}(\widetilde{\mathcal{R}}) &\leq \frac{1}{n} \mathbb{E}_\sigma \left[ \sup_{r \in [0,1]} \sum_{i=1}^n r \sigma_i \right] + \sqrt{\frac{2 \log en}{n}} \\ &\leq \left( \frac{1}{\sqrt{n}} + \sqrt{\frac{2 \log en}{n}} \right), \end{aligned}$$

which concludes the proof.  $\square$

**Corollary 1.** Under the hypotheses of Proposition 2, let  $\hat{r}$  denote the empirical minimizer and  $r^*$  the minimizer of the expected loss. Then, for any  $\delta > 0$ , with probability at least  $1 - \delta$ , the following inequality holds:

$$\mathbb{E}[\widetilde{L}(\hat{r}, \mathbf{b})] - \mathbb{E}[\widetilde{L}(r^*, \mathbf{b})] \leq 2C\left(\mathfrak{M}, m, n, \frac{\delta}{2}\right).$$

*Proof.* By the union bound, (7) and (8) hold simultaneously with probability at least  $1 - \delta$  if  $\delta$  is replaced by  $\delta/2$  in those expression. Adding both inequalities and using the fact that  $\hat{r}$  is an empirical minimizer yields the result.  $\square$

It is worth noting that our algorithm is well defined whether or not the buyers bid in equilibrium. Indeed, the algorithm consists of the minimization over  $r$  of an observable quantity. While we can guarantee convergence to a solution of (1) only when buyers play a symmetric BNE, our algorithm will still find an approximate solution to

$$\min_{r \in [0,1]} \mathbb{E}_{\mathbf{b}}[L(r, \mathbf{b})],$$

which remains a quantity of interest that can be close to (1) if buyers are close to the equilibrium.

## 5 CONVERGENCE OF EMPIRICAL EQUILIBRIA

A crucial assumption in the study of GSP auctions, including this work, is that advertisers bid in a Bayes-Nash equilibrium (Lucier et al., 2012; Sun et al., 2014). This assumption is partially justified by the fact that advertisers can infer the underlying distribution  $F$  using as observations the outcomes of the past repeated auctions and can thereby implement an efficient equilibrium.

In this section, we provide a stronger theoretical justification in support of this assumption: we quantify the difference between the bidding function calculated using observed empirical distributions and the true symmetric bidding function in equilibria. For the sake of notation simplicity, we will consider only the rank-by-bid GSP auction.

Let  $\mathcal{S}_v = (v_1, \dots, v_n)$  be an i.i.d. sample of values drawn from a continuous distribution  $F$  with density function  $f$ .

Assume without loss of generality that  $v_1 \leq \dots \leq v_n$  and let  $\mathbf{v}$  denote the vector defined by  $\mathbf{v}_i = v_i$ . Let  $\widehat{F}$  denote the empirical distribution function induced by  $\mathcal{S}_v$  and let  $\mathbf{F} \in \mathbb{R}^n$  and  $\mathbf{G} \in \mathbb{R}^n$  be defined by  $\mathbf{F}_i = \widehat{F}(v_i) = i/n$  and  $\mathbf{G}_i = 1 - \mathbf{F}_i$ .

We consider a *discrete* GSP auction where the advertiser's valuations are i.i.d. samples drawn from a distribution  $\widehat{F}$ . In the event where two or more advertisers admit the same valuation, ties are broken randomly. Denote by  $\widehat{\beta}$  the bidding function for this auction in equilibrium (when it exists). We are interested in characterizing  $\widehat{\beta}$  and in providing guarantees on the convergence of  $\widehat{\beta}$  to  $\beta$  as the sample size increases.

We first introduce the notation used throughout this section.

**Definition 3.** Given a vector  $\mathbf{F} \in \mathbb{R}^n$ , the backwards difference operator  $\Delta : \mathbb{R}^n \rightarrow \mathbb{R}^n$  is defined as:

$$\Delta \mathbf{F}_i = \mathbf{F}_i - \mathbf{F}_{i-1},$$

for  $i > 1$  and  $\Delta \mathbf{F}_1 = \mathbf{F}_1$ .

We will denote  $\Delta \Delta \mathbf{F}_i$  by  $\Delta^2 \mathbf{F}_i$ . Given any  $k \in \mathbb{N}$  and a vector  $\mathbf{F}$ , the vector  $\mathbf{F}^k$  is defined as  $\mathbf{F}_i^k = (\mathbf{F}_i)^k$ . Let us now define the discrete analog of the function  $z_s$  that quantifies the probability of winning slot  $s$ .

**Proposition 3.** In a symmetric efficient equilibrium of the discrete GSP, the probability  $\widehat{z}_s(v)$  that an advertiser with valuation  $v$  is assigned to slot  $s$  is given by

$$\begin{aligned} \widehat{z}_s(v) &= \sum_{j=0}^{N-s} \sum_{k=0}^{s-1} \binom{N-1}{j, k, N-1-j-k} \frac{\mathbf{F}_{i-1}^j \mathbf{G}_i^k}{(N-j-k)n^{N-1-j-k}}, \end{aligned}$$

if  $v = v_i$  and otherwise by

$$\widehat{z}_s(v) = \binom{N-1}{s-1} \lim_{v' \rightarrow v^-} \widehat{F}(v')^p (1 - \widehat{F}(v))^{s-1} =: \widehat{z}_s^-(v),$$

where  $p = N - s$ .

In particular, notice that  $\widehat{z}_s^-(v_i)$  admits the simple expression

$$\widehat{z}_s^-(v_i) = \binom{N-1}{s-1} \mathbf{F}_{i-1}^p \mathbf{G}_{i-1}^{s-1},$$

which is the discrete version of the function  $z_s$ . On the other hand, even though  $\widehat{z}_s(v_i)$  does not admit a closed-form, it is not hard to show that

$$\widehat{z}_s(v_i) = \binom{N-1}{s-1} \mathbf{F}_{i-1}^p \mathbf{G}_i^{s-1} + O\left(\frac{1}{n}\right). \quad (9)$$

Which again can be thought of as a discrete version of  $z_s$ . The proof of this and all other propositions in this section

are deferred to the Appendix. Let us now define the lower triangular matrix  $\mathbf{M}(s)$  by:

$$\mathbf{M}_{ij}(s) = -\binom{N-1}{s-1} \frac{n \Delta \mathbf{F}_j^p \Delta \mathbf{G}_i^s}{s},$$

for  $i > j$  and

$$\mathbf{M}_{ii}(s) = \sum_{j=0}^{N-s-1} \sum_{k=0}^{s-1} \binom{N-1}{j, k, N-1-j-k} \frac{\mathbf{F}_{i-1}^j \mathbf{G}_i^k}{(N-j-k)n^{N-1-j-k}}.$$

**Proposition 4.** If the discrete GSP auction admits a symmetric efficient equilibrium, then its bidding function  $\widehat{\beta}$  satisfies  $\widehat{\beta}(v_i) = \beta_i$ , where  $\beta$  is the solution of the following linear equation.

$$\mathbf{M}\beta = \mathbf{u}, \quad (10)$$

with  $\mathbf{M} = \sum_{s=1}^S c_s \mathbf{M}(s)$  and  $\mathbf{u}_i = \sum_{s=1}^S \left( c_s z_s(v_i) v_i - \sum_{j=1}^i \widehat{z}_s^-(v_j) \Delta \mathbf{v}_j \right)$ .

To gain some insight about the relationship between  $\widehat{\beta}$  and  $\beta$ , we compare equations (10) and (2). An integration by parts of the right-hand side of (2) and the change of variable  $G(v) = 1 - F(v)$  show that  $\beta$  satisfies

$$\begin{aligned} \sum_{s=1}^S c_s v z_s(v) - \int_0^v \frac{dz_s(t)}{dt} t dt &= \sum_{s=1}^S c_s \binom{N-1}{s-1} G(v)^{s-1} \int_0^v \beta(t) dF^p. \end{aligned} \quad (11)$$

On the other hand, equation (10) implies that for all  $i$

$$\mathbf{u}_i = \sum_{s=1}^S c_s \left[ \mathbf{M}_{ii}(s) \beta_i - \binom{N-1}{s-1} \frac{n \Delta \mathbf{G}_i^s}{s} \sum_{j=1}^{i-1} \Delta \mathbf{F}_j^p \beta_j \right]. \quad (12)$$

Moreover, by Lemma 2 and Proposition 10 in the Appendix, the equalities  $-\frac{n \Delta \mathbf{G}_i^s}{s} = \mathbf{G}_i^{s-1} + O\left(\frac{1}{n}\right)$  and

$$\mathbf{M}_{ii}(s) = \frac{1}{2n} \binom{N-1}{s-1} p \mathbf{F}_{i-1}^{p-1} \mathbf{G}_i^{s-1} + O\left(\frac{1}{n^2}\right),$$

hold. Thus, equation (12) resembles a numerical scheme for solving (11) where the integral on the right-hand side is approximated by the trapezoidal rule. Equation (11) is in fact a Volterra equation of the first kind with kernel

$$K(t, v) = \sum_{s=1}^S \binom{N-1}{s-1} G(v)^{s-1} p F^{p-1}(t).$$

Therefore, we could benefit from the extensive literature on the convergence analysis of numerical schemes for this type of equations (Baker, 1977; Kress et al., 1989; Linz, 1985). However, equations of the first kind are in general

Figure 2: (a) Empirical verification of Assumption 2. The blue line corresponds to the quantity  $\max_i \Delta\beta_i$ . In red we plot the desired upper bound for  $C = 1/2$ .

ill-posed problems (Kress et al., 1989), that is small perturbations on the equation can produce large errors on the solution. When the kernel  $K$  satisfies  $\min_{t \in [0,1]} K(t, t) > 0$ , there exists a standard technique to transform an equation of the first kind to an equation of the second kind, which is a well posed problem. Thus, making the convergence analysis for these types of problems much simpler. The kernel function appearing in (11) does not satisfy this property and therefore these results are not applicable to our scenario. To the best of our knowledge, there exists no quadrature method for solving Volterra equations of the first kind with vanishing kernel.

In addition to dealing with an uncommon integral equation, we need to address the problem that the elements of (10) are not exact evaluations of the functions defining (11) but rather stochastic approximations of these functions. Finally, the grid points used for the numerical approximation are also random.

In order to prove convergence of the function  $\hat{\beta}$  to  $\beta$  we will make the following assumptions

**Assumption 1.** *There exists a constant  $c > 0$  such that  $f(x) > c$  for all  $x \in [0, 1]$ .*

This assumption is needed to ensure that the difference between consecutive samples  $v_i - v_{i-1}$  goes to 0 as  $n \rightarrow \infty$ , which is a necessary condition for the convergence of any numerical scheme.

**Assumption 2.** *The solution  $\beta$  of (10) satisfies  $v_i, \beta_i \geq 0$  for all  $i$  and  $\max_{i \in 1, \dots, n} \Delta\beta_i \leq \frac{C}{\sqrt{n}}$ , for some universal constant  $C$ .*

Since  $\beta_i$  is a bidding strategy in equilibrium, it is reasonable to expect that  $v_i \geq \beta_i \geq 0$ . On the other hand, the assumption on  $\Delta\beta_i$  is related to the smoothness of the solution. If the function  $\beta$  is smooth, we should expect the approximation  $\hat{\beta}$  to be smooth too. Both assumptions can in practice be verified empirically, Figure 2 depicts the quantity  $\max_{i \in 1, \dots, n} \Delta\beta_i$  as a function of the sample size  $n$ .

**Assumption 3.** *The solution  $\beta$  to (2) is twice continuously differentiable.*

Figure 3: Approximation of the empirical bidding function  $\hat{\beta}$  to the true solution  $\beta$ . The true solution is shown in red and the shaded region represents the confidence interval of  $\hat{\beta}$  when simulating the discrete GSP 10 times with a sample of size 200. Where  $N = 3$ ,  $S = 2$ ,  $c_1 = 1$ ,  $c_2 = 0.5$  and bids were sampled uniformly from  $[0, 1]$

This is satisfied if for instance the distribution function  $F$  is twice continuously differentiable. We can now present our main result.

**Theorem 3.** *If Assumptions 1, 2 and 3 are satisfied, then, for any  $\delta > 0$ , with probability at least  $1 - \delta$  over the draw of a sample of size  $n$ , the following bound holds for all  $i \in [1, n]$ :*

$$|\hat{\beta}(v_i) - \beta(v_i)| \leq e^C \left[ \frac{\log(\frac{2}{\delta})^{\frac{N}{2}}}{\sqrt{n}} q\left(n, \frac{2}{\delta}\right)^3 + \frac{Cq(n, \frac{2}{\delta})}{n^{3/2}} \right].$$

where  $q(n, \delta) = \frac{2}{c} \log(nc/2\delta)$  with  $c$  defined in Assumption 1, and where  $C$  is a universal constant.

The proof of this theorem is highly technical, thus, we defer it to Appendix F.

## 6 EXPERIMENTS

Here we present preliminary experiments showing the advantages of our algorithm. We also present empirical evidence showing that the procedure proposed in Sun et al. (2014) to estimate valuations from bids is incorrect. In contrast, our density estimation algorithm correctly recovers valuations from bids in equilibrium.

### 6.1 SETUP

Let  $F_1$  and  $F_2$  denote the distributions of two truncated log-normal random variables with parameters  $\mu_1 = \log(.5)$ ,  $\sigma_1 = .8$  and  $\mu_2 = \log(2)$ ,  $\sigma = .1$ ; the mixture parameter was set to  $1/2$ . Here,  $F_1$  is truncated to have support in  $[0, 1.5]$  and the support of  $F_2 = [0, 2.5]$ . We consider a GSP with  $N = 4$  advertisers with  $S = 3$  slots and position factors  $c_1 = 1$ ,  $c_2 = .45$  and  $c_3 = 1$ . Based on the results of Section 5 we estimate the bidding function  $\beta$  with a sample of 2000 points and we show its plot in Figure 4. We proceed to evaluate the method proposed by Sun et al. (2014) for

Figure 4: Bidding function for our experiments in blue and identity function in red.

recovering advertisers valuations from bids in equilibrium. The assumption made by the authors is that the advertisers play a SNE in which case valuations can be inferred by solving a simple system of inequalities defining the SNE (Varian, 2007). Since the authors do not specify which SNE the advertisers are playing we select the one that solves the SNE conditions with equality.

We generated a sample  $\mathcal{S}$  consisting of  $n = 300$  i.i.d. outcomes of our simulated auction. Since  $N = 4$ , the effective size of this sample is of 1200 points. We generated the outcome bid vectors  $\mathbf{b}_1, \dots, \mathbf{b}_n$  by using the equilibrium bidding function  $\beta$ . Assuming that the bids constitute a SNE we estimated the valuations and Figure 5 shows an histogram of the original sample as well as the histogram of the estimated valuations. It is clear from this figure that this procedure does not accurately recover the distribution of the valuations. By contrast, the histogram of the estimated valuations using our density estimation algorithm is shown in Figure 5(c). The kernel function used by our algorithm was a triangular kernel given by  $K(u) = (1 - |u|)\mathbb{1}_{|u| \leq 1}$ . Following the experimental setup of Guerre et al. (2000) the bandwidth  $h$  was set to  $h = 1.06\hat{\sigma}n^{1/5}$ , where  $\hat{\sigma}$  denotes the standard deviation of the sample of bids.

Finally, we use both our density estimation algorithm and discriminative learning algorithm to infer the optimal value of  $r$ . To test our algorithm we generated a test sample of size  $n = 500$  with the procedure previously described. The results are shown in Table 1.

| Density estimation | Discriminative  |
|--------------------|-----------------|
| $1.42 \pm 0.02$    | $1.85 \pm 0.02$ |

Table 1: Mean revenue for our two algorithms.

## 7 CONCLUSION

We proposed and analyzed two algorithms for learning optimal reserve prices for generalized second price auctions. Our first algorithm is based on density estimation and therefore suffers from the standard problems associated with this family of algorithms. Furthermore, this algorithm is only well defined when bidders play in equilibrium. Our second algorithm is novel and is based on learning theory

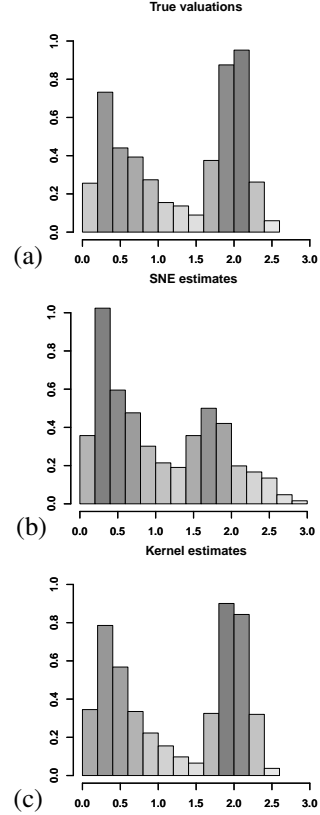

Figure 5: Comparison of methods for estimating valuations from bids. (a) Histogram of true valuations. (b) Valuations estimated under the SNE assumption. (c) Density estimation algorithm.

guarantees. We show that the algorithm admits an efficient  $O(nS \log(nS))$  implementation. Furthermore, our theoretical guarantees are more favorable than those presented for the previous algorithm of Sun et al. (2014). Moreover, even though it is necessary for advertisers to play in equilibrium for our algorithm to converge to optimality, when bidders do not play an equilibrium, our algorithm is still well defined and minimizes a quantity of interest albeit over a smaller set. We also presented preliminary experimental results showing the advantages of our algorithm. To our knowledge, this is the first attempt to apply learning algorithms to the problem of reserve price selection in GSP auctions. We believe that the use of learning algorithms in revenue optimization is crucial and that this work may preface a rich research agenda including extensions of this work to a general learning setup where auctions and advertisers are represented by features. Additionally, in our analysis, we considered two different ranking rules. It would be interesting to combine the algorithm of Zhu et al. (2009) with this work to learn both a ranking rule and an optimal reserve price. Finally, we provided the first analysis of convergence of bidding functions in an empirical equilibrium to the true bidding function. This result on its own is of great importance as it justifies the common assumption of advertisers playing in a Bayes-Nash equilibrium.

## Abstract

The identification of conditional dependences in longitudinal data is provided through structure learning of dynamic Bayesian networks (DBN). Several methods for DBN learning are concerned with identifying inter-slice dependences, but often disregard the intra-slice connectivity. We propose an algorithm that jointly finds the optimal inter and intra time-slice connectivity in a transition network. The search space is constrained to a class of networks designated by tree-augmented DBN, leading to polynomial time complexity. We assess the effectiveness of the algorithm on simulated data and compare the results to those obtained by a state of the art DBN learning implementation, showing that the proposed algorithm performs very well throughout the different experiments. Further experimental validation is made on real data, by identifying non-stationary gene regulatory networks of *Drosophila melanogaster*.

## 1 INTRODUCTION

Longitudinal data, also known as multivariate time series in the machine learning community, are obtained by conducting repeated measurements on a set of individuals. They arise in several contexts, such as biomedical and clinical studies, socio-economics and meteorology, and provide an opportunity for studying changes over time. In multivariate longitudinal data, each measurement or observation is a vector of variables, whose joint evolution is subject of analysis.

Multivariate longitudinal data can be modelled as a set of  $n$ -dimensional observations of a stochastic process over  $T$  sequential instants of time. The set of observations is expressed as  $\{\mathbf{x}^i[t]\}_{i \in \mathcal{I}, t \in \mathcal{T}}$ , where  $\mathcal{I}$  is the set of individuals being measured and  $\mathcal{T}$  is the set of time indices. Thus,

$\mathbf{x}^i[t] = (x_1^i[t], \dots, x_n^i[t]) \in \mathbb{R}^n$  is a single observation of  $n$  features, made at time  $t$  and referring to the individual  $i$ .

Observations are assumed to result from independent samples of a sequence of probability distributions  $\{\mathbb{P}_{\theta[t]}\}_{t \in \mathcal{T}}$ . While these distributions may be time-variant, they are considered constant across different individuals observed at the same time, such that  $\mathbf{x}^i[t] \sim \mathbb{P}_{\theta[t]}$  for all  $i \in \mathcal{I}$ . If the observations are also identically distributed over time, that is,  $\theta[t] = \theta$  for all  $t \in \mathcal{T}$ , the process is said to have a stationary or time-invariant distribution (henceforth simply referred to as a stationary process).

The identification of conditional independences in data provides an approximation to estimating the underlying probability distribution (Chow and Liu, 1968). Bayesian networks (BN) are a popular machine learning tool for this purpose, being able to represent complex processes that involve uncertainty. Dynamic Bayesian networks (DBN) extend BN in order to model temporal processes and are usually defined according to strong simplifying assumptions (Friedman et al., 1998; Murphy, 2002). A common premise is to consider the first-order Markov property, which states that attributes in time-slice  $t + 1$  only depend on those in time-slice  $t$ , but not on the past trajectory. Another frequent assumption is to consider a stationary process, which may be adequate in some cases, but does not hold in many interesting scenarios.

### 1.1 RELATED WORK

Methods for learning stationary DBN are essentially simple extensions of those employed to learn BN (Murphy, 2002). A common approach consists in defining a scoring function, which measures a network's goodness of fit to training data, and a search procedure to generate networks (Heckerman et al., 1995). In general, obtaining an optimal network is an NP-hard problem, because the search space is super-exponential in the number of attributes (Chickering et al., 1995).

Unlike the case of BN, however, it was recently shown that learning the inter-slice structure of DBN does not have

to be NP-hard (Dojer, 2006). This new hardness result is due to the relaxation of the acyclicity constraint on the transition network, since the unrolled network is always acyclic. In the same article, the author derived a polynomial complexity bound in the number of variables when using the minimum description length (MDL) or the Bayesian Dirichlet equivalence (BDe) scores. Relying on this result, Vinh et al. (2011b) further proposed a polynomial-time algorithm for learning optimal DBN using the mutual information tests (MIT) score.

While there is plenty of literature regarding the process of learning stationary first-order Markov networks, there are only a few references to learning more general classes of DBN. In fact, it was not until recently that some authors started to relax the standard stationarity assumption underlying graphical models. The following paragraphs present a brief review of such realizations.

The problem of model selection, that is, identifying a system for probabilistic inference that is efficient, accurate and informative is discussed in Bilmes (2000). With the purpose of performing classification, the author proposes a class of models where the conditional independences are determined by the values of certain nodes in the graph, instead of being fixed. This is accomplished by extending hidden Markov models (HMM) to include dependences among observations of different time-slices. The idea of a network whose edges can appear and disappear is further explored by other authors in a temporal context to model non-stationary processes.

An extension of the traditional discrete DBN model is defined in Robinson and Hartemink (2010), where an initial network of dependences and a set of incremental changes on its structure are learnt. The authors assume that the process is piecewise-stationary, having the number and times of the transitions (change points) to be estimated a posteriori. Prior knowledge regarding both the initial structure and the evolutionary behaviour of the network can be incorporated. By considering conjugate Dirichlet priors on the parameters, which are assumed to have a multinomial distribution, the marginal likelihood is computed exactly, resulting in the BDe metric. The authors extend this metric to incorporate the changes introduced by their new model.

The same approach is considered in Dondelinger et al. (2010), but concerning continuous data. The authors also differentiate the penalties for adding and removing edges in a network and allow different nodes to have distinct penalty terms, instead of a single hyperparameter for penalizing disparities between structures.

In more recent work, Grzegorzczak and Husmeier (2012) argue that there should be a trade-off between the often unrealistic stationarity assumption, modelled with constant parameters, and the opposite case of complete parameter independence over time, ignoring the evolutionary aspect

of the process. They acknowledge, however, that the latter case, which is considered in Dondelinger et al. (2010) and Robinson and Hartemink (2010), has the advantage of allowing the computation of the marginal likelihood in closed form. The authors introduce a scheme for coupling the parameters along time-slices, although keeping the network structure fixed.

Regarding undirected graphical models, Kolar et al. (2010) propose two methods for estimating the underlying time-varying networks of a stochastic process. They model each network as a Markov random field (MRF) with binary nodes. The first method assumes that the parameters change smoothly over time whereas the second considers piecewise constant parameters with abrupt changes. In both approaches, the estimator for the parameters is the result of a  $l_1$ -regularized convex optimization problem. These methods, however, only capture pairwise undirected relations between binary variables, resulting in a model which is far from being generally applicable.

## 1.2 OUR APPROACH

The algorithm we propose falls under the search and score paradigm. Many software implementations for learning DBN are concerned with identifying inter-slice dependences, but disregard the intra-slice connectivity or assume it is given by some prior network and kept fixed over time (Dojer et al., 2013; Murphy, 2001; Vinh et al., 2011a). We instead suggest an algorithm that simultaneously learns all these dependences.

As a consequence of considering intra-slice edges in the proposed algorithm, the relaxation of the acyclicity constraint proposed in Dojer (2006) no longer applies, and obtaining an optimal network becomes NP-hard. We approach this problem by limiting the search space to tree-augmented networks, that is, networks whose attributes have at most one parent in the same time-slice. This restriction does not prevent an attribute to have several parents from preceding slices, and also accounts for the algorithm's polynomial time complexity in the number of attributes. Moreover, even though tree structures appear to be a strong constraint, they have been shown to produce very good results in classification tasks, namely within the tree augmented naive Bayes (TAN) method (Friedman et al., 1997).

The remaining of the paper is organized as follows. Section 2 formally defines BN, provides a theoretical overview on learning this class of networks and introduces DBN by extension. Section 3 describes the proposed DBN structure learning algorithm and analyses its time complexity. Section 4 assesses its performance on simulated data and real data. Section 5 presents the conclusions of this work.

## 2 THEORETICAL BACKGROUND

A BN is a graphical representation of a joint probability distribution over a set of random variables (Pearl, 1988). It is defined as a triple  $B = (\mathbf{X}, G, \theta)$ , where:

- $\mathbf{X} = (X_1, \dots, X_n)$  is a random vector. Discrete random variables with a finite domain are considered;
- $G = (\mathbf{X}, E)$  is a directed acyclic graph (DAG) whose nodes are the elements of  $\mathbf{X}$  and edges  $E$  specify conditional dependences between the variables: each  $X_i$  is independent of its non-descendants given its parents  $\mathbf{pa}(X_i)$  in  $G$ ;
- $\theta = \{\theta_{ijk}\}$  is a set of parameters, specifying the local probability distributions of the network via

$$\theta_{ijk} = P_B(X_i = x_{ik} \mid \mathbf{pa}(X_i) = w_{ij}), \quad (1)$$

where  $i \in \{1, \dots, n\}$ ,  $j \in \{1, \dots, q_i\}$  and  $k \in \{1, \dots, r_i\}$ .  $r_i$  is the number of discrete states of  $X_i$ . The set of possible configurations of  $\mathbf{pa}(X_i)$ , i.e., the set of different combinations of values that the parents of  $X_i$  can take, is denoted by  $\{w_{i1}, \dots, w_{iq_i}\}$ , where  $q_i = \prod_{X_j \in \mathbf{pa}(X_i)} r_j$  is the number of all possible configurations.

A BN  $B$  defines a joint probability distribution over  $\mathbf{X}$ :

$$P_B(X_1, \dots, X_n) = \prod_{i=1}^n P_B(X_i \mid \mathbf{pa}(X_i)). \quad (2)$$

The problem of learning a BN, given a dataset comprising instances of  $\mathbf{X}$ , can be stated as finding the structure (DAG) and parameters that best match the training data. When measuring the goodness of fit of a network  $B$  to data  $D$  by means of a scoring function  $\phi$ , learning a BN consists of maximizing  $\phi(B, D)$  over the space of all networks with  $n$  attributes.

A decomposable scoring function can be expressed as a sum of local terms, each depending only on a node and its parents:

$$\phi(B, D) = \sum_{i=1}^n \phi_i(\mathbf{pa}(X_i), D). \quad (3)$$

Decomposability simplifies the process of calculating scores and provides an efficient way of evaluating incremental changes on a network.

The log-likelihood (LL) is a decomposable score which favours networks that are more likely to have generated the data. For a fixed structure  $G$ , assuming an underlying multinomial distribution, the network parameters are determined by maximum-likelihood estimation (MLE):

$$\{\hat{\theta}_{ijk} = \hat{P}_D(X_i = x_{ik} \mid \mathbf{pa}(X_i) = w_{ij}) = \frac{N_{ijk}}{N_{ij}}\} \quad (4)$$

where  $\hat{P}_D$  is the distribution induced by the observed frequency estimates,  $N_{ijk}$  is the number of instances where  $X_i$  takes its  $k$ -th value  $x_{ik}$  and the variables in  $\mathbf{pa}(X_i)$  take their  $j$ -th configuration  $w_{ij}$ , and  $N_{ij}$  is the number of instances where the variables in  $\mathbf{pa}(X_i)$  take their  $j$ -th configuration  $w_{ij}$  notwithstanding the value of  $X_i$ . Since the parameters are unambiguously found for a fixed network structure, the LL criterion depends only on the network  $G$ . Taking into account Eq. (2), and assuming that instances of  $D$  are independent and identically distributed (i.i.d.), the LL scoring function is expressed (Heckerman et al., 1995) as

$$\begin{aligned} \phi_{LL}(B, D) &= \log P(D \mid B) \\ &= \sum_{i=1}^n \sum_{j=1}^{q_i} \sum_{k=1}^{r_i} N_{ijk} \log \frac{N_{ijk}}{N_{ij}}. \end{aligned} \quad (5)$$

The minimum description length (MDL) score is an extension of the LL criterion, including a term for penalizing complex structures:

$$\phi_{MDL}(B, D) = \phi_{LL}(B, D) - \frac{1}{2} \log(N) |B|, \quad (6)$$

where  $N$  is the number of samples in  $D$  and  $|B|$  denotes the number of parameters of the network, given by:

$$|B| = \sum_{i=1}^n (r_i - 1) q_i. \quad (7)$$

While a BN defines a joint probability distribution over a fixed set of variables, a DBN extends this representation to model temporal processes (Friedman et al., 1998). Let  $\mathbf{X} = (X_1, \dots, X_n)$  be a random vector, composed by the attributes that are changed by some process. Furthermore, let  $\mathbf{X}[t] = (X_1[t], \dots, X_n[t])$  denote the instantiation of the attributes at discrete time  $t \in \mathbb{N}$ . A DBN encodes the joint probability distributions over all possible trajectories of a process.

The first-order Markov property states that future values only depend on present ones, not on the past trajectory, s.t.  $P(\mathbf{X}[t+1] \mid \mathbf{X}[0] \cup \dots \cup \mathbf{X}[t]) = P(\mathbf{X}[t+1] \mid \mathbf{X}[t])$ . A relaxation of this assumption is the higher-order Markov property, where nodes can have dependences on an arbitrary (but fixed) number of previous time-slices.

A non-stationary first-order Markov DBN describing a temporal process over  $T$  time-slices consists of:

- a prior network  $B^0$ , which specifies a distribution over the initial states  $\mathbf{X}[0]$ ;
- a set of transition networks  $B_t^{t+1}$  over the variables  $\mathbf{X}[t] \cup \mathbf{X}[t+1]$ , specifying the state transition probabilities, for  $0 \leq t < T$ .

A stationary network contains only one prior network and one transition network, being the latter unrolled over time.

Learning DBN typically refers to the transition network(s), as learning the prior network can be done directly using BN methods. Learning a transition network has the additional requirement that edges between slices must flow forward in time.

### 3 PROPOSED METHOD

The proposed algorithm is based on learning tree-like Bayesian networks. The Chow-Liu algorithm finds a tree with maximum mutual information (Chow and Liu, 1968), or, equivalently, a tree with maximum LL score. The algorithm works as follows: (i) a complete undirected graph weighted with the mutual information between each pair of nodes is built; (ii) an undirected spanning tree is extracted; and (iii) the optimal branching is retrieved by choosing an arbitrary node as the tree root and then setting the direction of all edges to be outward from it.

It was shown that the Chow-Liu algorithm can be adapted to use any decomposable scoring criterion  $\phi$  (Heckerman et al., 1995). In this case, the weight of an edge  $X_j \rightarrow X_i$  is assigned as  $\phi_i(\{X_j\}, D) - \phi_i(\{\}, D)$ , expressing the contribution of the edge, as measured by  $\phi$ , to the total network score. If  $\phi$  is score-equivalent, the weights of the edges  $X_j \rightarrow X_i$  and  $X_i \rightarrow X_j$  are the same, and so an undirected spanning tree is enough to retrieve the optimal branching. However, if the score is not score-equivalent, Edmond’s algorithm (Edmonds, 1967) needs to be used to find the maximum branching from a complete directed weighted graph (Heckerman et al., 1995).

In the temporal domain, nodes in  $\mathbf{X}[t + 1]$  can also have parents from previous time-slices. Our approach for learning DBN jointly learns inter and intra time-slice dependences. We propose to learn a tree network structure for the intra-slice dependences while limiting the number of parents from the preceding time-slices. That is, for each node in the current time-slice  $t + 1$  we allow one parent from the same time-slice (with the exception of the root node) and at most  $p$  parents from the preceding time-slices. We call the resulting transition network structure a tree-augmented DBN (tDBN). As we shall see next, the weight of an edge  $X_j[t + 1] \rightarrow X_i[t + 1]$  will account for the contribution of inter and intra-slice parents simultaneously. Therefore, due to inter-slice parents, the weights  $X_j[t + 1] \rightarrow X_i[t + 1]$  and  $X_i[t + 1] \rightarrow X_j[t + 1]$  are, in general, not the same. This forces us to resort to Edmond’s algorithm.

#### 3.1 OPTIMAL TREE-AUGMENTED DBN STRUCTURE LEARNING

Considering, for the sake of simplicity, the first-order Markov DBN paradigm, parents from the past can only be

long to the preceding slice. Let  $\mathcal{P}_{\leq p}(\mathbf{X}[t])$  be the set of subsets of  $\mathbf{X}[t]$  of cardinality less than or equal to  $p$ . If a node in  $\mathbf{X}[t + 1]$  is limited to having at most  $p$  parents from the past, its set of parents must belong to  $\mathcal{P}_{\leq p}(\mathbf{X}[t])$ . The optimal tDBN structure learning algorithm proceeds as follows.

First, for each node  $X_i[t + 1] \in \mathbf{X}[t + 1]$ , the best score and the set of parents  $\mathbf{X}_{ps}[t]$  in  $\mathcal{P}_{\leq p}(\mathbf{X}[t])$  that maximizes it are found. This optimization is formally expressed as

$$s_i = \max_{\mathbf{X}_{ps}[t] \in \mathcal{P}_{\leq p}(\mathbf{X}[t])} \phi_i(\mathbf{X}_{ps}[t], D_t^{t+1}), \quad (8)$$

where  $\phi_i$  denotes a local term of a decomposable scoring function  $\phi$  and  $D_t^{t+1}$  is the subset of observations of  $D$  concerning the time transition  $t \rightarrow t + 1$ . Then, also allowing one parent from the current time-slice, for each edge  $X_j[t + 1] \rightarrow X_i[t + 1]$ , the best score and the set of parents from the past that maximizes it are also found:

$$s_{ij} = \max_{\mathbf{X}_{ps}[t] \in \mathcal{P}_{\leq p}(\mathbf{X}[t])} \phi_i(\mathbf{X}_{ps}[t] \cup \{X_j[t + 1]\}, D_t^{t+1}). \quad (9)$$

A complete directed graph with nodes in  $\mathbf{X}[t + 1]$  is built, being the weight of each edge  $X_j[t + 1] \rightarrow X_i[t + 1]$  assigned as

$$e_{ij} = s_{ij} - s_i, \quad (10)$$

which expresses the gain in the total network score by including  $X_j[t + 1]$  as a parent of  $X_i[t + 1]$ , as opposed to leaving  $X_i[t + 1]$  only with parents in  $\mathbf{X}[t]$ . In general,  $e_{ij} \neq e_{ji}$ , and therefore a directed spanning tree must be found. Thus, to obtain the  $t \rightarrow t + 1$  transition network structure, the Edmonds’ algorithm for finding a maximum branching (Edmonds, 1967) is applied. The resulting directed tree immediately provides the network intra-slice connectivity (in  $t + 1$ ). In addition, for all the nodes except the root, their set of parents from the preceding time-slice is the solution for the optimization problem in Eq. (9). Similarly, the root node’s parents are given by the solution for the problem in Eq. (8).

The described procedure can jointly obtain the intra and inter-slice connectivity in a transition network. By repeatedly applying it to all the available time transitions, it is possible to retrieve the structure of a tree-augmented non-stationary first-order Markov DBN. A global view of this method is presented in Algorithm 1.

**Theorem 1.** *Algorithm 1 finds an optimal tDBN under a given decomposable scoring function.*

*Proof.* Let  $B$  be an optimal tDBN and  $T$  be the tree structure of  $B$  accounting only for the intra-slice dependences. Due to the optimality of  $B$ , its overall score is equal to

$$s_R + \sum_{X_j[t+1] \rightarrow X_i[t+1] \in T} s_{ij},$$

---

**Algorithm 1:** Optimal non-stationary first-order Markov tDBN structure learning

---

**Input:**  $\mathbf{X}$ : the set of network attributes;  
 $D$ : dataset of longitudinal observations over  $T$  time-slices;  
 $\phi$ : a decomposable scoring function

**Output:** A tree-augmented DBN structure

- 1 **For each** transition  $t \rightarrow t + 1$  :
  - 2     Build a complete directed graph in  $\mathbf{X}[t + 1]$
  - 3     Calculate the weight of all edges and the optimal set of parents of all nodes (Algorithm 2)
  - 4     Apply a maximum branching algorithm
  - 5     Extract transition  $t \rightarrow t + 1$  network using the maximum branching and the optimal set of parents calculated in Algorithm 2
  - 6 Collect transition networks to obtain DBN structure
- 

according to Eq. (8) and Eq. (9), where  $X_R$  is the root node of  $T$ .

Consider the constant  $K = \sum_i s_i$ . Finding an optimal tDBN for a given score  $\phi$  is the same as finding the optimal tDBN up to the constant  $K$ ; note that  $s_i$  does not depend on the structure  $T$ , nor  $B$ . By subtracting  $K$  to the score of  $B$  we obtain

$$\sum_{X_j[t+1] \rightarrow X_i[t+1] \in T} e_{ij},$$

according to Eq. (10). Observe that an optimal branching of the complete directed graph, where each edge  $X_j[t + 1] \rightarrow X_i[t + 1]$  is weighted with  $e_{ij}$ , is precisely  $T$ . Therefore, due to the soundness of Edmonds' algorithm, the output of Algorithm 1 is  $T$ , from which  $B$  can be recovered.  $\square$

### 3.2 COMPLEXITY ANALYSIS

The derivation of a complexity bound on the running time of Algorithm 1 is presented in the following.

**Theorem 2.** *The time complexity of Algorithm 1 is polynomial in the number of attributes  $n$ , linear in the the number of observations  $N$ , and exponential in the number of parents  $p$ .*

*Proof.* For each transition, the step of determining the edge weights and optimal sets of parents takes the most number of operations and determines the algorithm's growth rate. The iterative process starting at line 11 in Algorithm 2 is the most expensive overall. It calculates the weights for all edges in a complete graph with  $n$  nodes, which requires  $\mathcal{O}(n^2)$  iterations. For any edge, a score is evaluated for each possible set of parents in the preceding time-slice. The total number of parent sets is given by:

$$|\mathcal{P}_{\leq p}(\mathbf{X}[t])| = \sum_{i=1}^p \binom{n}{i} < \sum_{i=1}^p n^i \in \mathcal{O}(n^p). \quad (11)$$

---

**Algorithm 2:** Determining edge weights and optimal sets of parents (first-order Markov)

---

**Input:**  $\mathbf{X}[t], \mathbf{X}[t + 1]$ : sets of  $n$  nodes from two adjacent time-slices;  
 $p$ : upper bound on the number of parents from time-slice  $t$ ;  
 $D_t^{t+1}$ : dataset of observations concerning the time transition  $t \rightarrow t + 1$ ;

$\phi_{\text{child}[t+1]}(\text{parents}, \text{dataset})$ : a local term of  $\phi$

**Output:**  $E_{[n \times n]}$ : edge weights matrix;  
 $\text{parentsPastSlice}_{[n]}$ : optimal set of parents from time-slice  $t$ ;  
 $\text{parentsAllSlices}_{[n \times n]}$ : optimal set of parents from time-slices  $t$  and  $t + 1$

- 1  $\text{allParentSets} \leftarrow \mathcal{P}_{\leq p}(\mathbf{X}[t])$
  - 2 **For each**  $X_i[t + 1]$  :
  - 3      $\text{bestScore} \leftarrow -\infty$
  - 4     **For each**  $\mathbf{X}_{ps}[t] \in \text{allParentSets}$  :
  - 5          $\text{currentScore} \leftarrow \phi_i(\mathbf{X}_{ps}[t], D_t^{t+1})$
  - 6         **If**  $\text{bestScore} < \text{currentScore}$  :
  - 7              $\text{bestScore} \leftarrow \text{currentScore}$
  - 8              $\text{parentsPastSlice}_i \leftarrow \mathbf{X}_{ps}[t]$
  - 9     **For each**  $X_j[t + 1]$  :
  - 10          $E_{ij} \leftarrow -\text{bestScore}$
  - 11 **For each**  $X_i[t + 1]$  :
  - 12     **For each**  $X_j[t + 1]$  :
  - 13          $\text{bestScore} \leftarrow -\infty$
  - 14         **For each**  $\mathbf{X}_{ps}[t] \in \text{allParentSets}$  :
  - 15              $\text{currentScore}$
  - 16              $\leftarrow \phi_i(\mathbf{X}_{ps}[t] \cup \{X_j[t + 1]\}, D_t^{t+1})$
  - 17             **If**  $\text{bestScore} < \text{currentScore}$  :
  - 18                  $\text{bestScore} \leftarrow \text{currentScore}$
  - 19                  $\text{parentsAllSlices}_{ij} \leftarrow \mathbf{X}_{ps}[t]$
  - 20              $E_{ij} \leftarrow E_{ij} + \text{bestScore}$
- 

For calculating each score, all different network configurations must be considered. Assuming that  $r$  is the maximum number of discrete states a variable can take, and that a variable  $X_i[t + 1]$  has  $p + 1$  parents (one in  $\mathbf{X}[t + 1]$  and  $p$  in  $\mathbf{X}[t]$ ), there are  $\mathcal{O}(r^{p+2})$  different configurations. Each configuration needs to be counted over a dataset containing  $|D_t^{t+1}|$  observations, which can be stored in a  $|D_t^{t+1}| \times 2n$  sized matrix, thus requiring  $\mathcal{O}(|D_t^{t+1}|n)$  comparisons. Taking into account all the internal loops, the complexity of the outer cycle is  $\mathcal{O}(n^{p+3} r^{p+2} |D_t^{t+1}|)$ .

The efficient implementation of Edmonds' algorithm described in (Tarjan, 1977) has quadratic complexity in the number of nodes, hence being irrelevant to the overall bound. Algorithm 1, which learns a network structure for each of  $T$  time transitions, admits a worst-case complexity of  $\mathcal{O}(n^{p+3} r^{p+2} N)$ , where  $N = |D| = \sum_{t=0}^{T-1} |D_t^{t+1}|$ .  $\square$

### 3.3 EXTENSIONS TO STATIONARITY AND HIGHER-ORDER MARKOV

Algorithm 1 was presented in its non-stationary first-order Markov form. Nonetheless, adaptations for stationary or higher-order Markov processes are trivial and can be concisely described.

A stationary version of Algorithm 1 does not contain the for loop starting at line 1, because only one iteration is needed to find one transition network. In Algorithm 2, the entire dataset  $D$  is used in each score evaluation. Overall, since the number of examinations of each observation for learning the DBN structure is the same as in the non-stationary version, the time complexity remains the same, that is,  $\mathcal{O}(n^{p+3} r^{p+2} N)$ .

In a  $m$ -th-order Markov version of tDBN, regardless of process stationarity, nodes are allowed to have parents from  $m$  previous time-slices. Therefore, in Algorithm 2,  $\text{allParentSets} \leftarrow \mathcal{P}_{\leq p}(\mathbf{X}[t-m+1] \cup \dots \cup \mathbf{X}[t])$  and  $D_t^{t+1}$  is used instead of  $D_t^{t+1}$ . These changes worsen the algorithm’s time complexity, which can be roughly approximated by  $\mathcal{O}((nm)^{p+3} r^{p+2} N)$ .

## 4 EXPERIMENTAL RESULTS

In this section we describe the methodology used for evaluating the optimal tDBN learning algorithm and present the obtained results, in terms of speed and accuracy. Our algorithm was implemented in Java using an object-oriented approach and released under a free-software license<sup>1</sup>. Simulated data was first considered to evaluate the simpler stationary first-order Markov tDBN. As very good results were achieved, further assessment on real data with a non-stationary first-order Markov tDBN was used to learn time-varying gene regulatory networks from gene expression data of *Drosophila melanogaster*.

### 4.1 SIMULATED DATA

In the first set of experiments comprising simulated data, Banjo (et al., 2005), a state of the art DBN learning tool, was employed besides the tDBN learning algorithm for comparative purposes. Banjo was chosen for being able to also learn the intra-slice connectivity, as opposed to most DBN learning implementations. Throughout the experiments, an implementation’s ability to recover a known network structure was measured. This was accomplished by specifying a DBN (both its structure and parameters), sampling the network to generate observations and inputting the produced datasets to each implementation, in order to learn the underlying structure. The original and recovered networks were then compared by evaluating the precision

<sup>1</sup>Available at <http://josemonteiro.github.io/tDBN/> where additional experimental results are also provided.

Figure 1: Plot of the precision values achieved by the tDBN+LL learning algorithm for different values of input observations  $N$ . Three lines are shown, corresponding to complete tree-augmented networks with different number of attributes  $n$ , each attribute taking  $r = 8$  different states and having  $p = 2$  parents from the previous time-slice. Each point results from averaging the precision over 25 sampled datasets, with error bars denoting standard errors. Precision generally increases with  $N$  for every choice of  $n$ , attaining a plateau with  $N > 2000$ .

and recall metrics. In addition, to provide a unified score combining the two previous metrics, the  $F$ -measure was also calculated.

Because many methods only learn the inter-slice connectivity of DBN, Table 1 present the metrics taking into account (i) only the inter-slice edges, and (ii) all edges. The results in Table 1 are displayed as average statistics over 5 runs. Precision (Pre), recall (Rec) and  $F$ -measure ( $F_1$ ) values are presented as percentages, running time is in seconds;  $n$  is the number of network attributes,  $p$  is the number of parents from the preceding time-slice,  $r$  is the number of states of all attributes, and  $N$  is the number of observations. Values in bold correspond to the highest  $F$ -measure score in groups (i) or (ii); that is, one concerning the recovery of the inter-slice edges only and another concerning the recovery of all edges. Additional results and details concerning other experiments employing the tDBN learning algorithm are shown in Figures 1 and 2.

In the comparative tests, the stationary tDBN learning algorithm was employed using the LL and MDL scores. Banjo’s Markov lag interval was set between 0 and 1 to allow intra-slice edges. Its running time was set to 10 minutes, which was always longer than learning tDBN’s, and simulated annealing was used as search procedure. In all cases, the maximum number of parents was set according to the original network. The experiments were run on an Intel i5-3570 @ 3.40 GHz machine.

Table 1: Comparative structure recovery results on simulated data. Banjo’s running time is not shown, as it was always 600 seconds.

Four different network settings are considered in Table 1. The first two networks are complete tree-augmented DBN, in the sense that each attribute in  $\mathbf{X}[t + 1]$  has exactly  $p$  parents in  $\mathbf{X}[t]$  and at most one parent in  $\mathbf{X}[t + 1]$ . In these settings, the number of edges is always  $n(p + 1) - 1$ . On the other hand, the third network is an incomplete tree-augmented DBN, because the number of parents from the preceding slice is chosen at random between 1 and  $p$ . In the fourth network, there are no edges inside  $\mathbf{X}[t + 1]$ , corresponding to the traditional inter-sliced DBN concept.

According to each network setting, a network was created by randomly generating its structure and parameters using uniform distributions. An experimental group, corresponding to a line in Table 1, consisted of 5 independent datasets with the same number of observations, sampled from one of the generated networks. The presented values result from averaging the performance metrics over the datasets of a group.

From the experimental results in Table 1, it can be seen that the performance of the proposed algorithm consistently increases with  $N$ . In the first setting, the tDBN learning algorithm performs very well with either score, with LL having a slight advantage. This result was expected, since a complete tree-augmented DBN is biased towards tDBN, and LL assures that a necessary and sufficient number of edges is recovered. Banjo obtains a very good inter-slice precision, but only recovers one fifth of the original edges. Notice that Banjo’s global results deteriorate when  $N$  increases, which can be explained by decreasing performance while identifying the intra-slice connectivity.

In the second setting, the tDBN+LL learning algorithm globally outperforms the other implementations. The regularization effect of MDL is observed through lower recall levels, since the number of network parameters increases

with  $r$ . Nevertheless, tDBN+MDL greatly improves with  $N$  and already achieves very high precision for  $N = 700$ . Comparing to the first setting, Banjo is more conservative adding edges, and chooses none for  $N \leq 300$ .

In the third setting, the inter-slice precision of tDBN+LL does not exceed 50%, due to the recovery of exactly  $p$  parents, when the real number can be smaller than  $p$ . In this setting, tDBN+MDL clearly achieves the best performance. The penalizing term in MDL prevents false positive edges from being chosen, resulting in significantly higher precision values compared to LL. Banjo performs like in the first setting, being able to determine the correct parents and thus reaching high precision values with respect to the inter-slice connectivity.

Even though the last setting comprises a network without intra-slice edges, the tDBN learning algorithm performs well with either scoring function. In fact, the inter-slice metrics are comparable to the ones in the first setting. The  $F$ -measure values of LL and MDL are very similar, causing neither score to stand out. The recovery of an intra-slice tree, which is an inherent aspect of tDBN learning procedure, worsens the global performance of the algorithm. In this setting, Banjo obtains an excellent inter-slice result, correctly identifying all the dependences and reporting no false positives. On the other hand, the percentage of retrieved edges is quite low, resulting in unimpressive  $F$ -measure scores.

Overall, the tDBN learning algorithm obtained very good results. While tDBN+LL outperformed in the more complex second setting network, tDBN+MDL showed to be more robust, achieving at least one highest  $F$ -measure score in each setting. Banjo consistently identified high-precision sparse inter-sliced networks, but generally could not recover more than 20% of the existing data depen-

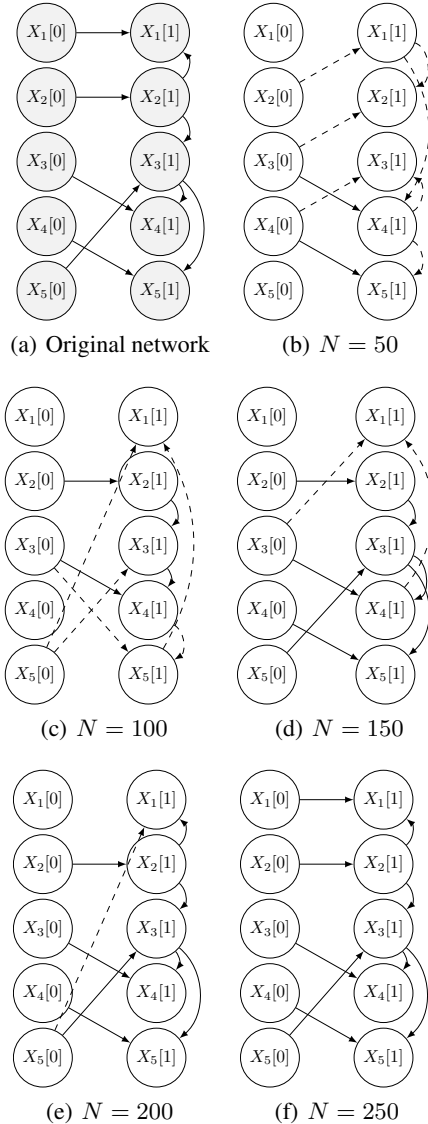

Figure 2: Example of the tDBN+LL learning algorithm’s ability to recover a known network. The original tree-augmented network has  $n = 5$  attributes, each taking  $r = 8$  different states and having one parent from the previous time-slice. Differing in the number of input observations  $N$ , five recovered networks are shown. Dashed edges are not present in the original network but are nevertheless recovered. As  $N$  increases, the recovered network structures become more similar to the original, being identical for  $N = 250$ .

dences.

## 4.2 DROSOPHILA MELANOGASTER DATA

The following experiments consisted in applying the tDBN learning algorithm to identify non-stationary gene regulatory networks of *Drosophila melanogaster*. Arbeitman

et al. (2002) published a dataset containing gene expression measurements of 4028 *Drosophila* genes over 67 time steps, covering the four major stages of morphogenesis: embryo, larva, pupa and adult. Some authors have focused on a small subset of this time series, consisting of eleven genes involved in wing muscle development (Guo et al., 2007; Robinson and Hartemink, 2010; Dondelinger et al., 2013). Consequently, to allow comparison to other methods, the same subset is considered herein. The *Drosophila* gene expression dataset was preprocessed in the same way as in the aforementioned references.

For learning the gene regulatory networks, the first-order Markov tDBN learning algorithm was employed with the MDL score, allowing at most two parents from the past. However, as the number of observations was small, there was not enough evidence for MDL to include more than one parent. Figure 3 presents the resulting networks in compact form, to facilitate comparison to networks inferred by other authors. Table 2 examines the identified gene interactions against the ones reported in other publications, in the form of matching percentages. Guo et al. (2007) predicted non-stationary undirected networks, while Dondelinger et al. (2013) inferred non-stationary DBN.

The results in Table 2 suggest that tDBN learning algorithm performed reasonably well. The embryonic and larval networks contain a significant number of known interactions that are present in at least one of the corresponding reported networks. On the other hand, the pupal and adult networks did not achieve this result. Some of the pupal interactions could be disjointly found on the networks of both authors, resulting in a higher combined matching rate. The adult network, however, retrieved few known interactions, even when comparing to both sources combined.

Table 2: Comparative structure learning results on *Drosophila melanogaster* data.

| Morphogenic stage                  | Embryonic | Larval | Pupal | Adult |
|------------------------------------|-----------|--------|-------|-------|
| Observed time-slices               | 31        | 10     | 18    | 8     |
| Matches (Guo et al., 2007)         | 25%       | 50%    | 40%   | 30%   |
| Matches (Dondelinger et al., 2013) | 75%       | 60%    | 30%   | 20%   |
| Matches (both sources)             | 75%       | 70%    | 60%   | 40%   |

As acknowledged by Dondelinger et al. (2013), an objective assessment regarding the accuracy of the learnt networks is not possible due to limited biological knowledge available, which leads to the absence of a gold standard. Furthermore, there are three reasons for which the obtained results should be interpreted carefully. First, despite the best efforts to follow the procedure in Zhao et al. (2006), the resulting preprocessed dataset was possibly not the same. Second, learnt interactions are suggestions of causal regulatory effects. Additional biological experiments are necessary for validating the inferred networks, as noted in Guo et al. (2007). Third, the small number of observations leads to the existence of many equivalent networks

with maximum score, but only one is reported by the tDBN learning algorithm.

## 5 CONCLUSION

We have presented a simple yet effective algorithm for learning the structure of DBN, jointly recovering the inter and intra time-slice connectivity. The tDBN learning algorithm has polynomial time complexity with respect to the number of attributes and can be applied to non-stationary Markov processes.

The stationary version of the algorithm achieved very good results on simulated datasets, showing to be competitive with state of the art algorithms in recovering underlying structures. Furthermore, encouraging results were obtained on real data with the non-stationary and higher-order Markov versions of tDBN, indicating a broad scope of applications for the proposed algorithm.

Finally, the application of our method to learn non-stationary processes could be improved in conjunction with change-point techniques, as investigated in Robinson and Hartemink (2010) and Dondelinger et al. (2010). In its current form, the tDBN learning algorithm cannot identify changes in the underlying distribution of data and thus the number of transition networks to learn, as well as adequate training data for each network, need to be previously specified.

## Abstract

Building efficient large-scale knowledge bases (KBs) is a longstanding goal of AI. KBs need to be first-order to be sufficiently expressive, and probabilistic to handle uncertainty, but these lead to intractable inference. Recently, tractable Markov logic (TML) was proposed as a non-trivial tractable first-order probabilistic representation. This paper describes the first inference and learning algorithms for TML, and its application to real-world problems. Inference takes time per query sublinear in the size of the KB, and supports very large KBs via parallelization and a disk-based implementation using a relational database engine. Query answering is fast enough for interactive and real-time use. We show that, despite the data being non-i.i.d. in general, maximum likelihood parameters for TML knowledge bases can be computed in closed form. We use our algorithms to build a very large tractable probabilistic KB from numerous heterogeneous data sets. The KB includes millions of objects and billions of parameters. Our experiments show that the learned KB outperforms existing specialized approaches on challenging tasks in information extraction and integration.

## INTRODUCTION

A knowledge base that continuously acquires knowledge and answers complex queries is a vision as old as the field of AI itself. The formal representation employed by such a KB needs to be at the level of first-order logic, in which inference is intractable. Many tractable subsets of first-order logic have been proposed (e.g., description logics, Horn KBs), but building large KBs further requires that the representation be probabilistic, for at least two reasons: most of the knowledge will necessarily be acquired from text, the Web, etc., which are inherently noisy and ambiguous, and

maintaining the consistency of large KBs is extremely difficult. First-order probabilistic representations like Markov logic have been developed, but they are again intractable, as are subsets like probabilistic Horn KBs and description logics. Recently, Domingos and Webb [2011] developed tractable Markov logic (TML), a subset of Markov logic that has expressiveness comparable to probabilistic Horn KBs and description logics but remains tractable. However, to date this was only a theoretical proposal, with no inference and learning algorithms beyond the basic inference required to prove tractability, and no real-world applications.

This paper develops highly scalable inference and learning algorithms for tractable probabilistic knowledge bases (TPKBs), using TML as the representation. After an initialization phase that computes the partition function of the TPKB in time linear in its size, queries are answered in sublinear time using a relational database implementation that allows for large disk-resident KBs and is easily parallelized. Maximum-likelihood parameter learning is done in closed form, and takes time linear in the size of the training data, which can therefore also be very large and disk-resident. Together these inference and learning algorithms make it possible to learn and reason with very large first-order probabilistic KBs.

As a test of our architecture and algorithms, we learn the structure and parameters of a TPKB from a multitude of very large data sets, and use it to answer a variety of queries. The resulting TPKB is larger than previous statistical relational models by at least an order of magnitude, with millions of objects and billions of parameters, yet allows for subsecond query answering times. Extensive experiments show the efficiency and effectiveness of the proposed framework for entity linking and resolution.

## RELATED WORK

Probabilistic description logic programs [17] combine DL programs under the answer set and well-founded semantics with independent choice logic [26]. Particular variants of light-weight description logics with probabilistic seman-

tics [11, 22, 24] have been proposed. However, these formalisms are too expressive to be tractable for the types of queries needed in large-scale applications, do not allow the modeling of data properties, and do not address the problem of parameter and structure learning.

TPKBs are related to **PROBLOG** [28] a probabilistic logic programming language that is generally intractable. **URDF** [19] is based on weighted **MAX-SAT** algorithms and is in principle intractable. It also does not support queries that ask for a distribution over objects, classes and relations given a subset of their attributes. Infinite relational models (IRMs) are non-parametric hierarchical models but are not tractable in general [13]. We leverage the hierarchy of TPKBs to estimate parameters on the level of classes and relation more robustly. This is related to shrinkage [18].

TPKBs are different from probabilistic databases [31] in that they represent general knowledge attached to class and relation hierarchies and do not assume tuple independence, that is, the independence of facts in the knowledge base. Moreover, inference in a TPKB is always at most linear in the size of the TPKB whereas inference complexity in PDBs depends on the query expression and can be costly.

Open information extraction [7] and other IE projects [2, 15] often use ad-hoc approaches and heuristics and do not provide a consistent joint distribution and query language. There exist several statistical relational systems employing relational database technology to facilitate queries over structured data [23, 33, 25]. However, the proposed systems are intractable. Recent work on statistical relational learning has focused on tractable probabilistic graphical models, that is, probabilistic models for which inference is efficient by design. Examples are relational sum-product networks [20], particular tractable fragments of probabilistic logics [32], and probabilistic soft logic [14]. None of these languages feature disk-based, sublinear inference algorithms or has been used to build a real-world tractable probabilistic knowledge base. There is related work in the context of information extraction and relation learning. Notable representative publications of this line of research are tensor factorizations of **YAGO** [21] and universal schemas [29]. These approaches do not facilitate a consistent probabilistic semantics and expressive query languages.

## TRACTABLE PROBABILISTIC KNOWLEDGE BASES

Tractable Markov logic (TML) [4] is a subset of Markov logic exploiting probabilistic class and part hierarchies to control complexity. In TML the domain is decomposed into parts, each part is drawn probabilistically from a class hierarchy, the part is further decomposed into parts according to its class, and so on. More recently, TML was extended

so as to also handle existence uncertainty [34]. Tractable probabilistic knowledge bases (TPKBs) accomplish this by defining a possible world as a set of objects and the truth values of the atoms in which they occur as arguments, rather than just as a set of truth values over a fixed universe of objects. TPKBs form the basis for the new algorithms in this paper. We extend them with attributes that can have discrete and continuous distributions. Attributes allow us to model typical properties of objects in real-world knowledge bases such as images, geographical locations, and mentions.

### Syntax

A TPKB is a set of class and object declarations. A class declaration specifies the subclasses, parts, attributes, and relations of the class, along with their distributions. It has the following form:

```

Class C {
  subclasses  $S_1 w_1, \dots, S_n w_n$ ;
  parts  $P_1[c_1] C_1, \dots, P_\ell[c_\ell] C_\ell$ ;
  attributes  $A_1 D_1 u_1, \dots, A_m D_m u_m$ ;
  relations  $R_1(\dots) v_1, \dots, R_k(\dots) v_k$ ;
}

```

Subclass declarations specify the direct subclasses (children) of  $C$  and their real-valued weights. Direct subclasses are assumed to be mutually disjoint and form a partition of the superclass.

Part declarations specify the parts every instance of  $C$  must have. Part declarations consist of a part name  $P_i$ , the part's class  $C_i$ , and the number  $c_i$  of parts of that type where  $c_i$  is optional and 1 by default. Two classes such that one is a descendant of the other in the class hierarchy never have a part with the same name.

Every attribute  $A$  has a domain  $D_i$  (e.g.,  $\{0, \dots, 10\}, \mathbb{R}$ ) and a weight function  $u_i : D_i \rightarrow \mathbb{R}$ . The weight function for a continuous domain must be efficiently integrable.

Each relation  $R_i(\dots)$  has the form  $R_i(P_a, \dots, P_z)$  where each of  $P_a, \dots, P_z$  is a part of  $C$ , that is, one of  $P_1, \dots, P_\ell$ , and the  $v_i$ 's are real-valued weights. Weights determine the probability that an object belongs to a direct subclass or that a relation is true as specified below. If a relation weight does not appear, then the relation is hard, that is, it must hold in every possible world.

Objects of the TPKB are introduced as parts, subparts, sub-subparts, etc., of a single *top object*. The top object is the sole instance of its class which is named the *top class*. The top class does not have superclasses. Given a set of class declarations, we can define the following concepts.

The *class hierarchy* is a directed graph whose nodes correspond to classes and whose edges correspond to direct

subclass relationships. The class hierarchy must be a forest.

The *part decomposition* is a directed graph whose nodes correspond to parts and with edges from each object to each of its possible parts. The part decomposition must be a tree with the top object as root node.

In addition to class declarations, TPKBs have object declarations which introduce evidence by specifying the names of the object as well as its subclass memberships, attribute values, and relations. An object declaration has the form

```
Path Name {
  S1, ..., Sn;
  A1 = D1, ...;
  R1(...), ..., ¬R1(...), ...;
}
```

where Path is the object's path from the top object in the part decomposition and Name the name given to the object. For instance, for a TPKB with top object World, World.Country<sub>1</sub>.State<sub>5</sub>.Capital Olympia { ... } is the declaration for object World.Country<sub>1</sub>.State<sub>5</sub>.Capital giving it the name Olympia. If, for instance, Country<sub>1</sub> was previously declared to be World.USA and State<sub>5</sub> to be USA.Washington, then Path could also be Washington.Capital.

The statement S<sub>1</sub>, ..., S<sub>n</sub>; expresses that S<sub>1</sub>, ..., S<sub>n</sub> are the only classes the object can be an instance of. Each statement A<sub>i</sub> = D, with D ∈ D<sub>i</sub>, is an attribute fact and denotes that the attribute is known to have value D. For every attribute A<sub>i</sub> of the object there exists at most one fact A<sub>a<sub>i</sub></sub> = D. Each statement R<sub>i</sub>(...) is a relation fact and denotes that the relation is known to be true, and each statement ¬R<sub>i</sub>(...) is a relation fact that denotes that the relation is known to be false. Object declarations are optional and may be empty, that is, they may have the form Path Name { }. Empty object declarations introduce evidence by declaring the object to exist in all possible worlds. Object declarations have the purpose of naming objects and introducing evidence and must be compatible with the class declarations. Table 1 depicts a typical set of class and object declarations.

## Semantics

The possible objects of a TPKB are the top object and every other object in the part decomposition. The Herbrand universe of a TPKB is the set of constants representing classes, paths representing objects, and constants representing attribute values. An *n*-ary *predicate* grounded with elements of the Herbrand universe is an *atom*. We define the binary predicate Is, where atom Is(O, C) is true if object O is of class C and false otherwise. Likewise, A(O, D) is an atom which is true if attribute A has value D for object O. Finally,

```

```

Table 1: Example class and object declarations of a TPKB. area is an attribute that models the area of an entity in square kilometers, and images a collection of images depicting entities.

R(O, ...) is an atom which is true if the relation R(...) is true for object O and false otherwise. We refer to class membership, attribute, and relation atoms and their negations as literals. A TPKB is a DAG of objects and their properties (classes, attributes, relations), and a possible world is a subtree of the DAG with values for the attributes and relations. More formally, a possible world **W** of a TPKB with top object O<sub>0</sub> and top class C<sub>0</sub> is a set of literals such that:

1. Is(O<sub>0</sub>, C<sub>0</sub>) ∈ **W**.
2. If Is(O, C) ∈ **W**, then
  - (a) if C has direct subclasses, then Is(O, S) ∈ **W** for exactly one direct subclass S and ¬Is(O, S') ∈ **W** for every other direct subclass S';
  - (b) for every part P of O declared to be of class C', Is(O.P, C') ∈ **W**;
  - (c) for every attribute A<sub>i</sub> declared for class C there is exactly one D ∈ D<sub>i</sub> with A<sub>i</sub>(O, D) ∈ **W** and ¬A<sub>i</sub>(O, D') ∈ **W** for every other D' ∈ D<sub>i</sub>; and
  - (d) for every relation R(...) declared for class C either R(O, ...) ∈ **W** or ¬R(O, ...) ∈ **W**; if R is hard, then R(O, ...) ∈ **W**.
3. No other literals are in **W**.

The set of objects that exist in a possible world is exactly the objects that occur as arguments of the class membership, relation, and attribute predicates. We write  $\mathcal{W}$  to denote the set of all possible worlds.

We write  $\text{Subs}(C)$ ,  $\text{Parts}(C)$ ,  $\text{Atts}(C)$  and  $\text{ReIs}(C)$  to denote the direct subclasses, parts, attributes, and relations declared for class  $C$ .

A possible subworld for object  $O$  and class  $C$  is defined as above with  $O_0$  replaced by  $O$  and  $C_0$  replaced  $C$ . The unnormalized distribution  $\phi$  over possible subworld  $\mathbf{W}$  without evidence, that is, without object declarations, is defined recursively as  $\phi(O, C, \mathbf{W}) = 0$  if  $\neg \text{Is}(O, C) \in \mathbf{W}$  or if a relation  $R$  of  $C$  is hard and  $\neg R(O, \dots) \in \mathbf{W}$  and otherwise as

$$\phi(O, C, \mathbf{W}) = \left( \sum_{S_i \in \text{Subs}(C)} e^{w_i} \phi(O, S_i, \mathbf{W}) \right) \times \left( \prod_{P_i \in \text{Parts}(C)} \phi(O, P_i, C_i, \mathbf{W})^{n_i} \right) \times \left( \prod_{A_i \in \text{Atts}(C)} \alpha(O, A_i, \mathbf{W}) \right) \times \left( \prod_{R_i \in \text{ReIs}(C)} \rho(O, R_i, \mathbf{W}) \right),$$

where  $\alpha(O, A_i, \mathbf{W}) = e^{u_i(D)}$  if  $A_i(O, D) \in \mathbf{W}$ . Moreover,  $\rho(O, R_i, \mathbf{W}) = e^{v_i}$  if  $R_i(O, \dots) \in \mathbf{W}$  and  $\rho(O, R_i, \mathbf{W}) = 1$  if  $\neg R_i(O, \dots) \in \mathbf{W}$ . If an object has no subclasses, parts, attributes, or relations, then the corresponding products in the above equation evaluate to 1.

The unnormalized probability of a possible world  $\mathbf{W}$  is now  $\phi(O_0, C_0, \mathbf{W})$ . The sub-partition function for object  $O$  and class  $C$  is

$$Z_{\mathcal{K}_{O,C}} = \sum_{\mathbf{W} \in \mathcal{W}} \phi(O, C, \mathbf{W}).$$

If  $O$  is the top object and  $C$  the top class, we simply write  $Z_{\mathcal{K}}$ . The probability of a possible world  $\mathbf{W}$  is

$$P(\mathbf{W}) = \frac{\phi(O_0, C_0, \mathbf{W})}{Z_{\mathcal{K}}}.$$

Sum-product networks (SPNs) are a class of deep probabilistic models in which one can perform fast exact inference [27]. An SPN is recursively constructed by forming sums and products of univariate distributions, and its partition function can be computed in time linear in its size. Every TPKB maps into a corresponding SPN such that the distribution of the TPKB is equivalent to the distribution of the SPN. The construction follows the recursive definition of the distribution over possible worlds  $\phi(O_0, C_0, \cdot)$ . Figure 1 depicts the SPN corresponding to the example TPKB

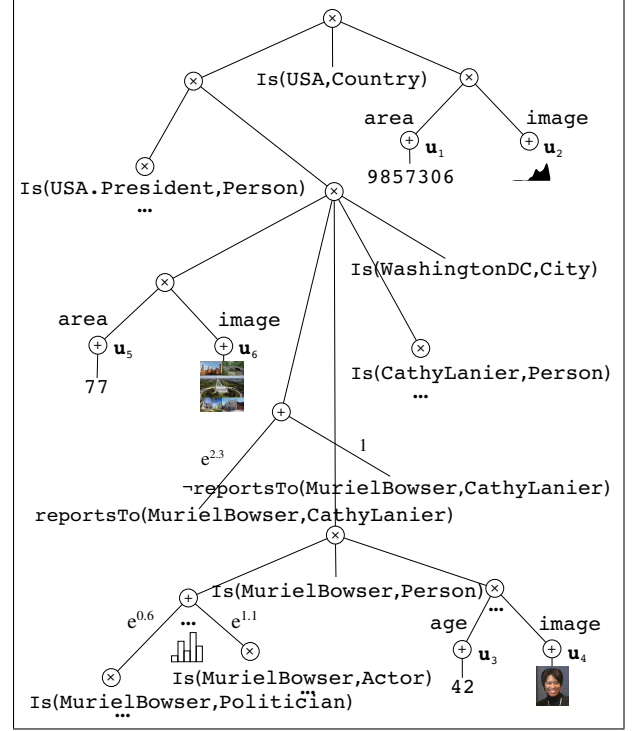

Figure 1: The SPN corresponding to the TPKB in Table 1.

of Table 1. The *size* of a TPKB is the number of objects times the number of classes each object is possibly an instance of. The proof of the following theorem can be found in the appendix.

**Theorem 1.** *The partition function of a TPKB can be computed in time linear in its size.*

We can also show that TPKBs are at least as expressive as the class of SPNs.

**Theorem 2.** *For every SPN there exists a TPKB with the same distribution and the size of the TPKB is linear in the size of the SPN.*

Hence, TPKBs include a large number of high-treewidth graphical models. These high-treewidth distributions are common in the real world, occurring whenever two subclasses of the same class have different subparts. TPKBs are non-trivial relational models that capture relational dependencies, multiple objects, existence uncertainty, etc. Also, even though data is not i.i.d. in general, closed-form maximum likelihood learning is possible given the TPKB's structure and complete data. Lifting in TPKBs is straightforward and makes the complexity of inference independent of the number of evidence-free objects.

The key assumption that TPKBs make to ensure tractability is that an object's attributes and relations are independent given its class. As a result, some distributions cannot be represented compactly. For example, an Ising model with

Figure 2: A part decomposition (left) with 6 objects and the class hierarchy (right) with two trees and 8 classes. Dashed arrows indicate which object was declared with which class. The numbers indicate the depth  $\ell$  of the layers in the part decomposition (left) and of the trees of the class hierarchy (right).

arbitrary structure may require an exponential number of classes to represent.

## INFERENCE

Object declarations introduce evidence in form of subclass, attribute, and relation facts and therefore influence the distribution of a TPKB by reducing the number of possible worlds with non-zero probability. The TPKB’s partition function is now the sum of the unnormalized probabilities of all possible worlds not contradicting the evidence. For a TPKB  $\mathcal{K}$  and a set of facts  $E$ , we write  $Z_{\mathcal{K}}(E)$  for the corresponding partition function.

There are several possible types of queries. For instance, we can ask for  $P(Q | E)$ , where  $E$  and  $Q$  are sets of facts pertaining to objects in  $\mathcal{K}$ . The answers to these queries can always be tractably computed as ratios of partition functions:

$$P(Q | E) = \frac{Z_{\mathcal{K}}(Q \cup E)}{Z_{\mathcal{K}}(E)}.$$

We can also perform MAP inference, that is, ask for the most probable possible world given evidence. This is possible in a TPKB simply by replacing sums over subclasses with maxes and performing a traceback.

For real-world knowledge bases with millions of objects and tens of thousand of relations and attributes, disk-based and parallel inference algorithms with sublinear running time are required. We now introduce a novel inference algorithm with these characteristics. To the best of our knowledge, this is the first sublinear exact inference algorithm that scales to millions of objects and is fully implemented using a relational database. The algorithm performs several relational queries, which allows us to take advantage of query evaluation plans, index structures, and caching strategies. Intuitively, the structure of the query expressions resembles the corresponding sum-product network where sum nodes correspond to join-and-sum operations and product nodes to join-and-multiply operations.

There are two distinct inference algorithms. The first one computes the partition function and, as a by-product, all sub-partition functions for objects and their possible classes (stored in table  $T_Z$ ) and the values of all sum nodes (stored in table  $T_{+S}$ ). It does this once offline, in time linear in the size of the TPKB.

The second algorithm computes, given evidence  $E$ , the *ratio* of the partition function with and without  $E$  (the marginal probability of  $E$ ), by propagating ratios of sub-partition functions with and without evidence.

To illustrate the algorithm, let us consider Figure 2 which depicts the part decomposition and the class hierarchy of a small TPKB. Every fact given by evidence  $E$  specifies either (a) the value of an attribute; (b) the truth value of a relation; (c) or the possible classes of an object. Evidence changes the sub-partition functions involving objects to which these attributes, relations, or subclasses apply. For instance, in Figure 2, if the sub-partition function for object  $O_2$  and its possible class  $C'_2$  is  $e^{w_s} e^{w_p} e^{w_a} e^{w_R}$ , and if evidence changes the factor pertaining to attributes from  $e^{w_a}$  to  $e^{w'_a}$  and leaves all other factors the same, then the ratio of the sub-partition functions with and without evidence is  $e^{w'_a} / e^{w_a}$ . The evidence also impacts the ratios of sub-partition functions with and without evidence,  $Z_{\mathcal{K}}^{(O_2, C)}(E) / Z_{\mathcal{K}}^{(O_2, C)}$ , for every superclass  $C$  of  $C'_2$  the object  $O_2$  can be an instance of (here: class  $C_2$ ). In Figure 2 these classes are depicted as shaded nodes in the second tree of the class hierarchy. Moreover, since  $O_2$  is a part of object  $O_1$ , the ratios of sub-partition functions for object  $O_1$  in layer 1 and the class it was declared with also change, and so on. Fortunately, we only need to compute the ratios for objects that are ancestors of the object whose sub-partition function is impacted by the evidence.

The inference algorithm propagates these ratios of sub-partition functions bottom-up through the TPKB’s structure to obtain  $Z_{\mathcal{K}}(E) / Z_{\mathcal{K}} = P(E)$ . The relational queries computing these ratios of sub-partition functions only involve tables changed by the evidence and, therefore, the complexity of the algorithm depends on the evidence and not the size of the TPKB.

The inference algorithm is shown in Algorithm 1. To avoid confusion with relations and attributes of the TPKB, we use the terms *table* for relations and *columns* for attributes in the relational algebra. Table  $T_Z(\text{Path}, \text{Class}, \text{subZ})$  with unique key  $(\text{Path}, \text{Class})$  represents the TPKB’s sub-partition functions. Hence,  $(O, C, Z) \in T_Z$  if and only if  $O$  can be an instance of class  $C$  and  $Z_{\mathcal{K}}(O, C) = Z$ . Analogously, we store the ratios of sub-partition function with and without evidence  $E$  in table  $T_Z^E$  with the same schema. We often write  $T_Z(O, C)$  to denote the value of the unique sub-partition function for object  $O$  and its possible class  $C$ .

Layer  $\ell$  of the part decomposition consists of all objects with depth (distance to the root node)  $\ell$ . Table

$T_{\text{Is}}^{\ell, E}(\text{Path}, \text{Class}, \text{Class}')$  represents, for every object  $O$  in layer  $\ell$ , its possible leaf classes  $C$  in the class hierarchy, and the classes  $C'$  it is declared with. The table, however, only stores objects and classes whose sub-partition function is impacted by the evidence  $E$ . These sub-partition functions can be efficiently computed using the structure of the TPKB.

Table  $T_{\text{Part}}$  represents the part decomposition of the TPKB. This table is used in lines 4 and 5 of Algorithm 1 to compute the table  $T_{\times P}^E(\text{Path}, \text{Class}, \text{subZ})$  with  $(O, C, Z) \in T_{\times P}^E$  if and only if object  $O$  is in layer  $\ell$  of the part decomposition,  $O$  is declared as instance of class  $C$ , and  $Z$  is the product of the ratios of sub-partition functions with and without evidence of  $O$ 's parts according to  $C$ .

Lines 6, 7, and 8 evaluate the attribute, relation, and part product nodes of the TPKB's SPN (the three product nodes in Figure 1). The table  $T_A^E(\text{Path}, \text{Class}, \text{subZ})$  stores, for each object and its possible classes, the ratio of the exponentiated summed weights of the attribute  $A$  with and without evidence  $E$ . The tables  $T_{R_i}^E(\text{Path}, \text{Class}, \text{subZ})$  are the analogous tables for relations. The operator  $\otimes$  computes a left outer join on the columns  $\text{Path}$  and  $\text{Class}$ , and multiplies the values of the tables'  $\text{subZ}$  columns. The join queries of lines 5 and 6 only involve attribute and relation tables changed by the evidence.

Line 11 stores the computed ratios of sub-partition functions with and without evidence to table  $T_Z^E$ . In Line 12 it is tested, for each object  $O$ , whether we have reached the node of the class  $O$  was declared with. If this is the case, we remove the corresponding tuple from  $T$  since the computation of sub-partition functions that involve these objects is finished.

Lines 19 and 20 evaluate the SPN's sum nodes. First, we perform a left outer join of the tables  $T$  and  $T_{\text{Sub}}^k$  to multiply the children of each sum node with their respective weight. Table  $T_{\text{Sub}}(\text{Class}, \text{Superclass}, \text{weight})$  represents the class hierarchy and the subclass weights. For each  $\text{Superclass}$  in layer  $k$  of the class hierarchy,  $T_{\text{Sub}}^k(\text{Class}, \text{Superclass}, \text{weight})$  stores the weight for each of its subclasses. Second, the operator  $\oplus$  performs a grouping on the columns  $\text{Path}$  and  $\text{Superclass}$  and sums the values of column  $\text{subZ}$  for each of the groups. Line 20 renames the column  $\text{Superclass}$  to  $\text{Class}$  and projects out superfluous columns. The result of these operations are the values  $Z$  by which the sub-partition function at the sum nodes is reduced by the evidence. Line 22 computes the ratio of the sum node for object  $O$  and class  $C$  with and without evidence:  $(T_{+S}(O, C) - Z)/T_{+S}(O, C)$ .

Steps 6-22 are repeated until we have computed the ratio of the sub-partition function with and without evidence for every object in layer  $\ell$  and each of its possible classes.

After running Algorithm 1 for  $\ell = h, \dots, 0$ , where  $h$  is the height the part decomposition, we have that  $T_Z^E(O_0, C_0) = Z_{\mathcal{K}}(E)/Z_{\mathcal{K}} = P(E)$ .

**Theorem 3.** *Let  $\mathcal{K}$  be a TPKB and let  $n(E)$  be the number of sub-partition functions changed by a set of facts  $E$ . Algorithm 1 computes the probability  $P(E)$  in time  $O(n(E))$  and independent of the size of  $\mathcal{K}$ .*

*Proof sketch.* This can be shown with a nested proof by induction on (a) the height of the part decomposition and (b) the height of the class trees of each object.  $\square$

Hence, inference time depends on the number of sub-partition functions changed by the evidence. This approach is different from caching previously computed values [10]. While we exploit this idea as well, the major advancement is the propagation of only those ratios of partition functions that are changed by the evidence.

Algorithm 1 can be parallelized by leveraging the structure of the TPKB's part decomposition and class hierarchy. First, the executions of Algorithm 1 on distinct trees of the class hierarchy are independent and can be performed in parallel. Moreover, for each layer of the part decomposition, the execution of the algorithm for an object in the layer is independent of the execution for any other object in the same layer. More generally, for any two objects, Algorithm 1 can be executed independently until we reach a

layer with the parent of the two objects. By using relational database systems for query processing, we can take advantage of existing parallelization strategies that detect these types of decompositions. We show below that this reduces the query evaluation time on multi-core architectures.

## LEARNING

The TPKB’s parameters are the weights associated with attributes, relations, and subclasses. The training data is an i.i.d. sample of possible worlds. Hence, a sample  $\{\mathbf{W}_1, \dots, \mathbf{W}_N\}$  is a multiset of  $N$  i.i.d. possible worlds. Note that, even if the sample consists of only one possible world (a mega-example), we can often still obtain robust parameter estimates due to the structure of a TPKB which features a large number of objects with the same class and, therefore, the same attributes and relations.

We derive closed-form maximum likelihood (ML) estimators of the parameters. We choose ML parameters that lead to a partition function with value 1. Since for each possible world, the classes for all objects are known and every object can only be an instance of one of a set of sibling classes, the expression for the likelihood is a product of factors. The log-likelihood, therefore, is a sum of terms and differentiating it with respect to a particular parameter leaves only the terms involving one particular attribute, at which point the MLE can be found in closed form for exponential family distributions.

Let  $n(C)$  be the number of objects  $O$  in all possible worlds in the training data such that  $O$  is an instance of class  $C$ . For each class  $C$ , the probabilities of its subclasses  $S_1, \dots, S_n$  are governed by a categorical distribution. The standard ML estimates of  $P(S_i|C)$ , therefore, are  $n(S_i)/n(C)$ . Due to the parameterization of TPKBs, the MLEs are the logarithms of these estimates. Hence  $\text{MLE}(w_i) = \log(n(S_i)/n(C))$ .

Analogously, we can derive the ML estimates for attributes and relations. For categorical attributes, let  $n_A(C, D)$  be the number of objects  $O$  in all possible worlds in the training data such that  $O$  is an instance of class  $C$  and has value  $D$  for attribute  $A$ . Moreover, let  $n_A(C)$  be the number of objects  $O$  in all possible worlds such that  $O$  is an instance of class  $C$  and has *some* value for attribute  $A$ . If attribute  $A$  is declared for class  $C$  and for none of  $C$ ’s superclasses, then  $\text{MLE}(\mathbf{u}(D)) = \log(n_A(C, D)/n_A(C))$ . If attribute  $A$  is declared for class  $C$ , then it is also (implicitly) declared for each of its subclasses. Let  $S$  be such a subclass of  $C$ . Then

$$\text{MLE}(\mathbf{u}(D)) = \log \frac{n_A(S, D)/n_A(S)}{n_A(C, D)/n_A(C)}.$$

These are ML estimates precisely because we set the empirical probability, that is, the probability of an instance of class  $S$  having attribute value  $D$ , to the exponentiated sum of the weight estimates for  $S$  and all its superclasses. If the distribution is identical for a class and one of its subclasses,

```

Class Capital {
  parts s City, o Country;
  attributes distance  $\mathbb{R} \mathbf{u}_1$ ;
}
Class Country {
  subclasses USA 1.1, ..., Italy 0.4;
  attributes area  $\mathbb{R} \mathbf{u}_3$ , image Images  $\mathbf{u}_4$ ;
}
Class Paris {
  founded  $\mathbb{N} \mathbf{u}_8$ ;
}

```

Table 2: Example class and object declarations of the TPKB based on the DBPEDIA ontology.

the MLE is 0 and we do not have to explicitly represent the attribute parameters for the subclass. This is advantageous as it results in sparser TPKBs. Note also that this parameterization is useful as we may not know an object’s most specific class during inference time.

The ML estimates for attributes with continuous distributions are derived analogously. As before, the ML estimate is based on the sufficient statistics for the attribute at class  $C$  and its superclass for which the attribute is also declared. For instance, for Gaussian variables, we compute the mean and standard deviation, and the MLE for the weight function for  $S$  subclass of  $C$  is

$$\text{MLE}(\mathbf{u}(x)) = \log \frac{(x - \mu_S)^2 / \sigma_S^2}{(x - \mu_C)^2 / \sigma_C^2}.$$

Relations are similar to Boolean attributes except that for relations we represent the positive case only. The weight of a relation at a class is the log ratio of the positive and negative count differences.

In order to smooth distributions that are defined on multiple levels of the class hierarchy, we recursively average the estimate for each class with the estimate for the superclass, with the combination weights determined by a form of cross-validation [18]. There are more sophisticated variants of shrinkage and other forms of hierarchical smoothing, but we leave this to future work.

So far, we have assumed that the training data is complete, that is, that for every object its class, its attribute values, and the truth values of relations are given. If attribute values, classes, or relation values are missing in the training data, we can use the EM algorithm [3], alternating between inferring the distributions of the missing values and finding the MLEs.

Structure learning involves the learning of the part decomposition and the class hierarchy. While this is beyond the scope of this paper, possible directions include adapting LearnSPN [9] and LearnRSPN [20] to TPKBs.

## TPKBS FOR INFORMATION EXTRACTION

There are several information extraction projects such as NELL [2], DBPEDIA [16, 1], the Google Knowledge Vault [5], and REVERB [7]. These systems parse large amounts of text and semi-structured data sources. Typical extractions are of the form  $\langle m_s, m_p, m_o \rangle$  where  $m_s$  is a *mention* of the subject,  $m_p$  of the predicate, and  $m_o$  of the object of a sentence. For instance,  $\langle \text{Obama, graduated from, Columbia} \rangle$ . A common problem is the grounding of these extractions in a canonical KB such as DBPEDIA. It is a challenging problem due to the inherent ambiguities of extractions and the problem of representing context. For instance, in the above example extractions, the mention *Obama* might refer to numerous individuals; *Columbia* to the district, the university, or a number of other possible entities; and *graduated from* might express that someone graduated from high school, college, etc. Only in conjunction with background knowledge is it possible to infer that the extraction mentions Barack Obama, 44th President of the US, and his being a graduate of Columbia University in New York.

We propose to use TPKBs to address the problem of joint entity linking. The TPKB has three objects  $s$ ,  $p$ , and  $o$ , representing the latent canonical subjects, predicates, and objects of extractions. Every possible class of the object  $p$  represents a relation type. For instance, DBPEDIA's canonical relation type `alumni`, which expresses a person having graduated from a university, is such a class. The representation of relation types as classes of object pairs is advantageous due to the type-token distinction: in order to perform entity linking one has to model objects as classes, not constants, since one predicts the class membership of  $s$  and  $o$  from their attributes. Since objects are represented as classes, we cannot use TPKB relations and, instead, represent relation types as classes of object pairs.

The objects  $s$  and  $o$  are declared as parts of object  $p$ . The classes of  $s$  and  $o$  depend on the class in which they were declared. For instance, in class `alumni`,  $s$  is declared to be of class `Person` and  $o$  to be of class `University`. In class `capital`,  $s$  is declared to be of class `populatedPlace` and  $o$  of class `City`. Objects  $s$  and  $o$  are declared as parts of  $p$  only in classes representing relations without subrelations.

The class hierarchy consists of three trees, representing the class structure of objects  $o$ ,  $s$ , and  $p$ , respectively. The leaf classes of the class trees of  $s$  and  $o$  are classes that represent canonical entities such as `BarackObama`. The structure of this TPKB allows us to model the dependencies between attributes, classes, and relation types in a tractable and principled way. It also allows us to disambiguate extractions based on geographical, temporal, and other numerical attributes in a principled manner.

Once the parameters of the TPKB are estimated, we can perform entity linking. For instance, given the extraction  $\langle \text{Obama, graduated from, Columbia} \rangle$  we compute the probability of the mention *Obama* referring to the canonical entity `BarackObama` using the query  $P(Q | E)$  with  $Q = \{Is(s, BarackObama)\}$  and  $E = \{mention(s, Obama), mention(p, graduated from), mention(o, Columbia)\}$ , where *mention* is an attribute modeling mentions.

### Experiments

We derived the class trees for objects  $s$  and  $o$  directly from the DBPEDIA ontology [16, 1]. The class tree for object  $p$  is derived from the relations in DBPEDIA, that is, every relation type in DBPEDIA is represented with a class object that  $p$  can be an instance of. In addition to the classes and relation types taken from the DBPEDIA ontology, we created one leaf class for each canonical entity. For instance, the DBPEDIA entity `BarackObama` is a leaf in the class hierarchy with attributes `birthYear`, `mention`, etc. Table 2 depicts a small selection of class declarations.

For several attributes such as `birthYear`, `elevation`, `geocoordinates`, etc. we used data from DBPEDIA to learn the parameters. To learn the attribute distributions for leaf classes, that is, classes modeling entities, we assumed a uniform distribution if, for one entity, more than one value was given for a particular attribute. For instance, if `Arnold` has values 1947 and 1946 for attribute `birthYear` then, following the maximum-likelihood principle, we assume that both values have probability 0.5. For the other classes, we pooled attribute values of the instances of each class and used histograms to model these distributions. For the attribute `mention` modeling mentions we used the WIKIPREP tool [8] to compute the conditional distribution of a canonical entity given a mention. We also learned the parameters of attributes for classes representing relation types. For instance, we introduced the attribute `diffBirthYear` which models a distributions over the absolute value of birth year differences.

The number of parameters of the resulting TPKB exceeds 1 billion and we model more than 1 million objects. We performed inference by running Algorithm 1 using a MySQL database system. Each query was answered in less than one second. The reduction in running time for computing the partition function was 31% for 2 cores, 47% for 4 cores, 49% for 6 cores, and 50% for 8 cores. We evaluated the learned TPKB empirically on two important problem classes.

### Entity Linking

For the entity linking experiments we used an existing gold standard [6] for aligning NELL triples to DBPEDIA entities. For each NELL triple of the form  $\langle m_s, m_p, m_o \rangle$ , we

| NELL relation              | Precision@1 |             |             | Recall@1    |             |       |

Table 3: Results for entity resolution experiments (left) and entity linking experiments (right). Bold numbers indicate significance (paired t-test;  $p < 0.05$ ) compared to the baselines.

performed the following two queries. The query (TPKB1)

$$P(\{Is(s, x), Is(o, y)\} \mid \{mention(s, m_s), mention(o, m_o)\})$$

asks for the marginal probability of  $s$  being entity  $x$  and  $o$  being entity  $y$ , conditioned on the NELL triple’s mentions. The result is a list of substitutions for variables  $x$  and  $y$  and the corresponding marginal probabilities.

We proceeded to manually align the subject and object mention with their classes in the TPKB. For instance, for the triple  $\langle \text{Obama, graduated from, Columbia} \rangle$ , we aligned Obama to the class Politician and Columbia to the class University. We then performed the previous query except that we added the set  $\{Is(s, C_s), Is(o, C_o)\}$  to the evidence (TPKB2). This query retrieves the probabilities of  $s$  being entity  $x$  and  $o$  being entity  $y$ , conditioned on the mentions and their class memberships. The results are given in Table 3 (left) and compared with a baseline given in [6]. There are other possible baselines such as matrix factorization methods [21, 29]. However, it is non-trivial to use these methods for the entity linking problem. This is because we have only mentions of entities and no data that links these mentions to relations and attributes in the canonical KBs. Precision@ $k$  and Recall@ $k$  is computed by retrieving the  $k$  most probable answer tuples. The results of the TPKB outperform the WikiLink baseline [6] substantially and are as efficient to compute. TPKB2, however, should only be used if high precision results are required.

### Entity Resolution

Entity resolution is the problem of determining whether two entities in two knowledge bases are equivalent. To evaluate the TPKB for entity linking we repeated the experiment of linking YAGO [12] to DBPEDIA conducted to evaluate the PARIS matching system [30]. Both knowledge bases use Wikipedia identifiers for their objects which gives us a large set of gold standard pairs for evaluation purposes. We manually aligned a set of attributes (datatype

properties) and classes between YAGO and the learned TPKB. We sampled 100,000 objects in YAGO, retrieved the aligned attributes for each object (labels, numerical attributes, etc.) and ran, for each entity, the query above, where we condition on the given value of attribute mention (TPKB1); and all other attributes for which a manual alignment existed (TPKB2). Table 3 shows that TPKBs are able to accurately link entities and compare favorably with specialized algorithms.

The learned TPKB is both efficient and accurate, outperforming existing problem-specific approaches.

## CONCLUSION

We presented a novel inference algorithm for TPKBs that is disk-based, parallel, and sublinear. We also derived closed-form maximum likelihood estimates for TPKB parameters. We used these results to learn a large TPKB from multiple data sources and applied it to information extraction and integration problems. The TPKB outperformed existing algorithms in accuracy and efficiency.

Future work will be concerned with more sophisticated smoothing approaches, the comparison of different learning strategies, and the problem of structure learning. We also plan to apply TPKBs to a wide range of problems that benefit from tractable probabilistic knowledge representations.

An open-source implementation of TPKBs is available at [alchemy.cs.washington.edu/lite2](http://alchemy.cs.washington.edu/lite2).

## Abstract

Arriving at the complete probabilistic knowledge of a domain, i.e., learning how all variables interact, is indeed a demanding task. In reality, settings often arise for which an individual merely possesses partial knowledge of the domain, and yet, is expected to give adequate answers to a variety of posed queries. That is, although precise answers to some queries, in principle, cannot be achieved, a range of plausible answers is attainable for each query given the available partial knowledge. In this paper, we propose the Multi-Context Model (MCM), a new graphical model to represent the state of partial knowledge as to a domain. MCM is a middle ground between Probabilistic Logic, Bayesian Logic, and Probabilistic Graphical Models. For this model we discuss: (i) the dynamics of constructing a contradiction-free MCM, i.e., to form partial beliefs regarding a domain in a gradual and probabilistically consistent way, and (ii) how to perform inference, i.e., to evaluate a probability of interest involving some variables of the domain.

## 1 INTRODUCTION

At an abstract level, an individual (also referred to as a reasoner) is faced with a domain where by “domain” we simply mean a collection of propositions or concepts which are mathematically encoded as Random Variables (RVs). To arrive at the complete probabilistic knowledge of the domain, i.e., to learn how all RVs in the domain probabilistically interact with one another, is indeed a demanding task. In reality, an individual is often faced with a domain for which she merely possesses *partial* knowledge—that is, she only knows how *some* (not all) RVs in the domain interact. To make the setting under study more tangible, consider the following case. Suppose that the probabilistic knowledge of a domain is represented by a Probabilis-

tic Graphical Model (PGM)  $\mathcal{B}$ , e.g., a Bayesian Network (BN). Then the reasoner comes across a new RV, say  $\psi$ , and would like to incorporate it into  $\mathcal{B}$  so as to achieve the complete probabilistic knowledge of the new domain (which now also includes  $\psi$ ). However, incorporation of  $\psi$  into  $\mathcal{B}$  would require knowledge of how  $\psi$  is probabilistically related to all the RVs already present in  $\mathcal{B}$ ; a knowledge which may be, quite plausibly, unavailable to the reasoner. An interesting question that now arises is how to handle situations where only partial knowledge as to how  $\psi$  is probabilistically related to  $\mathcal{B}$  is available. An example would be when the reasoner merely knows how  $\psi$  interacts probabilistically with only one RV, say  $\phi$ , in  $\mathcal{B}$ .

In this paper, a graphical model, namely, the Multi-Context Model (MCM) is proposed to represent the setting in which only partial probabilistic knowledge of a domain is available to the reasoner. More specifically, MCM is a graphical language to represent settings in which the Joint Probability Distribution (JPD) over all RVs is not available, but what is available instead is the JPDs over a collection of subsets of RVs of the domain (referred to as sub-domains or *contexts*). These contexts are potentially overlapping, i.e., they could share some RVs. As pointed out elegantly in (Pearl 1990), “*this state of partial knowledge is more common, because we often begin thinking about a problem through isolated frames, paying no attention to interdependencies.*” Along the same line of thought, it is plausible to assume that the probabilistic knowledge of the domain at the early primitive stage consists of a collection of disjoint contexts and as the reasoner acquires more knowledge as to how the variables in the model are related to one another and thus probabilistically interact, contexts gradually go through a process very much like an evolution: contexts start to share some variables, overlaps begin to emerge and, once enough knowledge is obtained, a number of contexts could merge thereby giving rise to bigger contexts. This naturally raises the following fundamental question: How could a collection of consistent, probabilistically sound, and potentially overlapping contexts emerge *gradually* over the course of time? In an attempt to answer this question we present a generative process of constructing a contradiction-free

MCM. Finally, we would like to note that the special case where the whole domain is modeled as a single context corresponds to the conventional way of modeling the probabilistic knowledge of a domain using a single PGM, e.g., by some BN.

Another yet crucial question which we address in this work—which is another motivation behind the development of the MCM—is how the task of inference (i.e., the evaluation of some probability of interest which is hereafter referred to as *query*) should be carried out in a domain which is modeled according to some MCM. A query does not necessarily belong to any one of the contexts in particular and, in fact, may involve RVs from different contexts.

The paper is structured as follows. After introducing the notation in Sec. 2, we define in Sec. 3 the MCM and drawing on the notion of probabilistic conditioning, a generative process of constructing a contradiction-free MCM is discussed. Then, in Sec. 4 we elaborate on the problem of inference in a multi-context setting, i.e., in a domain whose probabilistic knowledge is encoded as an MCM. In Sec. 5 we discuss the relevant past work and comment on the proposed model. Finally, Sec. 6 concludes the paper.

## 2 TERMINOLOGY AND NOTATION

In this section we present the mathematical notation and the terminology employed in this paper. Random quantities are denoted by bold-faced letters; their realizations are denoted by the same letter but non-bold. More specifically, RVs are denoted by lower-case bold-faced letters, e.g.,  $\mathbf{x}$ , while random vectors are denoted by upper-case bold letters, e.g.,  $\mathbf{X}$ .  $Val(\cdot)$  denotes the set of values a random quantity can take, e.g.,  $Val(\mathbf{x})$  is the set of all possible realizations of the RV  $\mathbf{x}$ . In this paper, we assume that all random quantities are discrete.

The JPD over the RVs  $\mathbf{x}_1, \dots, \mathbf{x}_n$  is denoted by  $\mathbb{P}(\mathbf{x}_1, \dots, \mathbf{x}_n)$ ; when  $\mathbf{x}_1, \dots, \mathbf{x}_n$  comprise a vector  $\mathbf{X}$  then  $\mathbb{P}(\mathbf{X}) := \mathbb{P}(\mathbf{x}_1, \dots, \mathbf{x}_n)$ . We will use the notation  $\mathbf{x}_{1:n}$  to denote the sequence of  $n$  RVs  $\mathbf{x}_1, \dots, \mathbf{x}_n$ . To simplify presentation and to prevent our expressions from becoming cumbersome, we incur the following abuse of notation: We denote the probability  $\mathbb{P}(\mathbf{x} = x)$  by  $\mathbb{P}(x)$  for some RV  $\mathbf{x}$  and its realization  $x \in Val(\mathbf{x})$ . Also,  $\mathbb{P}(\bar{x}) := \mathbb{P}(\mathbf{x} \neq x) = 1 - \mathbb{P}(x)$  for some  $x \in Val(\mathbf{x})$ , i.e.,  $\mathbb{P}(\bar{x})$  is the probability that  $\mathbf{x}$  takes on any value other than  $x$ . For conditional probabilities we will use the notation  $\mathbb{P}(x|y)$  instead of  $\mathbb{P}(\mathbf{x} = x|\mathbf{y} = y)$ . Similar notations will be used for the case of random vectors, i.e.,  $\mathbb{P}(X) := \mathbb{P}(\mathbf{X} = X)$ ,  $\mathbb{P}(\bar{X}) := \mathbb{P}(\mathbf{X} \neq X) = 1 - \mathbb{P}(\mathbf{X} = X) = 1 - \mathbb{P}(X)$ , and  $\mathbb{P}(X|Y) := \mathbb{P}(\mathbf{X} = X|\mathbf{Y} = Y)$ .

The subscript  $\downarrow$  on a probability, e.g.,  $\mathbb{P}(x|y)_{\downarrow}$ , denotes the minimum value the probability can take subject to the constraints induced by the available probabilistic knowl-

edge. Likewise, the subscript  $\uparrow$  on a probability denotes the maximum value the probability can take. Finally, the operator  $[\cdot]^+$  gives the positive part of its argument, i.e.,  $[a]^+ := \max\{0, a\}$  for any real-valued  $a$ .

## 3 MULTI-CONTEXT MODEL

As explained earlier, a *domain* is simply the set of all Random Variables (RVs) at hand. A *context* comprises a collection of RVs for which their JPD is precisely known, see Fig. 1(a). In general, two contexts could be disjoint (Fig. 1(b)) or overlapping (Fig. 1(c)).

Figure 1: Graphical representation of contexts: (a) Context associated to  $\mathbb{P}(\mathbf{a}, \mathbf{b}, \mathbf{X})$ . (b) Two disjoint contexts associated to  $\mathbb{P}(\mathbf{a}, \mathbf{b})$  and  $\mathbb{P}(\mathbf{Y}, \mathbf{t})$ . (c) Two overlapping contexts associated to  $\mathbb{P}(\mathbf{X}, \mathbf{Y}, \mathbf{t})$  and  $\mathbb{P}(\mathbf{Y}, \mathbf{z}, \mathbf{k})$ . The random vector  $\mathbf{Y}$  is referred to as the *induced* part in Sec. 3.

A *Multi-Context Model (MCM)* encodes the probabilistic knowledge of a domain as a collection of possibly overlapping contexts. This enables the handling of situations in which comprehensive knowledge of a domain is not available, but partial information is, in the form of JPDs of some subsets of the domain. Let us first motivate the proposed MCM by entertaining a simple yet enlightening example.

### 3.1 MOTIVATING EXAMPLE

Consider a domain consisting of the RVs  $\mathbf{y}, \mathbf{z}$  in addition to a set of  $n$  RVs,  $\mathbf{x}_{1:n}$ . A reasoner has formed a partial belief as to the probabilistic connections between the variables of the domain. More specifically, the reasoner knows precisely the JPDs  $\mathbb{P}(\mathbf{y}, \mathbf{z})$  and  $\mathbb{P}(\mathbf{x}_{1:n})$  but not the JPD  $\mathbb{P}(\mathbf{y}, \mathbf{z}, \mathbf{x}_{1:n})$ . This setting is described by an MCM that consists of two disjoint contexts, one associated to RVs  $\mathbf{y}, \mathbf{z}$  and the other to  $\mathbf{x}_{1:n}$ , as shown in Fig. 2.

Figure 2: Problem statement as an MCM.

Assume that the following query is posed: Given the available information, what could be said about  $\mathbb{P}(y|x_i)$  for some  $i = 1, \dots, n$ ? The RVs  $\mathbf{y}$  and  $\mathbf{x}_i$  belong to different contexts, therefore, the JPD of  $\mathbf{y}$  and  $\mathbf{x}_i$ ,  $\mathbb{P}(\mathbf{x}_i, \mathbf{y})$ , is not available. The best one can hope for is to derive the range within which  $\mathbb{P}(y|x_i)$  varies, namely,  $[\mathbb{P}(y|x_i)_{\downarrow}, \mathbb{P}(y|x_i)_{\uparrow}]$ .

Let us for the moment assume the objective is to find  $\mathbb{P}(y|x_i)_\downarrow$ . Based on the conventional methodology, i.e., the approach adopted by past work (cf. (Andersen and Hooker 1990; 1994; Hansen et al. 1995) and references therein) one has to write down *all* the information as a list of linear equations and solve it as a Linear Program (LP). The main drawback of the conventional approach is that it cannot distinguish between what information is relevant and what is irrelevant for the posed query, and hence what needs to and what need not be considered in answering the query. The price for this is that the number of parameters required to merely formulate the query as an LP is exponential in  $n$ .

The key point, however, is that what information is relevant (or irrelevant) depends directly on the posed query, i.e., it is query-dependent. The main advantage of the proposed MCM over previous approaches is that it enables answering a query in a computationally efficient manner by distinguishing the relevant information from the irrelevant for the given query. This is realized through adopting the notion of *inference grammar*; a concept which will be systematically defined later. For our example, following the inference rule we will provide in Sec. 4.2, one can easily get  $\mathbb{P}(y|x_i)_\downarrow = \left[ \frac{\mathbb{P}(y) - \mathbb{P}(\bar{x}_i)}{\mathbb{P}(x_i)} \right]_+$ .

The task of inference in an MCM is carried out on two different levels, which makes the task more computationally efficient:

- (i) High-Level Reasoning: at this level, through the use of inference grammar, the relevant quantities are identified (e.g.,  $\mathbb{P}(y)$  and  $\mathbb{P}(\bar{x}_i)$  in the case of our example).
- (ii) Low-Level Reasoning: the relevant quantities, identified in (i), can then be computed by employing inference algorithms which take advantage of the potentially rich independence structure governing the contexts. For example, it could very well be the case that for the JPD associated to  $\mathbf{x}_{1:n}$  a large number of conditional independence relations hold. In that case, stating the derivation of  $\mathbb{P}(\bar{x}_i)$  (i.e.,  $1 - \mathbb{P}(x_i)$ ) as an LP would be computationally inefficient<sup>1</sup> but unnecessary. Indeed, the task of finding  $\mathbb{P}(\bar{x}_i)$  could be accomplished in a computationally efficient way using one of the many inference methods developed for probabilistic graphical models; a key point that the previous approaches do not take advantage of.

As a final step, in order to derive the lower/upper bound to the posed query, the quantities identified in (i) and subsequently calculated in (ii) are stated and solved as an LP.

The idea behind “high-level reasoning” will be explained and clarified further in Sec. 4.2 and 4.3, while the concept

<sup>1</sup>The number of parameters required just to state the problem as an LP is exponential in  $n$ .

of “low-level reasoning” will be discussed in Sec. 4.1.

### 3.2 GENERATIVE PROCESS OF CONTRADICTION-FREE MCMS

The objective of the generative process we describe in this section is to provide a way to consistently<sup>2</sup> construct contexts, in a sequential manner, over a set of RVs. The act of constructing a context, i.e., of assigning a JPD to a subset of RVs, corresponds to forming a *subjective*<sup>3</sup> belief over those RVs. In this light, the act of constructing multiple contexts corresponds to *gradually* forming subjective beliefs over a number of subsets of variables in the domain; hence every context symbolizes an established belief over the RVs involved in that context.

We introduce this problem by considering a simple case shown in Fig. 3(a). Suppose there are three RVs, namely,

Figure 3: Generative process for contradiction-free Multi-Context Model. The dash-dotted contexts cannot be freely assigned.

$\mathbf{x}$ ,  $\mathbf{y}$ , and  $\mathbf{z}$ , present in the domain and let us consider the following question: Could one assign  $\mathbb{P}(\mathbf{x}, \mathbf{y})$  and  $\mathbb{P}(\mathbf{y}, \mathbf{z})$ , *freely* and *gradually* in a consistent manner, over the three variables without introducing any sort of contradiction? It is easy to verify that the answer is positive. Indeed, one could start off by assigning  $\mathbb{P}(\mathbf{x}, \mathbf{y})$ . This assignment would, of course, induce the marginal  $\mathbb{P}(\mathbf{y})$  and one can write  $\mathbb{P}(\mathbf{y}, \mathbf{z}) = \mathbb{P}(\mathbf{y})\mathbb{P}(\mathbf{z}|\mathbf{y})$ . Then, to complete this task, one would just need to proceed with assigning  $\mathbb{P}(\mathbf{z}|\mathbf{y})$ . This process could be referred to as a *generative* process of the assignment of  $\mathbb{P}(\mathbf{x}, \mathbf{y})$  and  $\mathbb{P}(\mathbf{y}, \mathbf{z})$  over  $\mathbf{x}$ ,  $\mathbf{y}$ , and  $\mathbf{z}$  without introducing any inconsistencies, in a gradual manner. Indeed, free-assignment refers to the act of freely assigning the non-induced, e.g.,  $P(\mathbf{z}|\mathbf{y})$ , part of the *to-be-formed* belief, e.g.,  $P(\mathbf{y}, \mathbf{z})$ . In other words, free-assignment signifies the observation that the already-formed belief does not impose any constraints on the non-induced part of the to-be-formed belief.

<sup>2</sup>That is, without introducing any form of contradictory result with respect to any probability assignment.

<sup>3</sup>One must not interpret the subjectivity of belief as “total disconnectivity from the reality.” Thus, we adopt the Bayesian interpretation of probability in this section. The avid reader is referred to (Chalmers 1976). An adherent to the frequentist interpretation of probability could think of contexts as being empirically constructed from a collection of data and thus skip Sec. 3.2 and proceed directly to the next section.

Let us now consider the case shown in Fig. 3(b). Could one assign  $\mathbb{P}(\mathbf{x}, \mathbf{y})$ ,  $\mathbb{P}(\mathbf{y}, \mathbf{z})$ , and  $\mathbb{P}(\mathbf{x}, \mathbf{z})$  freely and gradually in a consistent manner over the three variables without introducing any sort of contradiction? After some investigation, one can see that the answer is negative (Pearl 1985). Not surprisingly, the reason for this has to do with the existence of a loop in the model: once  $\mathbb{P}(\mathbf{x}, \mathbf{y})$  and  $\mathbb{P}(\mathbf{y}, \mathbf{z}) = \mathbb{P}(\mathbf{y})\mathbb{P}(\mathbf{z}|\mathbf{y})$  are assigned<sup>4</sup>, then  $\mathbb{P}(\mathbf{x}, \mathbf{z})$  cannot be assigned freely. This is due to the fact that  $\mathbb{P}(\mathbf{x}, \mathbf{z})$  has to satisfy some non-trivial conditions imposed by the already assigned contexts  $\mathbb{P}(\mathbf{x}, \mathbf{y})$  and  $\mathbb{P}(\mathbf{y}, \mathbf{z})$  (Pearl 1985).

In summary, whenever it comes to generating a new context, the JPD associated to that context has to be separated into two parts: (i) the part induced by the already existing contexts, and (ii) the part containing new variables which have never been so far associated to any context (i.e., non-induced part). The key point in the generation of contradiction-free MCMs is that the former part has to be induced by some context which, itself, is already present in the domain. That is, all the induced parts have to be already contained within some context. Otherwise, to include the induced parts—each constrained by the context it is already in—in a new context, the newly created context would have to satisfy some nontrivial constraints and therefore could not be *freely* assigned.

Figure 4: MCM for  $\mathbb{P}(\mathbf{a}, \mathbf{b}, \mathbf{c})$ ,  $\mathbb{P}(\mathbf{b}, \mathbf{d})$ , and  $\mathbb{P}(\mathbf{b}, \mathbf{c}, \mathbf{e})$ .

Let us discuss one final case to further clarify the process. Consider the multi-context model in Fig. 4. Could this model be constructed freely and gradually in a probabilistically consistent manner? The answer is positive. We first assign  $\mathbb{P}(\mathbf{a}, \mathbf{b}, \mathbf{c})$ , then we assign  $\mathbb{P}(\mathbf{b}, \mathbf{c}, \mathbf{e}) = \mathbb{P}(\mathbf{b}, \mathbf{c})\mathbb{P}(\mathbf{e}|\mathbf{b}, \mathbf{c})$  where  $\mathbb{P}(\mathbf{b}, \mathbf{c})$  is induced by our first assignment of  $\mathbb{P}(\mathbf{a}, \mathbf{b}, \mathbf{c})$ . Finally, we assign  $\mathbb{P}(\mathbf{b}, \mathbf{d}) = \mathbb{P}(\mathbf{b})\mathbb{P}(\mathbf{d}|\mathbf{b})$  where  $\mathbb{P}(\mathbf{b})$  is induced by our first assignment of  $\mathbb{P}(\mathbf{a}, \mathbf{b}, \mathbf{c})$ . A closer look reveals that this is not the only way we can gradually construct a contradiction-free model in this case: we could have performed the assignments in a different order<sup>5</sup>. Of course, the only thing which would have been different would be the induced probabilities. That is, if one does the assignment in the following

<sup>4</sup> $\mathbb{P}(\mathbf{y})$  is induced by the assignment of  $\mathbb{P}(\mathbf{x}, \mathbf{y})$ .

<sup>5</sup>Yet, this is not always the case: suppose there are four RVs in the domain, namely,  $\mathbf{a}$ ,  $\mathbf{b}$ ,  $\mathbf{c}$  and  $\mathbf{d}$  and we would like to assign  $\mathbb{P}(\mathbf{a}, \mathbf{b})$ ,  $\mathbb{P}(\mathbf{b}, \mathbf{c})$ , and  $\mathbb{P}(\mathbf{c}, \mathbf{d})$ . Performing the assignments in the order (1) –  $\mathbb{P}(\mathbf{a}, \mathbf{b})$ , (2) –  $\mathbb{P}(\mathbf{b}, \mathbf{c})$ , (3) –  $\mathbb{P}(\mathbf{c}, \mathbf{d})$  would not introduce any inconsistencies, in contrast to using the order (1) –  $\mathbb{P}(\mathbf{a}, \mathbf{b})$ , (2) –  $\mathbb{P}(\mathbf{c}, \mathbf{d})$ , (3) –  $\mathbb{P}(\mathbf{b}, \mathbf{c})$ .

order: (1)– $\mathbb{P}(\mathbf{b}, \mathbf{d})$ , (2)– $\mathbb{P}(\mathbf{a}, \mathbf{b}, \mathbf{c})$ , (3)– $\mathbb{P}(\mathbf{b}, \mathbf{c}, \mathbf{e})$  then the first assignment of  $\mathbb{P}(\mathbf{b}, \mathbf{d})$  will induce  $\mathbb{P}(\mathbf{b})$  for the second assignment of  $\mathbb{P}(\mathbf{a}, \mathbf{b}, \mathbf{c}) = \mathbb{P}(\mathbf{b})\mathbb{P}(\mathbf{a}, \mathbf{c}|\mathbf{b})$  and the second assignment will induce  $\mathbb{P}(\mathbf{b}, \mathbf{c})$  for the third assignment  $\mathbb{P}(\mathbf{b}, \mathbf{c}, \mathbf{e}) = \mathbb{P}(\mathbf{b}, \mathbf{c})\mathbb{P}(\mathbf{e}|\mathbf{b}, \mathbf{c})$ .

## 4 INFERENCE IN MCMS

In this section we consider *evidential* inference problems in multi-context settings. The objective is to evaluate (to the extent possible) a probability of the form  $\mathbb{P}(\mathbf{O} = O|\mathbf{E} = E)$ , called a *query*, where  $\mathbf{O}$  and  $\mathbf{E}$  are two mutually exclusive sets of RVs. The set  $\mathbf{E}$  is the set of evidence variables and  $\mathbf{O}$  is the set of RVs for which we are interested in knowing with what probability they take on the value  $O$ , upon the observation of  $\mathbf{E} = E$ . In multi-context settings, inference problems can be categorized into two broad classes:

- Intra-Contextual Inference Problems: For which the sets  $\mathbf{E}$  and  $\mathbf{O}$  both belong to the same context.
- Inter-Contextual Inference Problems: For which the sets  $\mathbf{E}$  and  $\mathbf{O}$  do not belong to a single context and, therefore, more than one context is involved in the inference problem.

In what follows, we will elaborate on these two cases.

### 4.1 INTRA-CONTEXTUAL INFERENCE PROBLEM

One advantage of MCMs is that, once an inference problem is found to be an intra-contextual inference problem, one can take advantage of the rich independence structure potentially governing the context to accomplish the task of inference in a computationally efficient way. For instance, if the probabilistic knowledge of a context is presented in a form of a BN, then one can benefit from a variety of exact or approximate methods already developed for BNs. For a comprehensive study of such methods the reader is referred to (Koller and Friedman 2009). Hence, it is of great interest to have contexts whose probabilistic knowledge can be represented in some form of a PGM with sufficiently rich independence structure for which inference problems can be solved in a computationally efficient way. For example, if the probabilistic knowledge of a context is to be modeled according to some BN, we would like that BN to be as sparsely connected as possible and enjoy low tree-width to ensure computational efficiency for the task of inference (Chandrasekaran, Srebro, and Harsha 2008).

### 4.2 INTER-CONTEXTUAL INFERENCE PROBLEM: INFERENCE GRAMMAR

In this section, we turn our attention to the task of inter-contextual inference. The RVs involved in the query for

the inter-contextual inference problem do not belong to a single context. For this reason, the answer to the query is inevitably in the form of an interval indicating a lower and upper bound for the query. Since  $\mathbb{P}(E|O) + \mathbb{P}(\bar{E}|O) = 1$  we have  $\mathbb{P}(E|O)_\uparrow = 1 - \mathbb{P}(\bar{E}|O)_\downarrow$ . Therefore, we can focus our attention on the minimization problem (i.e., identifying a lower bound to the probability of interest) realizing that any maximization problem (i.e., identifying an upper bound to the probability of interest) could be cast as a minimization problem and vice versa.

First, we are going to consider some simple queries which are posed to some example MCMs. These MCMs are depicted in Fig. 5(a-c). The goal here is to develop some insight as to which variables are indeed relevant and which are deemed irrelevant for a given query and the corresponding MCM.

Figure 5: Sample inference rules given for some inter-contextual inference problems. The RVs involved in the query are shown in blue.

We begin by considering a simple case: the disjoint MCM shown in Fig. 5(a). The rule to evaluate  $\mathbb{P}(X|Y)_\downarrow$  is also given in Fig. 5(a). Interestingly enough, the expression only requires the intra-contextual quantities  $\mathbb{P}(X)$  and  $\mathbb{P}(Y)$  and it does not depend on any other RV present in the domain. In other words, as far as  $\mathbb{P}(X|Y)_\downarrow$  is concerned, the MCM shown in Fig. 5(a) is equivalent to a much simpler MCM: the one corresponding to having only two disjoint contexts described by  $\mathbb{P}(\mathbf{X})$  and  $\mathbb{P}(\mathbf{Y})$ . Next, we take the MCM given in Fig. 5(b) where there is an overlap between the context containing  $\mathbf{X}$  and the one containing  $\mathbf{Y}$ . The overlapping part consists of the random vector  $\mathbf{Z}$ . The rule to evaluate  $\mathbb{P}(X|Y, Z)_\downarrow$  is given in Fig. 5(b). Now, consider the MCM shown in Fig. 5(c) where we have the same setting we had in previous case but a new random variable  $\mathbf{t}$  is added in the overlapping region. Notice that the expression for  $\mathbb{P}(X|Y, Z, t)_\downarrow$  given in Fig. 5(c) is the same expression given for  $\mathbb{P}(X|Y, Z)_\downarrow$  in Fig. 5(b) with the substitution of  $Z, t$  instead of  $Z$ . That is,  $Z$  in Fig. 5(b) and  $Z, t$  in Fig. 5(c) are representing the same thing, namely, “all the variables in the overlapping region”, and in that respect, they are ultimately the same. The rules are

very much like sentences in predicate logic for which variables merely serve as place-holders.

The derivation of the rules given in Fig. 5(a-c) is not presented here. However, using the proof presented in Sec. A-II of Appendix (to identify the relevant variables) and subsequently following the methodology outlined in Sec. A-III of Appendix (to visualize the partitions and reason out the extent they overlap) it should be straightforward to derive the presented rules.

The sample set of rules presented is by no means exhaustive, nonetheless, due to the idea of context transformation that will be discussed in Sec. 4.3, they can be applied to a wide range of interesting inter-contextual inference problems. We would like to clarify that our ultimate objective is *not* to compute and provide the complete set of rules that can answer all possible queries and for all possible MCMs, since simply, the set is infinite in size. What we need, therefore, is an algorithm, let us call it  $\mathcal{I}^*$ , that can provide the answer to the posed query being given an MCM as an input. The presented rules provide insights and hints to the nature of  $\mathcal{I}^*$  which needs to be devised to ideally handle *any* arbitrary query posed to *any*<sup>6</sup> MCM. In a sense, we can get a glimpse of the nature of  $\mathcal{I}^*$  through analyzing the presented rules. In other words, the derived rules serve as a lens through which one can study  $\mathcal{I}^*$ . In Sec. A-I of Appendix a simple version of  $\mathcal{I}^*$  that can handle arbitrary MCMs is outlined.

The motivation behind giving this sample set of rules can now be summarized in the following.

1. To shed light on the general nature of a rule (which reflects on the nature of  $\mathcal{I}^*$ ). More specifically, to illustrate that a rule enjoys two key properties, namely: (i) scale-invariance, (ii) resemblance to sentences in predicate logic, in that in both cases, variables are mere place-holders. For this resemblance we refer to  $\mathcal{I}^*$  as *inference grammar*.
2. To demonstrate that a rule is telling us which intra-contextual quantities are essential and which are irrelevant for a particular inter-contextual query.
3. To emphasize the key property that a rule derived under a specific MCM remains valid for and can be applied to infinitely many other MCMs all of which are linked through the notions of nestedness and transformation; hence generalization is achieved.
4. To lay down the foundation of *transformation* and *nestedness* which both play crucial roles in understanding the underlying machinery behind  $\mathcal{I}^*$ .

<sup>6</sup>Although we believe that the MCMs generated through the generative process outlined in Sec. 3.2 are more cognitively plausible, nonetheless, from a pure mathematical point of view, it would be of interest to find an algorithm which could handle *any* MCM.

Next, we discuss another key property of the inference rules, namely, that of *scale-invariance*. Consider once again the case in Fig. 2. Now let us derive  $\mathbb{P}(x_i|y)_\downarrow$ , and  $\mathbb{P}(X|y)_\downarrow$  where  $\mathbf{X} \triangleq \mathbf{x}_{1:n}$ . Using the rule given in Fig. 5(a), one arrives at the following results:  $\mathbb{P}(x_i|y)_\downarrow = \left[\frac{\mathbb{P}(x_i) - \mathbb{P}(\bar{y})}{\mathbb{P}(y)}\right]^+$ , and  $\mathbb{P}(X|y)_\downarrow = \left[\frac{\mathbb{P}(X) - \mathbb{P}(\bar{y})}{\mathbb{P}(y)}\right]^+$ . In other words, the expressions remain the same, regardless of the dimension of the quantity of interest, i.e., be it a single RV or be it a random vector comprised of many RVs. In this respect, once again, the inference rules resemble expressions in predicate logic. The intuition on the scale invariance is provided in Sec. A-III of Appendix.

It is worth noting that  $\mathcal{I}^*$  formulates the inter-contextual inference problem as a Linear Programming (LP) optimization (cf. Sec. A-I of Appendix). The key issues to consider are: (i) what RVs have to be included in the LP, and (ii) the abstraction level  $\mathcal{I}^*$  should choose to encode the RVs identified in step (i) for the LP, i.e., the parametrization of RVs identified in step (i) for the LP. In what follows, the concepts of nestedness and transformation are put forth. Once the two are introduced, one could apply a single rule (e.g., one in Fig. 5(a)) to a much larger number of MCMs; in fact to infinitely many MCMs.

### 4.3 INTER-CONTEXTUAL INFERENCE PROBLEM: NESTEDNESS AND TRANSFORMATION

Figure 6: Inter-Contextual Inference Problem: Transformation and hierarchical construct. As one proceeds from the left to the right, a more comprehensive knowledge of domain is assumed to be available, of course hypothetically.

The nested property, or *nestedness*, refers to the fact that every MCM can be considered as an element of a family of MCMs. That family contains all MCMs which through marginalization can produce the original MCM. In such a case we simply say that the nested property holds between the original MCM and the family. The process of going from the original MCM to one of the members of the family is referred to as *transformation*. For example, the MCM containing three contexts  $\{\mathbf{x}\}$ ,  $\{\mathbf{y}\}$ , and  $\{\mathbf{z}\}$  shown in Fig. 6(a) is a member of a family of MCMs containing two contexts  $\{\mathbf{x}, \mathbf{y}\}$  and  $\{\mathbf{z}\}$ , shown in Fig. 6(b), one of which is associated to a *family* of JPDs over  $\mathbf{x}$  and  $\mathbf{y}$  (the dash-dotted circle in Fig. 6(b)) which, if marginalized, produces the same  $\mathbb{P}(\mathbf{x})$  and  $\mathbb{P}(\mathbf{y})$  in the original MCM (left-most MCM). Mathematically, the set of all

JPDs over RVs  $\mathbf{x}$  and  $\mathbf{y}$  which, if marginalized, produce specific marginal probability distributions  $\mathbb{P}(\mathbf{x})$  and  $\mathbb{P}(\mathbf{y})$  is denoted by  $\{\mathbb{P}(\mathbf{x}, \mathbf{y})\} \models \mathbb{P}(\mathbf{x}) \wedge \mathbb{P}(\mathbf{y})$ . The notion of the nested property enables us to look at one MCM as a subset of another larger MCM. The nested property, furthermore, enables one to sort MCMs in a hierarchical construct as illustrated in Fig. 6 where moving from the left to the right corresponds to moving from lower levels of hierarchy to higher levels.

Figure 7: Transformation: Sample case.

To convey the idea, consider the case illustrated in Fig. 7. Suppose the query of interest is  $\mathbb{P}(x|y, R)_\downarrow$ . Then, one can first transform the original (left-most) MCM into the MCM shown in the middle, and subsequently into the right-most MCM. Hence, using the right-most MCM and the rule given in Fig. 5(b), one can write  $\mathbb{P}(x|y, R)_\downarrow = \left[\frac{\mathbb{P}(x|R) - \mathbb{P}(\bar{y}|R)}{\mathbb{P}(y|R)}\right]^+ = \left[\frac{\mathbb{P}(x|R) - 1 + \mathbb{P}(y|R)}{\mathbb{P}(y|R)}\right]^+$ . If we had the knowledge of  $\mathbb{P}(y|R)$  then the expression given above would have been sufficient to derive  $\mathbb{P}(x|y, R)_\downarrow$ . However, since  $\mathbb{P}(y|R)$  is *not* known, we need to go through one more step. This is precisely due to, and emphasizes, the fact that by working on the right-most MCM we implicitly presumed that we were equipped with more knowledge than we really had. Using the middle MCM and the rule given in Fig. 5(a), one can conclude  $\mathbb{P}(y|R)_\downarrow = \left[\frac{\mathbb{P}(y) - \mathbb{P}(R)}{\mathbb{P}(R)}\right]^+$ . Altogether<sup>7</sup>,  $\mathbb{P}(x|y, R)_\downarrow = \left(\left[\frac{\mathbb{P}(x|R) - 1 + \mathbb{P}(y|R)}{\mathbb{P}(y|R)}\right]^+\right)_\downarrow = \left[\frac{\mathbb{P}(x|R) - 1 + \mathbb{P}(y|R)_\downarrow}{\mathbb{P}(y|R)_\downarrow}\right]^+$ . It is worth noting that the same rule would apply if instead of the random vector  $\mathbf{R}$  we were dealing with the random variable  $\mathbf{a}$ , i.e., to find  $\mathbb{P}(x|y, a)_\downarrow$  one could use the same expression given for  $\mathbb{P}(x|y, R)_\downarrow$  by substituting  $a$  in place of  $R$  in all the expressions. Arguments of this kind are made possible due to the idea of transformation which enables us to analyze the transformed MCM (e.g., the middle one in Fig. 7) rather than the original MCM (the left-most one in Fig. 7). Furthermore, the concept of transformation highlights a key idea: if a piece of information (i.e., an intra-contextual quantity) is irrelevant in the transformed MCM for the posed query, it must have been irrelevant in the original MCM in the first place. This statement, once again, sheds light on what intra-contextual quantities are relevant or irrelevant to derive a posed inter-contextual query on a given MCM.

<sup>7</sup>This is due to the observation that for function  $f(y) = \left(\frac{k+y}{y}\right)$  when  $k < 0$ ,  $\min_{1 \geq y \geq t > 0} f(y) = \left(\frac{k+t}{t}\right)$ .

## 5 DISCUSSION

We will now discuss related work so as to build a connection between ours and previous attempts to incorporate partial probabilistic knowledge of a domain in the task of inference.

Attempting to combine Probabilistic Logic and BNs, the authors in (Andersen and Hooker 1990; 1994) formulate the inference problem as an optimization problem subject to non-linear constraints so as to incorporate the conditional independence relations embedded in the BN. However, in our proposed framework, the issue of dealing with conditional independence relations does not arise at all, because these relations are dealt with during the derivation process of intra-contextual probabilities.

The authors of (Hansen et al. 1995) point out that one could avoid non-linear optimization when the value for a conditional probability is at least imprecisely known. For example, the constraint  $\mathbb{P}(a|b) = \mathbb{P}(a)$ , if the value for  $\mathbb{P}(a)$  is known either precisely or imprecisely within some interval  $[\alpha, \beta]$ , can be written as

$$\frac{\mathbb{P}(a, b)}{\mathbb{P}(b)} = \mathbb{P}(a) \in [\alpha, \beta] \Leftrightarrow \begin{cases} \mathbb{P}(a, b) - \alpha\mathbb{P}(b) > 0, \\ \mathbb{P}(a, b) - \beta\mathbb{P}(b) < 0. \end{cases}$$

Hence, the independence  $\mathbb{P}(a|b) = \mathbb{P}(a)$  can be formulated as a number of linear constraints. However, the main drawback of this approach is that encoding a conditional independence relation such as  $\mathbb{P}(\mathbf{x}|\mathbf{y}, \mathbf{a}_1, \dots, \mathbf{a}_n) = \mathbb{P}(\mathbf{x}|\mathbf{y})$  requires a number of linear equations that is exponential in  $n$  to be introduced into the optimization problem (Andersen and Hooker 1994).

Drawing on the idea of Context-Specific Independence (CSI) (Boutilier et al. 1996), the authors of (Geiger and Heckerman 1991) propose the Bayesian Multinet model which aims at taking advantage of the existing CSIs to perform inference, by modeling a single BN as multiple context-specific BNs. Translated into our multi-context setting, the Bayesian Multinet model corresponds to the case where the whole domain is modeled as a single BN, i.e., a single-context MCM, that can be decomposed into multiple BNs each being valid for a specific instantiation of some RVs in the domain.

The authors of (Thone, Guntzer, and Kiebling 1992) point out the same concerns which led us to propose MCM, namely: (i) If unverified (in)dependencies are imposed between the variables in the domain then implausible results may arise; (ii) PGMs require one to have complete probabilistic knowledge of a domain which may not be available. Motivated by these, (Thone, Guntzer, and Kiebling 1992) gives a collection of rules to carry out inference in a domain. Broadly speaking, this work is similar to ours in spirit with the main distinction being the level of abstraction chosen to perform inference. In (Thone, Guntzer, and

Kiebling 1992) inference is performed in a very local and rule-based fashion and conditional independence relations are dealt with directly which complicates the task at hand; a task which is futile when it comes to dealing with domains of many variables. In our case, by introducing the notion of context and encoding conditional independence relations within contexts we avoid having to contemplate the intra-contextual inference problem and leave this task for the corresponding context. This way, we can take advantage of the possibly rich independence structure governing the context and carry out the intra-contextual inference problem in a computationally efficient manner.

Finally, let us discuss some interesting aspects of the proposed model.

The degree of belief is encoded mathematically in the form of a probability distribution over the variables contained within the context. Furthermore, in the process of partial belief formation (which leads to the formation of contexts) the reasoner is ignorant as to how various contexts probabilistically interact (are related), except that, some contexts may in fact share a number of variables in between and hence overlap. Later on, in the process of the derivation of the query posed to the reasoner, this ignorance manifests in the uncertainty region represented by the min/max values for the inter-contextual query of interest. In other words, if the reasoner incurs ignorance as to the (in)dependency structure governing the variables present in the domain, then later on, in the process of derivation of the posed query, the reasoner has to pay the price by merely arriving at a *probability interval* rather than a point probability as an answer to the query of interest. Yet, the knowledge of the underlying dependency structure is a fundamental knowledge whose availability to the reasoner should *not* be postulated as an inevitability but as an advantaged position.

The evolutionary process of MCM does not enforce a specific gradual expansion path, for the claim of MCM is merely that *any partial belief formation as to the domain can be modeled in the framework depicted by MCM*. That is, the reasoner may arrive at different MCMs, depending on the order in which the reasoner encounters different concepts and also depending on her background knowledge as to the nature of the potential connections between a collection of variables. Simply put, the order according to which the reasoner comes about knowing the concepts or propositions of the domain does matter (cf. the discussion on the order of belief formation in Sec. 3.2).

MCM enables one to carry out inference without having to commit to any unjustified or uncertain independence assumptions. In light of this, contexts symbolize the regions of the domain over which an (in)dependence structure is presumed and hence, the growth and merging of contexts indicates the formation of new (in)dependence structures over some parts of the domain which previously were un-

structured. In short, MCM is meant to be invoked in circumstances where the observations and the a priori knowledge combined are not sufficient for the reasoner to form the full JPD over all of the domain variables and yet, quite crucially, the reasoner is reluctant to submit to any unjustified assumptions to compensate for such inadequacy of knowledge.

## 6 CONCLUSION

In an attempt to establish a middle ground between Bayesian Logic and Probabilistic Logic (Andersen and Hooker 1990; 1994), on one side, and PGMs<sup>8</sup> on the other, we proposed the Multi-Context Model to represent the state of partial knowledge regarding a domain. The generative process for the gradual construction of contradiction-free MCMs was discussed. The task of Inference for MCM was studied and, along the path, the notions of inference grammar, nestedness, and transformation were introduced. A short version of  $\mathcal{I}^*$  without the scale-invariance property was provided in Appendix. It is worth noting that scale-invariance property can be achieved with a minor change to the last step of the proposed algorithm.

## APPENDIX

### A-I $\mathcal{I}_{non-scale}^*$ : A short version of $\mathcal{I}^*$ without scale-invariance property

$\mathcal{I}^*$  aims at minimally parameterizing the information contained in an MCM so that the posed inter-contextual query can be stated as an LP with the fewest number of parameters. As pointed out earlier in Sec. 4.2,  $\mathcal{I}^*$  has to decide on the following: (i) what RVs have to be included in the LP, and (ii) the abstraction level required to minimally encode the information on the RVs identified in step (i) for the LP, in our case, the parametrization of the identified RVs.

In what follows, a simple algorithm,  $\mathcal{I}_{non-scale}^*$ , is sketched which only performs (i) and ignores (ii). In other words,  $\mathcal{I}_{non-scale}^*$  identifies the relevant RVs needed to derive the *exact* lower/upper bound for the inter-contextual query, however, it does not aim at minimally encoding them into the LP<sup>9</sup>.  $\mathcal{I}_{non-scale}^*$  consists of three steps:

(1) Identify all the RVs involved in the posed query (e.g., in  $P(X|Y, z)$  these are the random vector  $X$ , random vector  $Y$  and RV  $z$ ).

(2a) If any two of the already identified RVs belong to two

<sup>8</sup>For instance, Bayesian Networks (Pearl 1986), Markov Networks (Koller and Friedman 2009), and Chain Graphs (Buntine 1995).

<sup>9</sup>To read more on this, the reader is referred to the discussion on scale-invariance property in Sec. 4.2 and Sec. A-III of Appendix.

overlapping contexts, identify all the *overlapping* RVs between these two contexts (e.g., in Fig. 5(b) and for the query  $P(X|Y)$  for which step (1) would identify  $X$  and  $Y$ , random vector  $Z$  in the overlapping region must be identified as well).

(2b) If any two of the already identified RVs belong to two contexts connected through a chain of overlapping contexts: identify all the RVs contained in all the *overlapping* regions of the chain of contexts.

(3) Parameterize only the identified RVs in steps (1), (2a), and (2b) (remove all the other RVs from the MCM—there is no need to encode the information on any other RVs not identified in steps (1), (2a), and (2b)).

■

It should be noted that whether the posed query involves minimization or maximization does not affect which RVs need to be identified by  $\mathcal{I}_{non-scale}^*$ . Finally, It is worth noting that with a minor modification to step (3) of  $\mathcal{I}_{non-scale}^*$ , the scale-invariance property could be achieved. The modification has to do with the question of how to *minimally* encode the information on each RV identified in steps (1), (2a), and (2b) of  $\mathcal{I}_{non-scale}^*$ .

To demonstrate the operation of  $\mathcal{I}_{non-scale}^*$  on a more complicated MCM that involves loops, consider the following example sketched in Fig. 8(a). The query of interest is  $\mathbb{P}(X|Y)_{\downarrow}$ .

Figure 8: (a) Sample MCM. The RVs involved in the posed query are depicted in blue. (b) In Step (1)  $X$  and  $Y$  are identified; in step (2b) the RVs  $b$ ,  $d$  as well as  $a$ ,  $c$ , and  $e$  are identified. According to step (3) of  $\mathcal{I}_{non-scale}^*$  all of the information as to the RVs  $X$ ,  $Y$ ,  $b$ ,  $d$ ,  $a$ ,  $c$ , and  $e$  has to be stated as an LP to derive the query.

Next, we are going to sketch the proof for  $\mathcal{I}_{non-scale}^*$ . Let us first state the claim formally and then provide the proof.

### A-II Proof for $\mathcal{I}_{non-scale}^*$ :

**Lemma:** *Given a posed query and an MCM, if all the information on the RVs identified in steps (1) to (2b) of  $\mathcal{I}_{non-scale}^*$  is stated and then solved as an LP, the exact solution (i.e., a min or max) can be derived for the posed*

query; all the remaining information available in the MCM is deemed irrelevant to the derivation of the query, hence the sufficiency.

**Proof:** Our proof is constructive. In the proof we entertain two ideas, namely (i) the idea of generative process and, particularly, that of *conditioning* also used in Sec. 3.2, and (ii) the notion we refer to as the *locality of information*. Suppose that all the RVs discussed in steps (1) to (2b) of  $\mathcal{I}_{non-scale}^*$  are identified. The key insight is that the information on how the remaining RVs probabilistically interact with each other is completely local in nature and, therefore, irrelevant to the derivation of the posed query. To see this, one can start off with the identified RVs and then in a gradual fashion add on<sup>10</sup> the rest of the RVs (through the idea of conditioning discussed in Sec. 3.2). Quite crucially, this very process of adding the non-identified RVs to the model can be done completely in a local fashion, i.e., without imposing any constraints on how the identified RVs probabilistically interact. The mere fact that those RVs can be added into the model: (i) subsequent to the identified ones, and (ii) without inducing any sort of constraints on the identified ones, deems them irrelevant to the derivation of the query. ■

### A-III Scale-Invariance Property: Intuition

Here, we will provide a proof for the example on scale-invariance property given in Sec. 4.2. Although the proof is provided for a special query, the methodology used in the proof provides an insightful way of *visualizing* an inference problem. The idea behind the proof is very simple and related to visualizing the connection of a RV to the underlying sample space using Venn diagrams. Without loss of generality, we assume that all the RVs present in the domain are binary<sup>11</sup>. Random vector  $\mathbf{X} = \mathbf{x}_{1:n}$  partitions the sample space  $\Omega$  into  $2^n$  disjoint regions each of which corresponds to a realization of  $\mathbf{X}$ . If each realization of the random vector  $\mathbf{x}_{1:n}$  corresponds to a binary number (i.e., binary-coding the realizations), then one can conclude  $Val(\mathbf{X}) = \{0, 1, \dots, 2^n - 1\}$ . Let us index the partitions by their corresponding realization of  $\mathbf{X}$ . An illustrative example of an induced partitioning of the sample space  $\Omega$  due to random vector  $\mathbf{X} = \mathbf{x}_{1:n}$  is depicted in Fig. 9(a), and a partitioning induced by RVs  $\mathbf{y}$  and  $\mathbf{z}$  is sketched in Fig. 9(b). We note that the mere knowledge of the distribution function of a random quantity does not provide one with the knowledge of the underlying partitions. For this particular example, since the JPD over  $\mathbf{X}, \mathbf{y}, \mathbf{z}$  is not available, the knowledge of how the partitions induced by  $\mathbf{y}, \mathbf{z}$  (Fig. 9(b)) and the ones induced by  $\mathbf{X}$  (Fig. 9(a)) interact, i.e., to what extent they overlap,

remains unspecified. Therefore, since  $\mathbb{P}(X|y) = \frac{\mathbb{P}(X,y)}{\mathbb{P}(y)}$ , to minimize (maximize)  $\mathbb{P}(X|y)$ , the quantity  $\mathbb{P}(X, y)$  has to be minimized (maximized). Pictorially, the minimization (maximization) of  $\mathbb{P}(X, y)$  corresponds to the minimization (maximization) of the overlap between the partitions corresponding to the events  $\{\mathbf{X} = X\}$  and  $\{\mathbf{y} = y\}$ ; hence, very simply,  $\mathbb{P}(X, y)_\downarrow = [\mathbb{P}(X) + \mathbb{P}(y) - 1]^+$  and  $\mathbb{P}(X, y)_\uparrow = \min\{\mathbb{P}(X), \mathbb{P}(y)\}$ . The key point, which yields the scale-invariance property, is that to derive the minimum (maximum) overlap between the partitions corresponding to the events  $\{\mathbf{X} = X\}$  and  $\{\mathbf{y} = y\}$  the information as to how the other partitions—corresponding to the other realizations of the present RVs in the model—interact with one another neither needs to be known nor to be encoded into the LP; a fact which results in not requiring to encode the information as to the other realizations. Hence the only pieces of information that are required to be encoded and then solved as an LP are  $\mathbb{P}(X)$  and  $\mathbb{P}(y)$ . The same line of reasoning could be adopted for  $\mathbb{P}(x_i|y)$ . The idea of scale-invariance, therefore, aims to avoid the encoding of the information as to the partitions induced on  $\Omega$  which are yet deemed to be irrelevant to the derivation of the posed query; hence one needs to encode solely the relevant ones into the LP.

Figure 9: Sample Space: (a) Partitioning induced on  $\Omega$  due to  $\mathbf{X} = \mathbf{x}_{1:n}$ . The blue region corresponds to the partition associated to the event  $\{\mathbf{x}_i = 0\}$  and the red one to that of  $\{\mathbf{X} = i\}$  where  $i \in Val(\mathbf{X})$ . (b) Partitioning induced on  $\Omega$  due to RVs  $\mathbf{y}$  and  $\mathbf{z}$ . The blue region corresponds to the partition associated to the event  $\{\mathbf{y} = 0\}$ .

## Abstract

Stochastic gradient descent (SGD) has been regarded as a successful optimization algorithm in machine learning. In this paper, we propose a novel annealed gradient descent (AGD) method for non-convex optimization in deep learning. AGD optimizes a sequence of gradually improved smoother mosaic functions that approximate the original non-convex objective function according to an annealing schedule during the optimization process. We present a theoretical analysis on its convergence properties and learning speed. The proposed AGD algorithm is applied to learning deep neural networks (DNNs) for image recognition on MNIST and speech recognition on Switchboard. Experimental results have shown that AGD can yield comparable performance as SGD but it can significantly expedite training of DNNs in big data sets (by about 40% faster).

## 1 INTRODUCTION

The past few decades have witnessed the success of gradient descent algorithms in machine learning. By only calculating the local gradient information of the loss function, gradient descent (GD) algorithms may provide reasonably good optimization results for different types of problems. Among many, *stochastic gradient descent (SGD)* is a very popular method for modern learning systems, which only use one or a few randomly-selected training samples to update the model parameters in each iteration (Bottou, 1998). In comparison to the batch GD algorithms, SGD requires far less computing resources especially when it deals with a huge task involving big data. In (LeCun and Bottou, 2004), it has been proved that SGD can process asymptotically more training samples than batch GD algorithms given the same amount of computing resources. (Roux et al., 2012) proposed a new SGD framework that can achieve

a linear convergence rate for strongly-convex optimization problems. In (Shamir and Zhang, 2013), the performance of SGD was analyzed on a number of non-smooth convex objective functions and a bound on the expected optimization errors was provided. On the other hand, SGD also has its own drawbacks. The random noise introduced by data sampling leads to noisy gradient estimates, which may slow down the convergence speed and degrade the performance (Murata and Amari, 1999). Moreover, because of its sequential nature, SGD is hard to parallelize. More recently, several different methods have been proposed to parallelize SGD to accelerate its training speed for big-data applications. Initially, some researchers have proposed to implement the SGD method across multiple computing nodes that are synchronized for updating model parameters. Unfortunately, it has been found that the delay by the required server synchronization is always much longer than the time needed to calculate the gradient. Therefore, several other methods have been proposed to parallelize SGD without frequent synchronization among computing nodes. For example, Zinkevich et al. (2009) has presented a parallelized SGD algorithm, which dispatches all training samples into several computing nodes to update the parameters independently, and the final models will be combined by averaging all separate models at the end of each training epoch. Moreover, Bockermann and Lee (2012) have proved that the performance of this parallelized SGD algorithm depends on the number of SGD runs, and they have successfully used it to train large-scale support vector machines. However, the convergence of this simple parallelized SGD method requires that the learning process is convex. Moreover, Agarwal and Duchi (2012) have shown that the delays introduced by asynchronous model updates can be asymptotically neglected when we optimize a smooth and convex problem. Similarly, Feng et al. (2011) has proposed a parallelized SGD framework called *HOGWILD!*, which has mostly removed the memory locking and synchronization. However, it has found that this method works well only for sparse models. In summary, these parallelized SGD methods heavily rely on the assumptions that the learning problems are convex and/or sparse. These methods may suf-

for the performance degradation when dealing with more general non-convex optimization problems such as those in deep learning.

Recently, deep learning (Bengio, 2009) has achieved huge successes in many real-world applications, such as speech recognition and computer vision. It becomes a very interesting problem to learn large-scale deeply-structured neural networks, such as *deep neural networks (DNNs)*, from big data sets. We know that the training of DNNs is highly non-convex. Moreover, it is relatively expensive to compute the gradients of the objective function for DNNs since it needs to run the time-consuming back-propagation algorithm. To accelerate the large scale DNN training for big data, it has proposed a weight sharing method in (LeCun et al., 1989), which reduces the number of free parameters in the neural network and thus speeds up the training procedure. Even though today’s development of computing hardware makes it possible to train large DNNs directly, it is still very slow to train state-of-the-art DNNs for many real-world applications since the major training of DNNs still depends on the mini-batch SGD algorithm. Therefore, it is much needed in deep learning to develop new optimization methods that are faster to solve large-scale training problems in deep learning. One idea is ‘starting small’ (Elman, 1993), in which the network training will begin from simple training data with small working memory, and gradually increase the data complexity and network memory. This process simulates the learning procedure of human beings, especially in some complex domains like language. Krueger et al. have implemented the so-called ‘shaping’ learning in the neural network training (Krueger and Dayan, 2009). During the training, the task is split into several sub-components and a suitable training sequence is used to boost the training speed. In (Bengio et al., 2009), Bengio et al. have proposed a training strategy for deep learning called curriculum learning. The basic idea is to start the learning process from small tasks that are easy to solve, and gradually increase the complexity of the tasks in the later learning stage. Experimental results imply that when using a suitable curriculum, this training strategy may provide a similar performance as unsupervised pre-training and it helps the algorithm to find a better local minimum. The curriculum learning method can serve as an important basis for the work in this paper.

In this paper, we propose a new algorithm called *annealed gradient descent (AGD)*. Instead of directly optimizing the original non-convex objective function, the basic idea of AGD is to optimize a low resolution approximation function that may be smoother and easier to optimize. Furthermore, the approximation resolution is gradually improved according to an annealing schedule over the optimization course. In this work, we have proposed to approximate a non-convex objective function based on some pre-trained codebooks, where the approximation precision can be eas-

ily controlled by choosing different number of codewords in the codebook. In comparison with (Bengio et al., 2009), the main contribution of this paper is that AGD provides a suitable way for approximation (through pre-trained codebooks), and more importantly, we show a bound for the difference between the parameters derived by AGD and the regular GD algorithms. This new method has several advantages: Firstly, the low resolution approximation by codebooks lead to a much smoother risk function, which may result in finding a good local minimum more easily. Secondly, because the size of each codebook is much smaller than that of the training set, we can use a fast batch algorithm to learn the model at the beginning and this part can be easily parallelized. In this work, we have applied AGD to training DNNs for various tasks to verify its efficiency and effectiveness. Experiments have shown that the AGD algorithm yields about 40% speed-up in total training time of DNNs, and also leads to similar recognition performance as the regular mini-batch SGD.

The remainder of this paper is organized as follows. In section 2, we provide some background information about empirical risk function and two kinds of gradient descent algorithm. Section 3 shows the mosaic risk function and some related theoretical analysis. In section 4, we present the proposed AGD algorithm. Section 5 reports experiments on different tasks, and we conclude this paper in section 6.

## 2 PRELIMINARIES

In this section, we first review some preliminary definitions in machine learning, which serve as important notation bases for this work.

### 2.1 EMPIRICAL RISK FUNCTION

In machine learning, we normally use a *loss function*,  $Q(x, y, \theta)$ , to measure the ‘cost’ of a given event  $x$  ( $y$  is the corresponding label of  $x$ ) and the underlying model parameters are denoted as  $\theta$ , and the expected value of the loss function is the so-called *expected risk function*,  $R(\theta)$ :

$$R(\theta) = \mathbf{E}[Q(x, y, \theta)] \triangleq \int Q(x, y, \theta) dP(x, y) \quad (1)$$

where  $P(x, y)$  denotes the ground truth distribution over all possible events. The fundamental goal of many machine learning problems is to minimize the above expected risk function. In practice, however, it is extremely hard to do so because  $P(x, y)$  is always unknown. Therefore, In practice, we normally use a finite training set that includes  $N$  independent pairs of sample  $O_N = \{(x_1, y_1), (x_2, y_2), \dots, (x_N, y_N)\}$ , which are presumably randomly sampled from the above unknown distribution. Based on the training set, we may derive the so-called *empirical risk function*,  $R_N(\theta)$ , to approximate the expected

risk function in eq.(1):

$$R(\theta) \approx R_N(\theta) = \frac{1}{N} \sum_{n=1}^N Q(x_n, y_n, \theta) \quad (2)$$

If the training set is sufficiently large, under some minor conditions, minimizing the empirical risk function in eq.(2) may also minimize the expected risk function in eq.(1) (Vapnik, 1998). For notational clarity, without confusion, we drop label  $y_n$  from the loss function for the rest of this paper.

## 2.2 GRADIENT DESCENT ALGORITHM

To minimize the empirical risk function, we can use gradient descent algorithms, which update  $\theta$  along the direction of the negative gradient based on a pre-defined learning rate  $\lambda$ . Generally speaking, there are two different types of gradient descent algorithms: batch gradient descent (batch GD) and stochastic gradient descent (SGD).

In each iteration, the batch GD considers all of the training samples to calculate the average gradient and then update the parameters accordingly:

$$\begin{aligned} \hat{\theta}_{t+1} &= \hat{\theta}_t - \lambda_t \cdot \nabla_{\theta} R_N(\hat{\theta}_t) \\ &= \hat{\theta}_t - \lambda_t \cdot \frac{1}{N} \sum_{n=1}^N \frac{\partial Q(x_n, \hat{\theta}_t)}{\partial \theta} \end{aligned} \quad (3)$$

where  $\lambda_t$  is the learning rate at iteration  $t$ . In contrast, SGD only takes one training sample (which is randomly sampled from the training set) into account in each iteration:

$$\bar{\theta}_{t+1} = \bar{\theta}_t - \lambda_t \cdot \frac{\partial Q(x_n, \bar{\theta}_t)}{\partial \theta}. \quad (4)$$

If we set a suitable learning rate, under some conditions, both batch GD and SGD can finally converge to a local minimum  $\theta^*$  of the empirical risk function (Bottou, 2004). In practice, to reduce variance of the estimated gradients in SGD, a variant SGD, called mini-batch SGD, is normally used, where a small set (called mini-batch) of randomly selected data samples are used to estimate the gradient for each model update, as opposed to only one sample in SGD.

As we know, the batch GD works well for convex optimization while SGD may be used to solve non-convex optimization problems due to the random noises in its gradient estimation. Meanwhile, SGD requires far less computing resources in comparison to batch algorithms, but on the downside, its convergence speed is very slow due to sampling noise, and it is very hard to parallelize SGD. Therefore, when dealing with some large scale tasks, SGD may run very slowly. In this paper, we propose a new optimization method to solve some large-scale non-convex optimization problems in deep learning. The new method will be compared with SGD in terms of convergence speed and learning performance.

## 3 THE MOSAIC RISK FUNCTION

Some previous work has considered the problem of critical points (including local optima and saddle points) in non-convex optimizations. According to (Choromanska et al., 2014), some poor local minima may hinder the optimization process especially in small-scale neural networks. (Dauphin et al., 2014) argued that for the practical high dimensional problems, the saddle points may become the most difficult problem to deal with, rather than local optima. In practice, any local search algorithms may be easily trapped into a nearby shallow local optimum point or saddle point, which makes it hard for optimization to proceed further. SGD relies on the sampling noise to alleviate this problem. Another way to tackle this problem is to optimize a smoother approximation of the original rugged non-convex function. In this work, we propose to approximate the original objective function based on a relatively small codebook, which is generated by clustering the whole training set. In this way, we may provide a low resolution approximation of the objective function, which is much smoother and easier to optimize with simple local search algorithms.

Assume we use a discrete codebook, denoted as  $C = \{c_1, c_2, \dots, c_M\}$ , where  $M \ll N$ , to approximate the original training set. For a training sample  $x_n$ , we select its nearest codeword in  $C$  as its approximation:

$$c^{(n)} = \arg \min_{c_m \in C} \|x_n - c_m\| \quad (5)$$

and the quantization error  $\epsilon_n$  is  $\|x_n - c^{(n)}\|$ .

Next, we may derive a low resolution risk function  $\tilde{R}_{\epsilon}$ , called *mosaic risk function*, to approximate the empirical risk function  $R_N(\theta)$  (where  $\epsilon \equiv \max_n \epsilon_n$ ):

$$\tilde{R}_{\epsilon}(\theta) = \frac{1}{N} \sum_{n=1}^N Q(c^{(n)}, \theta) = \sum_{m=1}^M \frac{\omega_m}{N} \cdot Q(c_m, \theta) \quad (6)$$

where  $\omega_m$  is the number of training samples in the whole training set that are approximated by the codeword  $c_m$ , i.e.,  $\omega_m = \sum_{n=1}^N \delta(c^{(n)} - c_m)$ , where  $\delta(\cdot)$  denotes the Kronecker delta function.

Assume that the loss function  $Q(x, \theta)$  is twice Lipschitz-continuous with respect to the input sample  $x$  and the model parameter  $\theta$ , that is,

$$\|Q(x_i, \theta) - Q(x_j, \theta)\| < L_0 \|x_i - x_j\| \quad (7)$$

$$\|Q'(x_i, \theta) - Q'(x_j, \theta)\| < L_1 \|x_i - x_j\| \quad (8)$$

$$\|Q(x, \theta_i) - Q(x, \theta_j)\| < L_0 \|\theta_i - \theta_j\| \quad (9)$$

$$\|Q'(x, \theta_i) - Q'(x, \theta_j)\| < L_1 \|\theta_i - \theta_j\| \quad (10)$$

In this case, it is easy to show that for any  $\theta$ , the mosaic risk function can provide a bounded approximation for the

empirical risk function:

$$\| R_N(\theta) - \tilde{R}_\epsilon(\theta) \| < \epsilon \cdot L_0 \quad (\forall \theta). \quad (11)$$

When we deal with a non-convex loss function, the mosaic risk function will give a very important benefit due to its low resolution: because we use a smaller codebook to approximate the training set, and one codeword may represent a large number of different training samples, the mosaic risk function normally corresponds to a smoother curve that may get rid of a lot of critical points comparing with the original empirical risk function. (Bengio et al. (2009) may support this argument.) Therefore, if we use the gradient descent method to optimize the mosaic risk function, named as *mosaic gradient descent (MGD)*, we can find its local minimum much easier and much faster, and this local minimum on mosaic risk function is a good initialization for further learning. If we can use a batch algorithm to optimize the mosaic risk function, it may significantly speed up the training phase due to a smaller number of codewords.

When we use MGD to minimize the mosaic risk function, we can get the following parameter update sequence:

$$\tilde{\theta}_{t+1} = \tilde{\theta}_t - \lambda_t \cdot \nabla_{\theta} \tilde{R}_\epsilon = \tilde{\theta}_t - \lambda_t \sum_{m=1}^M \frac{\omega_m}{N} \cdot \frac{\partial Q(c_m, \tilde{\theta}_t)}{\partial \theta} \quad (12)$$

Obviously, MGD generates a different sequence of the model parameters  $\tilde{\theta}_t$ .

Moreover, we may extend the above MGD to a stochastic version using only a random mini-batch of data for each model update in eq.(12) rather than the whole training set. All data in the selected mini-batch are approximated by codewords as in eq.(5). This is called mini-batch MGD. Of course, it may be better to use a much larger batch size in mini-batch MGD than that of mini-batch SGD to explore the overall structure of the mosaic function.

In the following, we will show that under some minor conditions, minimization of the mosaic risk function leads to convergence into a bounded neighborhood of a local optimum of the empirical risk function. Moreover, we also show that MGD may provide faster a convergence rate than GD and SGD under certain conditions.

### 3.1 CONVERGENCE ANALYSIS

As we know, if the learning rates satisfy some minor conditions, the batch GD algorithm in eq. (3) is guaranteed to converge to a critical point of the empirical risk function. In the following, let's first compare the MGD update sequence in eq.(12) with the GD update in eq.(3). Obviously, we have the following lemma:

**Lemma 1 (MGD vs. GD)** *Assume that the two update sequences in eq. (3) and eq. (12) start from the same initial*

*parameters  $\theta_0$ , and use the same sequence of learning rates  $\lambda_t$ , then we have:*

$$\| \tilde{\theta}_t - \hat{\theta}_t \| < \epsilon \cdot L_1 \cdot \sum_{\tau=1}^{t-1} \lambda_\tau \quad (13)$$

**Proof:** (1) At  $t = 1$ , assume that GD and MGD start from the same initialization  $\theta_0$  and share the same sequence of learning rate. Based on the Lipschitz-continuous condition in eq. (8), it is easy to show:

$$\begin{aligned} \| \tilde{\theta}_1 - \hat{\theta}_1 \| &= \frac{\lambda_0}{N} \left\| \sum_{n=1}^N \frac{\partial Q(x_n, \theta_0)}{\partial \theta_0} - \sum_{n=1}^N \frac{\partial Q(c^{(n)}, \theta_0)}{\partial \theta_0} \right\| \\ &\leq \frac{\lambda_0}{N} \cdot \sum_{n=1}^N \left\| \frac{\partial Q(x_n, \theta_0)}{\partial \theta_0} - \frac{\partial Q(c^{(n)}, \theta_0)}{\partial \theta_0} \right\| \\ &\leq \frac{\lambda_0}{N} \cdot L_1 \cdot \sum_{n=1}^N \| x_n - c^{(n)} \| \\ &\leq \epsilon \cdot L_1 \cdot \lambda_0 \end{aligned} \quad (14)$$

(2) Assume that the Lemma 1 holds for  $t$ , i.e.,

$$\| \tilde{\theta}_t - \hat{\theta}_t \| < \epsilon \cdot L_1 \cdot \sum_{\tau=1}^{t-1} \lambda_\tau. \quad (15)$$

For  $t + 1$ , considering the condition in eq. (10), we have:

$$\begin{aligned} &\| \tilde{\theta}_{t+1} - \hat{\theta}_{t+1} \| \\ &= \| (\tilde{\theta}_t - \hat{\theta}_t) + \frac{\lambda_t}{N} \sum_{n=1}^N \left( \frac{\partial Q(x_n, \hat{\theta}_t)}{\partial \theta} - \frac{\partial Q(c^{(n)}, \tilde{\theta}_t)}{\partial \theta} \right) \| \\ &\leq \| \tilde{\theta}_t - \hat{\theta}_t \| + \frac{\lambda_t}{N} \sum_{n=1}^N \left\| \frac{\partial Q(x_n, \hat{\theta}_t)}{\partial \theta} - \frac{\partial Q(c^{(n)}, \tilde{\theta}_t)}{\partial \theta} \right\| \\ &\leq \epsilon \cdot L_1 \cdot \sum_{\tau=1}^{t-1} \lambda_\tau + \lambda_t \cdot L_1 \cdot \| x_n - c^{(n)} \| \\ &= \epsilon \cdot L_1 \cdot \sum_{\tau=1}^t \lambda_\tau \end{aligned} \quad (16)$$

Therefore, Lemma 1 also holds for  $t + 1$ . ■

Lemma 1 means that if we run both MGD and the batch GD algorithm for  $t$  iterations, the difference between two resultant model parameters is bounded and it is proportional to the maximum quantization error,  $\epsilon$ , in the mosaic function.

Based on Lemma 1, we have the following theorem:

**Theorem 2 (MGD vs. GD)** *When we use the empirical risk function eq. (2) to measure the two parameters  $\tilde{\theta}_t$  in eq. (12) and  $\hat{\theta}_t$  in eq.(3), the difference is also bounded as:*

$$\| R_N(\tilde{\theta}_t) - R_N(\hat{\theta}_t) \| \leq \epsilon \cdot L_0 \cdot L_1 \cdot \sum_{\tau=1}^t \lambda_\tau \quad (17)$$

**Proof:** Based on the condition in eq.(7) we have:

$$\begin{aligned}
& \| R_N(\tilde{\theta}_t) - R_N(\hat{\theta}_t) \| = \\
& \frac{1}{N} \cdot \left\| \sum_{n=1}^N (Q(x_n, \tilde{\theta}_t) - Q(x_n, \hat{\theta}_t)) \right\| \\
& \leq \frac{1}{N} \cdot \sum_{n=1}^N \| Q(x_n, \tilde{\theta}_t) - Q(x_n, \hat{\theta}_t) \| \quad (18) \\
& \leq L_0 \cdot \| \tilde{\theta}_t - \hat{\theta}_t \| \\
& \leq L_0 \cdot \epsilon \cdot L_1 \cdot \sum_{\tau=1}^t \lambda_\tau. \quad \blacksquare
\end{aligned}$$

In Lemma 1 and Theorem 2, the bounds are proportional to the summation of all used learning rates. However, in many deep learning practices such as DNN/CNN training, we need to use a sequence of quickly-decayed learning rates to guarantee the convergence. In these situations, the summation of all learning rates is clearly bounded. Therefore, Theorem 2 shows that model parameters  $\tilde{\theta}_t$  derived by MGD provide a good estimation of  $\hat{\theta}_t$  learned by the regular batch GD algorithm when they are measured with the empirical risk function. The difference is bounded by a quantity proportional to the quantization error in the mosaic function. As a result, if the quantization error is sufficiently small, MGD converges into a bounded neighborhood of a critical point of the original empirical risk function.

### 3.2 FASTER LEARNING

Here we study the learning speed of MGD. If we want to optimize the empirical risk function  $R_N(\theta)$  up to a given precision  $\rho$ , i.e.,  $\| \theta - \theta^* \| < \rho$ , by using batch gradient descent in eq. (3), it will take  $O(\log \frac{1}{\rho})$  iterations, and the complexity of each iteration is  $O(N)$ . Thus the overall complexity of the batch algorithm is  $O(N \log(\frac{1}{\rho}))$  (Bottou, 2012).

Alternatively, we can run the MGD algorithm on eq. (12) for  $t$  iterations, and based on Lemma 1 we have:

**Lemma 3** *If we run the MGD algorithm in eq. (12) for  $t$  iterations, the model parameters can reach the precision as:*

$$\| \tilde{\theta}_t - \theta^* \| < \rho + \epsilon \cdot L_1 \cdot \sum_{\tau=1}^t \lambda_\tau \quad (19)$$

and the overall computational complexity of MGD is  $O(M \cdot t)$ .

Based on Lemma 3, we can have Theorem 4 as below:

**Theorem 4 (MGD vs. GD)** *Assume there exists a codebook  $C$  containing  $M$  codewords, which can approximate the whole training set well enough, and  $M$  is sufficiently*

*small, i.e.*

$$\epsilon \ll \frac{\rho}{L_1 \cdot \sum_{\tau=1}^t \lambda_\tau} \quad \text{and} \quad M < \frac{N \cdot O(\log(\frac{1}{\rho}))}{t} \quad (20)$$

*then to reach the same optimization precision, optimizing the mosaic risk function using MGD requires less computing resources and yields faster convergence speed than the batch GD in eq. (3).*

Similar to Theorem 4, we also have Theorem 5 that compares the resource requirement between MGD and SGD:

**Theorem 5 (MGD vs. SGD)** *In SGD, we need to run  $O(\frac{1}{\rho})$  iterations to achieve the optimization precision  $\rho$  (Bottou, 1998). Similar to Theorem 4, if we find a codebook which satisfies the quantization error requirement and remains sufficiently small as follows:*

$$\epsilon \ll \frac{\rho}{L_1 \cdot \sum_{\tau=1}^t \lambda_\tau} \quad \text{and} \quad M < \frac{1}{t} \cdot O(\frac{1}{\rho}) \quad (21)$$

*then MGD will require less computation resource than SGD to achieve the optimization precision  $\rho$ .*

In the case of big data, i.e.,  $N$  is extremely large ( $N \gg M$ ), or in an early stage of optimization, when we only require a rough optimization precision, i.e.,  $\rho$  is allowed to be relatively large, such codebook may exist. In these cases, it may be beneficial to run MGD instead of GD or SGD since MGD has faster convergence speed than batch GD and SGD. Moreover, as opposed to pure serial computation in SGD, the gradient computation in each MGD iteration can be easily parallelized. Therefore, MGD may provide an even faster training speed if multiple computing units are available.

## 4 ANNEALED GRADIENT DESCENT

Theorems 4 and 5 imply that MGD may possibly converge faster than either GD or SGD but it remains unclear how to find a codebook that simultaneously satisfy both conditions in these theorems. Moreover, we may require different levels of optimization precision in various stages of a training process. For example, at the beginning, when all model parameters stay far away from any local optimal point, we may not need to calculate a very accurate gradient, i.e.,  $\rho$  is allowed to be relatively large at this time. On the other hand, as the parameters move towards a close neighborhood of an optimal point, we may require a very small  $\rho$  to perform an accurate local search to converge more effectively. As suggested by eq.(20), the required quantization error,  $\epsilon$ , is proportionally related to  $\rho$ . For a fixed set of training data, the quantization error,  $\epsilon$ , in turn depends on the size of the codebook,  $M$ . This suggests we use an annealing schedule of  $\{\epsilon_1, \epsilon_2, \dots\}$  (with  $\epsilon_{i+1} < \epsilon_i$ ) for

the whole training process, where  $\epsilon$  gradually decreases as training continues. At the beginning, we can use a small low resolution codebook (relatively big  $\epsilon$ ) to run MGD to learn model parameters. As training proceeds, we gradually reduce  $\epsilon$  by using increasingly larger codebooks. At the final stage, we may even use all original training samples to fine-tune the model parameters.

Therefore, the basic idea of annealed gradient descent (AGD) is to construct deeply-structured hierarchical codebooks, in which quantization error  $\epsilon$  slowly decreases from the top layer down to the bottom layer, and the last layer is finally connected to the original training set. During the training procedure, we first start from the top to use each layer of codebooks to do MGD updates in eq.(12) and gradually move down the hierarchy based on a pre-specified annealing schedule until we finally use the training samples to fine-tune the model parameters. If a proper annealing schedule is used, this annealed learning process may accelerate the training speed as implied by Theorems 4 and 5. More importantly, it may help to converge to a better local optimum at the end because AGD optimizes much smoother mosaic objective functions from the early stage of training.

In this section, we first briefly discuss the hierarchical codebooks, and then present the AGD training algorithm.

### 4.1 HIERARCHICAL CODEBOOKS

In this work, we use a regular K-means based top-down hierarchical clustering algorithm (Zhou et al., 2015) to construct the required hierarchical codebooks, where the centroid of each cluster is used as a codeword for each layer. The structure of the hierarchical codebooks is shown in Figure 1.

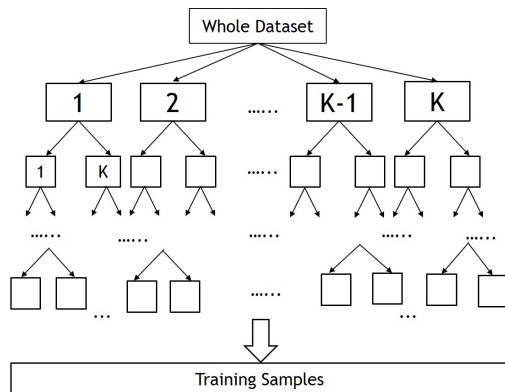

Figure 1: Illustration of a hierarchical codebook for AGD

When building the codebooks, we first divide the training set into several subsets based on the class labels of data samples (each subset only contains all training samples

from one class label), then conduct the hierarchical top-down K-means clustering on each subset. Note that the clustering process is very easy to parallelize because all subsets are independent with each other and we can run hierarchical K-means on them separately. In the K-means clustering, we first define a suitable  $K$ , then use K-means to split each subset into  $K$  clusters. The centroids of all clusters are used to build the first layer of codebooks. Next, we continuously apply the K-means clustering on all clusters to further divide them into  $K$  sub-clusters to derive the codebooks in the next layer. We repeat this procedure several times until the quantization error in the last layer becomes small enough. Finally, we connect the original training samples at the bottom as the leaf nodes to obtain a hierarchical codebook as shown in Figure 1, in which the sizes of the codebooks are gradually increased from the top layer to the bottom layer. In this way, the K-means codewords in the various layers of the hierarchy may be used to approximate each training sample in the leaf node up to different precision levels as required in the following AGD algorithm.

### 4.2 ANNEALED GRADIENT DESCENT ALGORITHM

In AGD, we first specify an annealing schedule, i.e.,  $\{\epsilon_1, \epsilon_2, \dots\}$  ( $\epsilon_{i+1} < \epsilon_i$ ). In each epoch of AGD, for each training sample in the selected data mini-batch, we select a codeword from the uppermost layer of the hierarchical codebooks that barely satisfies the required quantization error  $\epsilon_i$ , to construct the mosaic function for MGD at this stage. Since  $\epsilon_i$  gradually decreases in the annealing schedule, we slowly move to use more and more precise codewords (eventually the original data samples) in AGD. In AGD, a hierarchical search list is constructed for each layer in  $C$  based on the average quantization errors in K-means. As a result, in each AGD step, the corresponding codewords can be found very efficiently based on this search list. The annealed gradient descent (AGD) algorithm is shown as in Algorithm 1. During the AGD training, we may even use varying batch sizes. For example, we can start from a very large batch size (even the whole training set) at the beginning and slowly decrease the batch size from epoch to epoch. In general, we normally use much larger batch sizes than those used in the regular mini-batch SGD. If a suitable annealing schedule is specified, many initial AGD epochs may be designated to run faster MGD with smaller codebooks, yielding faster training speed than the mini-batch SGD or GD in overall.

## 5 EXPERIMENTS

In this section, we apply the proposed AGD algorithm to learning sigmoid fully connected deep neural networks (DNNs) for image recognition in the MNIST database and

Table 1: The total training time of K-means clustering.

| Database    | Number of CPUs | Training Time |
|-------------|----------------|---------------|
| MNIST       | 5              | 4.3 (hr)      |
| Switchboard | 8              | 9.2 (hr)      |

speech recognition in the Switchboard database. AGD and the regular mini-batch SGD are both used to train DNNs based on the minimum cross-entropy error criterion. AGD is compared with mini-batch SGD in terms of the total training time and the final recognition performance.

For each data set, we first use a standard K-means algorithm to build a deeply-structured hierarchical codebook. We use  $K = 5$  in MNIST and  $K = 4$  in Switchboard, which can result in a hierarchical codebook with sufficient depth. In our experiments, the MNIST database contains 10 classes and Switchboard contains 8991 classes, thus the hierarchical K-means has a good potential for parallel training. Here, the K-means clustering procedure is parallelized among multiple CPUs to speed it up as much as possible. In our experiments, the total running time of the K-means clustering is about 4.3 hours in MNIST (using 5 CPUs) and about 9.2 hours in Switchboard (using 8 CPUs), as shown in Table 1. If we use more CPUs, the K-means running time can be further reduced. As shown later, the K-means training time is not significant when comparing with the necessary DNN training times. And if we use more CPUs to do K-means, the clustering time can be further reduced (approximately less than 3 hours for MNIST and less than 5 hours for Switchboard). Moreover, for each database we only need to run K-means once and after that we can use the same codebook to train DNNs based on different annealing schedules. Therefore, we do not take into account the running time of the K-means clustering in the following comparisons. Note that no pre-training is used for DNNs in our experiments.

## 5.1 MNIST: IMAGE RECOGNITION

The MNIST database (LeCun et al., 1998) contains 60,000 training images and 10,000 test images, and the images are 28-by-28 in size. Here, we use data augmentation through image deformation at the beginning of each epoch to en-

large the training set as in (Ciresan et al., 2010). We use the configuration of 3-hidden-layer DNNs (1500, 1000, 500 nodes in each hidden layer) in (Ciresan et al., 2010) as our network structures and use SGD and AGD to do network training. Following (Ciresan et al., 2010), we fine-tune all hyper-parameters towards the best possible performance. In SGD, we use a mini-batch of 10 samples and an initial learning rate of 0.4. Notice that in MNIST experiments we do not use momentum during the training phase. In MGD, we use a larger mini-batch size of 4500 and an initial learning rate of 0.8. The training process runs for 550 epochs to guarantee the convergence of the augmented MNIST database.

As we know, we should shrink the learning rates during the training process for better convergence. Specifically, when the training mean square error (MSE) becomes smaller than a pre-defined threshold  $r$ , we use the formula

$$\lambda_{t+1} = \lambda_t \cdot \frac{p}{p+t}$$

to gradually decrease the learning rate, where  $p$  is a pre-defined constant to control the decreasing speed of the learning rates. In our experiments, we set  $r = 0.17$  and  $p = 10000$ . As for the AGD annealing schedule in MNIST, we start from  $\epsilon_1 = 7.5$  (this value is based on the average quantization error in the first layer of the codebook) and  $\epsilon_{i+1} = 0.999 \cdot \epsilon_i$ .

During the annealing phase we use MGD to train the network while in the regular phase we use SGD with the same configurations as the baseline. Note that we only do image deformation during the regular phase. In Figure 2, we have shown the learning curves of both SGD and AGD in terms of cross-entropy and classification error rate on the MNIST training set. Since each MGD epoch runs much faster than a SGD epoch, all learning curves are plotted as a function of total training time instead of epochs.

From the two pictures in Figure 2 we can see that AGD (in blue) finishes the same number of epochs much earlier than SGD (in red). In addition, in Table 2, we also give the total training time and the best classification error on the test set for both AGD and SGD. From results in Figure 2 and Table 2, we can see that the proposed AGD training algorithm yields slightly better classification performance in the test set, and more importantly reduces the total DNN training time by about 40%.

## 5.2 SWITCHBOARD: SPEECH RECOGNITION

Switchboard is a 320-hour English transcription task, which contains 332,576 utterances in its training set (amounting to about 126 millions of training samples in total). We select the standard NIST Hub5e2000 as the test

Figure 2: Learning curves on the MNIST training set (Left: cross entropy error; Right: classification error) of SGD and AGD as a function of elapsed training time.

Table 2: Comparison between SGD and AGD in terms of total training time (using one GPU) and the best classification error rate on MNIST.

| Method | Training Time | Test Error |
|--------|---------------|------------|
| SGD    | 38.8 (hr)     | 0.47%      |
| AGD    | 23.6 (hr)     | 0.46%      |

set in this work, which has 1831 utterances.<sup>1</sup> Following (Seide et al., 2011; Bao et al., 2013; Pan et al., 2012), we train a 6-hidden-layer DNN with 2048 nodes per layer based on the minimum cross-entropy criterion. We compare the cross entropy and frame classification errors on the training and test sets to evaluate the performance of SGD and AGD, meanwhile we also evaluate word error rates in speech recognition for the test set.

Here we use similar hyper-parameters as in (Pan et al., 2012; Xue et al., 2014). For example, we use a mini-batch of 1024 samples and an initial learning rate of 0.2 in SGD, and a mini-batch of 6144 and an initial learning rate of 1.0 in MGD. We use 0.9 as the momentum in both SGD and MGD. We run 10 epochs in SGD and 17 epochs in AGD. During the training process, we need to shrink the learning rates slowly. Specifically, we multiply the learning rate by 0.8 every epoch after the 5-th epoch in SGD and the 12-th epoch in AGD. Note that our SGD baseline is solid and comparable with the best results reported on this task

<sup>1</sup>Due to the copyright issue, all Switchboard experiments were conducted at NELSLIP, University of Science and Technology of China.

(Seide et al., 2011; Hinton et al., 2012; Xue et al., 2014) in terms of both training speed and recognition performance.

As for the AGD annealing schedule in Switchboard, unlike MNIST, it starts from an initial value  $\epsilon_1$  (17.5 in this case), and use the formula

$$\epsilon_{i+1} = \epsilon_i - \Delta_\epsilon$$

to reduce  $\epsilon_i$  by subtracting a constant value every epoch until it reaches the pre-defined value (8.5 in this case). The reason for this formula is that we run much less epochs here. In Switchboard, we have evaluated three different annealing schedules to show how they affect the training speed and the final recognition performance as shown in Table 3. In these three schedules, we use different values for  $\Delta_\epsilon$ , e.g. 1.0, 0.9 and 0.8 respectively. We can see that the annealing schedule 1 ( $\Delta_\epsilon = 1.0$ ) decreases fastest and it provides the best performance but relatively slower training speed. In contrast, schedule 3 ( $\Delta_\epsilon = 0.8$ ) gives the fastest training speed but slightly worse performance because more epochs will be dispatched to run MGD.

Figure 3 shows the learning curves of both SGD and AGD (using the annealing schedule with  $\Delta_\epsilon = 1$ ) in terms of cross-entropy and frame errors on the Switchboard training set as a function of elapsed training time. Clearly, AGD runs much faster than SGD on Switchboard as well. Meanwhile, AGD can also achieve a slightly better local minimum than SGD as measured in both figures.

In Table 3, we give the total training times and the word error rates in speech recognition. We report the experimental results for all 3 different annealing schedules. The results have shown that the proposed AGD method can yield similar recognition performance with much faster training

Figure 3: Learning curves on the Switchboard training set (Left: cross entropy error; Right: frame classification error) of SGD and AGD as a function of elapsed training time.

Table 3: Comparison between SGD and AGD in terms of total training time (using one GPU) and word error rate in speech recognition on Switchboard.

| Method                          | Training Time | Word Error |
|---------------------------------|---------------|------------|
| SGD                             | 114.05 (hr)   | 16.4%      |
| AGD ( $\Delta_\epsilon = 1.0$ ) | 78.79 (hr)    | 16.3%      |
| AGD ( $\Delta_\epsilon = 0.9$ ) | 66.63 (hr)    | 16.7%      |
| AGD ( $\Delta_\epsilon = 0.8$ ) | 55.35 (hr)    | 17.5%      |

speed than SGD (about a 30% to 40% reduction in total training time) when a suitable annealing schedule is used. Results in Table 3 also imply how quantization errors in the codebooks may affect the final classification performance: a slower schedule means more epochs will be dispatched to run MGD, which uses each layer of the codebooks to train the DNNs. In this case, the quantization error of the codebook may bring about some negative influence on the performance but provide faster learning speed. In practice, when we are sensitive to the total training time of DNNs, we may use slower decreasing schedules to accelerate the DNN training dramatically.

## 6 CONCLUSIONS

In this paper, we have proposed a new annealed gradient descent (AGD) algorithm for non-convex optimization in deep learning, which can converge to a better local minimum with faster speed when compared with the regular mini-batch SGD algorithm. In this work, AGD has been applied to training large scale DNNs for image classifi-

cation and speech recognition tasks. Experimental results have shown that AGD significantly outperforms SGD in terms of the convergence speed. Therefore, the AGD algorithm is especially suitable for the large scale non-convex optimization problems in deep learning. In the future, we may apply AGD to training convolutional neural networks (CNNs) for other more challenging image recognition tasks, where we may build the hierarchical codebooks by clustering image patches instead of the whole input images. Moreover, AGD may be applied to the recently proposed unsupervised learning algorithm in (Zhang and Jiang, 2015; Zhang et al., 2015) as well.

## Acknowledgments

This work was partially supported by an NSERC discovery grant from the Canadian Federal Government. The first author is supported by a scholarship from China Scholarship Council (CSC). We appreciate Dr. Pan Zhou from NELSIP, University of Science and Technology of China for his help in conducting the Switchboard experiments in this paper.

## Abstract

Max-product belief propagation (BP) is a popular message-passing algorithm for computing a maximum-a-posteriori (MAP) assignment in a joint distribution represented by a graphical model (GM). It has been shown that BP can solve a few classes of Linear Programming (LP) formulations to combinatorial optimization problems including maximum weight matching and shortest path, i.e., BP can be a distributed solver for certain LPs. However, those LPs and corresponding BP analysis are very sensitive to underlying problem setups, and it has been not clear what extent these results can be generalized to. In this paper, we obtain a generic criteria that BP converges to the optimal solution of given LP, and show that it is satisfied in LP formulations associated to many classical combinatorial optimization problems including maximum weight perfect matching, shortest path, traveling salesman, cycle packing and vertex cover. More importantly, our criteria can guide the BP design to compute fractional LP solutions, while most prior results focus on integral ones. Our results provide new tools on BP analysis and new directions on efficient solvers for large-scale LPs.

## 1 INTRODUCTION

Graphical model (GM) has been one of powerful paradigms for succinct representations of joint probability distributions in variety of scientific fields (Yedidia et al., 2005; Richardson and Urbanke, 2008; Mezard and Montanari, 2009; Wainwright and Jordan, 2008). GM represents a joint distribution of some random vector to a graph structured model where each vertex corresponds to a random variable and each edge captures to a conditional dependency between random variables. In many applications involving GMs, finding maximum-a-posteriori (MAP) assignment in GM is an important inference task, which is

known to be computationally intractable (i.e., NP-hard) in general (Chandrasekaran et al., 2008). Max-product belief propagation (BP) is the most popular heuristic for approximating a MAP assignment of given GM, where its performance has been not well understood in loopy GMs. Nevertheless, BP often shows remarkable performances even on loopy GM. Distributed implementation, associated ease of programming and strong parallelization potential are the main reasons for the growing popularity of the BP algorithm. For example, several software architectures for implementing parallel BPs were recently proposed (Low et al., 2010; Gonzalez et al., 2010; Ma et al., 2012) by different research groups in machine learning communities.

In the past years, there have been made extensive research efforts to understand BP performances on loopy GMs behind its empirical success. Several characterizations of the max-product BP fixed points have been proposed (Weiss and Freeman, 2001; Vinyals et al., 2010), whereas they do not guarantee the BP convergence in general. It has also been studied about the BP convergence to the correct answer, in particular, under a few classes of loopy GM formulations of combinatorial optimization problems: matching (Bayati et al., 2005; Sanghavi et al., 2011; Huang and Jebara, 2007; Salez and Shah, 2009), perfect matching (Bayati et al., 2011), matching with odd cycles (Shin et al., 2013) and shortest path (Ruozzi and Tatikonda, 2008). The important common feature of these instances is that BP converges to a correct MAP assignment if the Linear Programming (LP) relaxation of the MAP inference problem is tight, i.e., it has no integrality gap. In other words, BP can be used an efficient distributed solver for those LPs, and is presumably of better choice than classical centralized LP solvers such as simplex methods (Dantzig, 1998), interior point methods (Thapa, 2003) and ellipsoid methods (Khachiyan, 1980) for large-scale inputs. However, these theoretical results on BP are very sensitive to underlying structural properties depending on specific problems and it is not clear what extent they can be generalized to, e.g., the BP analysis for matching problems (Bayati et al., 2005; Sanghavi et al., 2011; Huang and Jebara, 2007; Salez and Shah, 2009) are not extended to even for perfect matching

ones (Bayati et al., 2011). In this paper, we overcome such technical difficulties for enhancing the power of BP as a LP solver.

**Contribution.** We establish a generic criteria for GM formulations of given LP so that BP converges to the optimal LP solution. By product, it also provides a sufficient condition for a unique BP fixed point. As one can naturally expect given prior results, one of our conditions requires the LP tightness. Our main contribution is finding other sufficient generic conditions so that BP converges to the correct MAP assignment of GM. First of all, our generic criteria can rediscover all prior BP results on this line, including matching (Bayati et al., 2005; Sanghavi et al., 2011; Huang and Jebara, 2007), perfect matching (Bayati et al., 2011), matching with odd cycles (Shin et al., 2013) and shortest path (Ruozi and Tatikonda, 2008), i.e., we provide a unified framework on establishing the convergence and correctness of BPs in relation to associated LPs. Furthermore, we provide new instances under our framework: we show that BP can solve LP formulations associated to other popular combinatorial optimizations including perfect matching with odd cycles, traveling salesman, cycle packing and vertex cover, which are not known in the literature. While most prior known BP results on this line focused on the case when the associated LP has an integral solution, the proposed criteria naturally guides the BP design to compute fractional LP solutions as well (see Section 4.2 and Section 4.4 for details).

Our proof technique is built upon on that of Sanghavi et al. (2011) where the authors construct an alternating path in the computational tree induced by BP to analyze its performance for the maximum weight matching problem. Such a trick needs specialized case studies depending on the associated LP when the path reaches a leaf of the tree, and this is one of main reasons why it is not easy to generalize to other problems beyond matching. The main technical contribution of this paper is providing a way to avoid the issue in the BP analysis via carefully analyzing associated LP polytopes.

The main appeals of our results are providing not only tools on BP analysis, but also guidelines on BP design for its high performance, i.e., one can carefully design a BP given LP so that it satisfies the proposed criteria. We run such a BP for solving the famous traveling salesman problem (TSP), and our experiments show that BP outperforms other popular heuristics (see Section 5). Our results provide not only new tools on BP analysis and design, but also new directions on efficient distributed (and parallel) solvers for large-scale LPs and combinatorial optimization problems.

**Organization.** In Section 2, we introduce necessary backgrounds for the BP algorithm. In Section 3, we provide the main result of the paper, and several concrete applications to popular combinatorial optimizations are described

in Section 4. In Section 5, we show empirical performances of BP algorithms for solving TSP.

## 2 PRELIMINARIES

### 2.1 GRAPHICAL MODEL

A joint distribution of  $n$  (binary) random variables  $Z = [Z_i] \in \{0, 1\}^n$  is called a Graphical Model (GM) if it factorizes as follows: for  $z = [z_i] \in \{0, 1\}^n$ ,

$$\Pr[Z = z] \propto \prod_{i \in \{1, \dots, n\}} \psi_i(z_i) \prod_{\alpha \in F} \psi_\alpha(z_\alpha),$$

where  $\{\psi_i, \psi_\alpha\}$  are (given) non-negative functions, so-called factors;  $F$  is a collection of subsets

$$F = \{\alpha_1, \alpha_2, \dots, \alpha_k\} \subset 2^{\{1, 2, \dots, n\}}$$

(each  $\alpha_j$  is a subset of  $\{1, 2, \dots, n\}$  with  $|\alpha_j| \geq 2$ );  $z_\alpha$  is the projection of  $z$  onto dimensions included in  $\alpha$ .<sup>1</sup> In particular,  $\psi_i$  is called a variable factor. Figure 1 depicts the graphical relation between factors  $F$  and variables  $z$ .

Figure 1: Factor graph for the graphical model  $\Pr[z] \propto \psi_{\alpha_1}(z_1, z_3)\psi_{\alpha_2}(z_1, z_2, z_3)\psi_{\alpha_3}(z_2, z_3, z_4)$ , i.e.,  $F = \{\alpha_1, \alpha_2, \alpha_3\}$  and  $n = 4$ . Each  $\alpha_j$  selects a subset of  $z$ . For example,  $\alpha_1$  selects  $\{z_1, z_3\}$ .

Assignment  $z^*$  is called a maximum-a-posteriori (MAP) assignment if  $z^* = \arg \max_{z \in \{0, 1\}^n} \Pr[z]$ . This means that computing a MAP assignment requires us to compare  $\Pr[z]$  for all possible  $z$ , which is typically computationally intractable (i.e., NP-hard) unless the induced bipartite graph of factors  $F$  and variables  $z$ , so-called factor graph, has a bounded treewidth (Chandrasekaran et al., 2008).

### 2.2 MAX-PRODUCT BELIEF PROPAGATION

The (max-product) BP algorithm is a popular heuristic for approximating the MAP assignment in GM. BP is implemented iteratively; at each iteration  $t$ , BP maintains four messages  $\{m_{\alpha \rightarrow i}^t(c), m_{i \rightarrow \alpha}^t(c) : c \in \{0, 1\}\}$  between every variable  $z_i$  and every associated  $\alpha \in F_i$ , where  $F_i := \{\alpha \in F : i \in \alpha\}$ ; that is,  $F_i$  is a subset of  $F$  such that all  $\alpha$  in  $F_i$  are associated with  $z_i$ . The messages

<sup>1</sup>For example, if  $z = [0, 1, 0]$  and  $\alpha = \{1, 3\}$ , then  $z_\alpha = [0, 0]$ .

are updated as follows:

$$m_{\alpha \rightarrow i}^{t+1}(c) = \max_{z_\alpha: z_i=c} \psi_\alpha(z_\alpha) \prod_{j \in \alpha \setminus i} m_{j \rightarrow \alpha}^t(z_j) \quad (1)$$

$$m_{i \rightarrow \alpha}^{t+1}(c) = \psi_i(c) \prod_{\alpha' \in F_i \setminus \alpha} m_{\alpha' \rightarrow i}^t(c). \quad (2)$$

Where each  $z_i$  only sends messages to  $F_i$ ; that is,  $z_i$  sends messages to  $\alpha_j$  only if  $\alpha_j$  selects/includes  $i$ . The outer-term in the message computation (1) is maximized over all possible  $z_\alpha \in \{0, 1\}^{|\alpha|}$  with  $z_i = c$ . The inner-term is a product that only depends on the variables  $z_j$  (excluding  $z_i$ ) that are connected to  $\alpha$ . The message-update (2) from variable  $z_i$  to factor  $\psi_\alpha$  is a product containing all messages received by  $z_i$  in the previous iteration, except for the message sent by  $\psi_\alpha$  itself.

One can reduce the complexity by combining (1) and (2) as:

$$m_{i \rightarrow \alpha}^{t+1}(c) = \psi_i(c) \prod_{\alpha' \in F_i \setminus \alpha} \max_{z_{\alpha'}: z_i=c} \psi_{\alpha'}(z_{\alpha'}) \times \prod_{j \in \alpha' \setminus i} m_{j \rightarrow \alpha'}^t(z_j).$$

The BP fixed-point of messages is defined as  $m^{t+1} = m^t$  under the above updating rule. Given a set of messages  $\{m_{i \rightarrow \alpha}(c), m_{\alpha \rightarrow i}(c) : c \in \{0, 1\}\}$ , the so-called BP marginal beliefs are computed as follows:

$$b_i[z_i] = \psi_i(z_i) \prod_{\alpha \in F_i} m_{\alpha \rightarrow i}(z_i). \quad (3)$$

This BP algorithm outputs  $z^{BP} = [z_i^{BP}]$  where

$$z_i^{BP} = \begin{cases} 1 & \text{if } b_i[1] > b_i[0] \\ ? & \text{if } b_i[1] = b_i[0] \\ 0 & \text{if } b_i[1] < b_i[0] \end{cases}.$$

It is known that  $z^{BP}$  converges to a MAP assignment after a sufficient number of iterations, if the factor graph is a tree and the MAP assignment is unique. However, if the graph contains cycles, the BP algorithm is not guaranteed to converge a MAP assignment in general.

### 3 CONVERGENCE AND CORRECTNESS OF BELIEF PROPAGATION

In this section, we provide the main result of this paper: a convergence and correctness criteria of BP. Consider the following GM: for  $x = [x_i] \in \{0, 1\}^n$  and  $w = [w_i] \in \mathbb{R}^n$ ,

$$\Pr[X = x] \propto \prod_i e^{-w_i x_i} \prod_{\alpha \in F} \psi_\alpha(x_\alpha), \quad (4)$$

where  $F$  is the set of non-variable factors and the factor function  $\psi_\alpha$  for  $\alpha \in F$  is defined as

$$\psi_\alpha(x_\alpha) = \begin{cases} 1 & \text{if } A_\alpha x_\alpha \geq b_\alpha, C_\alpha x_\alpha = d_\alpha \\ 0 & \text{otherwise} \end{cases},$$

for some matrices  $A_\alpha, C_\alpha$  and vectors  $b_\alpha, d_\alpha$ . Now we consider the Linear Programming (LP) corresponding the above GM:

$$\begin{aligned} & \text{minimize} && w \cdot x \\ & \text{subject to} && \psi_\alpha(x_\alpha) = 1, \quad \forall \alpha \in F \\ & && x = [x_i] \in [0, 1]^n. \end{aligned} \quad (5)$$

One can easily observe that the MAP assignments for GM (4) corresponds to the (optimal) solution of LP (5) if the LP has an integral solution  $x^* \in \{0, 1\}^n$ . As stated in the following theorem, we establish other sufficient conditions so that the max-product BP can indeed find the LP solution.

**Theorem 1** *The max-product BP on GM (4) with arbitrary initial message converges to the solution of LP (5) if the following conditions hold:*

- C1. LP (5) has a unique integral solution  $x^* \in \{0, 1\}^n$ , i.e., it is tight.
- C2. For every  $i \in \{1, 2, \dots, n\}$ , the number of factors associated with  $x_i$  is at most two, i.e.,  $|F_i| \leq 2$ .
- C3. For every factor  $\psi_\alpha$ , every  $x_\alpha \in \{0, 1\}^{|\alpha|}$  with  $\psi_\alpha(x_\alpha) = 1$ , and every  $i \in \alpha$  with  $x_i \neq x_i^*$ , there exists  $\gamma \subset \alpha$  such that

$$|\{j \in \{i\} \cup \gamma : |F_j| = 2\}| \leq 2$$

$$\begin{aligned} \psi_\alpha(x'_\alpha) = 1, & \quad \text{where } x'_k = \begin{cases} x_k & \text{if } k \notin \{i\} \cup \gamma \\ x_k^* & \text{otherwise} \end{cases} \\ \psi_\alpha(x''_\alpha) = 1, & \quad \text{where } x''_k = \begin{cases} x_k & \text{if } k \in \{i\} \cup \gamma \\ x_k^* & \text{otherwise} \end{cases} \end{aligned}.$$

Since Theorem 1 holds for arbitrary initial messages, the conditions C1, C2, C3 also provides the uniqueness of BP fixed-points in term of marginal beliefs, as follows.

**Corollary 2** *The BP fixed-points of GM (4) have the same marginal beliefs if conditions C1, C2, C3 hold.*

The conditions C2, C3 are typically easy to check given GM (4) and the uniqueness in C1 can be easily guaranteed via adding random noises, where we provide several concrete examples in Section 4. On the other hand, the integral property in C1 requires to analyze LP (5), where it has been extensively studied in the field of combinatorial optimization (Schrijver, 2003). Nevertheless, Theorem 1 provides important guidelines to design BP algorithms, ir-respectively of the LP analysis. For example, in Section 5, we report empirical performances of BP following the above guideline for solving the traveling salesman problem, without relying on whether the corresponding LP has an integral solution or not.

### 3.1 PROOF OF THEOREM 1

To begin with, we define some necessary notation. We let  $\mathcal{P}$  denote the polytope of feasible solutions of LP (5):

$$\mathcal{P} := \{x \in [0, 1]^n : \psi_\alpha(x_\alpha) = 1, \forall \alpha \in F\}.$$

Similarly,  $\mathcal{P}_\alpha$  is defined as

$$\mathcal{P}_\alpha := \left\{x \in [0, 1]^{|\alpha|} : \psi_\alpha(x_\alpha) = 1\right\}.$$

We first state the following key technical lemma.

**Lemma 3** *There exist universal constants  $K, \eta > 0$  for LP (5) such that if  $z \in [0, 1]^n$  and  $0 < \varepsilon < \eta$  satisfy the followings:*

1. *There exist at most two violated factors for  $z$ , i.e.,  $|\{\alpha \in F : z_\alpha \notin \mathcal{P}_\alpha\}| \leq 2$ .*
2. *For each violated factor  $\alpha$ , there exist  $i \in \alpha$  such that  $z_\alpha^\dagger \in \mathcal{P}_\alpha$ , where  $z^\dagger = z + \varepsilon e_i$  or  $z^\dagger = z - \varepsilon e_i$  and  $e_i \in \{0, 1\}^n$  is the unit vector whose  $i$ -th coordinate is 1,*

*then there exists  $z^\ddagger \in \mathcal{P}$  such that  $\|z - z^\ddagger\|_1 \leq \varepsilon K$ .*

The proof of Lemma 3 is presented in Section 3.2. Now, from Condition C1, it follows that there exists  $\rho > 0$  such that

$$\rho := \inf_{x \in \mathcal{P} \setminus x^*} \frac{w \cdot x - w \cdot x^*}{\|x - x^*\|_1} > 0. \quad (6)$$

We let  $\hat{x}^t \in \{0, 1, ?\}^n$  denote the BP estimate at the  $t$ -th iteration for the MAP computation. We will show that under Conditions C1-C3,

$$\hat{x}^t = x^*, \quad \text{for } t > \left(\frac{w_{\max}}{\rho} + 1\right) K,$$

where  $w_{\max} = \max_j |w_j|$  and  $K$  is the universal constant in Lemma 3. Suppose the above statement is false, i.e., there exists  $i \in \{1, 2, \dots, n\}$  such that  $\hat{x}_i^t \neq x_i^*$  for  $t > \left(\frac{w_{\max}}{\rho} + 1\right) K$ . Under the assumption, we will reach a contradiction.

Now we construct a tree-structured GM  $T_i(t)$ , popularly known as the computational tree (Weiss and Freeman, 2001), as follows:

1. Add  $y_i \in \{0, 1\}$  as the root variable with variable factor function  $e^{-w_i y_i}$ .
2. For each leaf variable  $y_j$  and for each  $\alpha \in F_j$  and  $\psi_\alpha$  is not associated with  $y_j$  in the current tree-structured GM, add a factor function  $\psi_\alpha$  as a child of  $y_j$ .
3. For each leaf factor  $\psi_\alpha$  and for each variable  $y_k$  such that  $k \in \alpha$  and  $y_k$  is not associated with  $\psi_\alpha$  in the current tree-structured GM, add a variable  $y_k$  as a child of  $\psi_\alpha$  with variable factor function  $e^{-w_k y_k}$ .

4. Repeat Step 2, 3  $t$  times.

Suppose the initial messages of BP are set by 1, i.e.,  $m_{j \rightarrow \alpha}(\cdot)^0 = 1$ . Then, if  $x_i^* \neq \hat{x}_i^t$ , it is known (Weiss, 1997) that there exists a MAP configuration  $y^{MAP}$  on  $T_i(t)$  with  $y_i^{MAP} \neq x_i^*$  at the root variable. For other initial messages, one can guarantee the same property under changing weights of leaf variables of the tree-structured GM. Specifically, for a leaf variable  $k$  with  $|F_k = \{\alpha_1, \alpha_2\}| = 2$  and  $\alpha_1$  being its parent factor in  $T_i(t)$ , we reset its variable factor by  $e^{-w_k y_k}$ , where

$$w'_k = w_k - \log \frac{\max_{z_{\alpha_2}: z_k=1} \psi_{\alpha_2}(z_{\alpha_2}) \prod_{j \in \alpha_2 \setminus k} m_{j \rightarrow \alpha_2}^0(z_j)}{\max_{z_{\alpha_2}: z_k=0} \psi_{\alpha_2}(z_{\alpha_2}) \prod_{j \in \alpha_2 \setminus k} m_{j \rightarrow \alpha_2}^0(z_j)}. \quad (7)$$

This is the reason why our proof of Theorem 1 goes through for arbitrary initial messages. For notational convenience, we present the proof for the standard initial message of  $m_{j \rightarrow \alpha}^0(\cdot) = 1$ , where it can be naturally generalized to other initial messages using (7).

Now we construct a new valid assignment  $y^{NEW}$  on the computational tree  $T_i(t)$  as follows:

1. Initially, set  $y^{NEW} \leftarrow y^{MAP}$ .
2. Update the value of the root variable of  $T_i(t)$  by  $y_i^{NEW} \leftarrow x_i^*$ .
3. For each child factor  $\psi_\alpha$  of root  $i \in \alpha$ , choose  $\gamma \subset \alpha$  according to Condition C3 and update the associated variable by  $y_j^{NEW} \leftarrow x_j^* \forall j \in \gamma$ .
4. Repeat Step 2,3 recursively by substituting  $T_i(t)$  by the subtree of  $T_i(t)$  of root  $j \in \gamma$  until the process stops (i.e.,  $i = j$ ) or the leaf of  $T_i(t)$  is reached (i.e.,  $i$  does not have a child).

One can notice that the set of revised variables in Step 2 of the above procedure forms a path structure  $Q$  in the tree-structured GM. We first, consider the case that both ends of the path  $Q$  touch leaves of  $T_i(t)$ , where other cases can be argued in a similar manner. Define  $\zeta_j$  and  $\kappa_j$  be the number of copies of  $x_j$  in path  $Q$  with  $x_j^* = 1$  and  $x_j^* = 0$ , respectively, where  $\zeta = [\zeta_j], \kappa = [\kappa_j] \in \mathbb{Z}_+^n$ . Then, from our construction of  $y^{NEW}$ , one can observe that

$$y^{NEW} = y^{MAP} + \zeta - \kappa$$

$$w \cdot y^{MAP} - w \cdot y^{NEW} = w \cdot (\kappa - \zeta).$$

If we set  $z = x^* + \varepsilon(\kappa - \zeta)$  where  $0 < \varepsilon < \min\{1/2t, \eta\}$ , then one can check that  $z$  satisfies the conditions of Lemma 3 using Conditions C2, C3. Hence, from Lemma 3, there exists  $z^\ddagger \in \mathcal{P}$  such that

$$\|z^\ddagger - z\|_1 \leq \varepsilon K$$

$$\|z^\ddagger - x^*\|_1 \geq \varepsilon(\|\zeta\|_1 + \|\kappa\|_1 - K) \geq \varepsilon(t - K).$$

where  $z = x^* + \varepsilon(\kappa - \zeta)$ . Hence, it follows that

$$\begin{aligned} 0 < \rho &\leq \frac{w \cdot z^\dagger - w \cdot x^*}{\|z^\dagger - x^*\|_1} \\ &\leq \frac{w \cdot z + \varepsilon w_{\max} K - w \cdot x^*}{\varepsilon(t - K)} \\ &= \frac{\varepsilon w \cdot (\kappa - \zeta) + \varepsilon w_{\max} K}{\varepsilon(t - K)} \\ &= \frac{w \cdot (\kappa - \zeta) + w_{\max} K}{t - K} \end{aligned}$$

Furthermore, if  $t > \left(\frac{w_{\max}}{\rho} + 1\right) K$ , the above inequality implies that

$$\begin{aligned} w \cdot y^{MAP} - w \cdot y^{NEW} &= w \cdot (\kappa - \zeta) \\ &\geq \rho t - (w_{\max} + \rho) K > 0. \end{aligned}$$

This contradicts to the fact that  $y^{MAP}$  is a MAP configuration. This completes the proof of Theorem 1.

### 3.2 PROOF OF LEMMA 3

One can write  $\mathcal{P} = \{x : Ax \geq b\} \subset [0, 1]^n$  for some matrix  $A \in \mathbb{R}^{m \times n}$  and vector  $b \in \mathbb{R}^m$ , where without loss of generality, we can assume that  $\|A_i\|_2 = 1$  where  $\{A_i\}$  is the set of row vectors of  $A$ . We define

$$\mathcal{P}_\varepsilon = \{x : Ax \geq b - \varepsilon \mathbf{1}\},$$

where  $\mathbf{1}$  is the vector of ones. Then, one can check that  $z \in \mathcal{P}_\varepsilon$  for  $z, \varepsilon$  satisfying conditions of Lemma 3. Now we aim for finding a universal constant  $K$  satisfying

$$\text{dist}(\mathcal{P}, \mathcal{P}_\varepsilon) := \max_{x \in \mathcal{P}_\varepsilon} (\min_{y \in \mathcal{P}} \|x - y\|_1) \leq \varepsilon K,$$

which leads to the conclusion of Lemma 3.

To this end, for  $\xi \subset [1, 2, \dots, m]$  with  $|\xi| = n$ , we let  $A_\xi$  be the square sub-matrix of  $A$  by choosing  $\xi$ -th rows of  $A$  and  $b_\xi$  is the  $n$ -dimensional subvector of  $b$  corresponding  $\xi$ . Throughout the proof, we only consider  $\xi$  such that  $A_\xi$  is invertible. Using this notation, we first claim the following.

**Claim 4** *If  $A_\xi$  is invertible and  $v_\xi := A_\xi^{-1} b_\xi \in \mathcal{P}$ , then  $v_\xi$  is a vertex of polytope  $\mathcal{P}$ .*

**Proof.** Suppose  $v_\xi$  is not a vertex of  $\mathcal{P}$ , i.e. there exist  $x, y \in \mathcal{P}$  such that  $x \neq y$  and  $v_\xi = \lambda x + (1 - \lambda)y$  for some  $\lambda \in (0, 1/2]$ . Under the assumption, we will reach a contradiction. Since  $\mathcal{P}$  is a convex set,

$$\frac{3\lambda}{2}x + \left(1 - \frac{3\lambda}{2}\right)y \in \mathcal{P}. \quad (8)$$

However, as  $A_\xi$  is invertible,

$$A_\xi \left( \frac{3\lambda}{2}x + \left(1 - \frac{3\lambda}{2}\right)y \right) \neq b_\xi. \quad (9)$$

From (8) and (9), there exists a row vector  $A_i$  of  $A_\xi$  and the corresponding element  $b_i$  of  $b_\xi$  such that

$$A_i \cdot \left( \frac{3\lambda}{2}x + \left(1 - \frac{3\lambda}{2}\right)y \right) > b_i.$$

Using the above inequality and  $A_i \cdot (\lambda x + (1 - \lambda)y) = b_i$ , one can conclude that

$$A_i \cdot \left( \frac{\lambda}{2}x + \left(1 - \frac{\lambda}{2}\right)y \right) < b_i,$$

which contradict to  $\frac{\lambda}{2}x + \left(1 - \frac{\lambda}{2}\right)y \in \mathcal{P}$ . This completes the proof of Claim 4.  $\square$

We also note that if  $v$  is a vertex of polytope  $\mathcal{P}$ , there exists  $\xi$  such that  $A_\xi$  is invertible and  $v = A_\xi^{-1} b_\xi$ . We define the following notation:

$$\mathcal{I} = \{\xi : A_\xi^{-1} b_\xi \in \mathcal{P}\} \quad \mathcal{I}_\varepsilon = \{\xi : A_\xi^{-1} (b_\xi - \varepsilon \mathbf{1}) \in \mathcal{P}_\varepsilon\},$$

where Claim 4 implies that  $\{v_\xi := A_\xi^{-1} b_\xi : \xi \in \mathcal{I}\}$  and  $\{u_{\xi, \varepsilon} := A_\xi^{-1} (b_\xi - \varepsilon \mathbf{1}) : \xi \in \mathcal{I}_\varepsilon\}$  are sets of vertices of  $\mathcal{P}$  and  $\mathcal{P}_\varepsilon$ , respectively. Using the notation, we show the following claim.

**Claim 5** *There exists  $\eta > 0$  such that  $\mathcal{I}_\varepsilon \subset \mathcal{I}$  for all  $\varepsilon \in (0, \eta)$ .*

**Proof.** Suppose  $\eta > 0$  satisfying the conclusion of Claim 5 does not exist. Then, there exists a strictly decreasing sequence  $\{\varepsilon_k > 0 : k = 1, 2, \dots\}$  converges to 0 such that  $\mathcal{I}_{\varepsilon_k} - \mathcal{I} \neq \emptyset$ . Since  $|\{\xi : \xi \subset [1, 2, \dots, m]\}| < \infty$ , there exists  $\xi'$  such that

$$|\mathcal{K} := \{k : \xi' \in \mathcal{I}_{\varepsilon_k} - \mathcal{I}\}| = \infty. \quad (10)$$

For any  $k \in \mathcal{K}$ , observe that the sequence  $\{u_{\xi', \varepsilon_\ell} : \ell \geq k, \ell \in \mathcal{K}\}$  converges to  $v_{\xi'}$ . Furthermore, all points in the sequence are in  $\mathcal{P}_{\varepsilon_k}$  since  $\mathcal{P}_{\varepsilon_\ell} \subset \mathcal{P}_{\varepsilon_k}$  for any  $\ell \geq k$ . Therefore, one can conclude that  $v_{\xi'} \in \mathcal{P}_{\varepsilon_k}$  for all  $k \in \mathcal{K}$ , where we additionally use the fact that  $\mathcal{P}_{\varepsilon_k}$  is a closed set. Because  $\mathcal{P} = \bigcap_{k \in \mathcal{K}} \mathcal{P}_{\varepsilon_k}$ , it must be that  $v_{\xi'} \in \mathcal{P}$ , i.e.,  $v_{\xi'}$  must be a vertex of  $\mathcal{P}$  from Claim 4. This contradicts to the fact  $\xi' \notin \mathcal{I}$ . This completes the proof of Claim 5.  $\square$

From the above claim, we observe that any  $x \in \mathcal{P}_\varepsilon$  can be expressed as a convex combination of  $\{u_{\xi, \varepsilon} : \xi \in \mathcal{I}\}$ , i.e.,  $x = \sum_{\xi \in \mathcal{I}} \lambda_\xi u_{\xi, \varepsilon}$  with  $\sum_{\xi \in \mathcal{I}} \lambda_\xi = 1$  and  $\lambda_\xi \geq 0$ . For all  $\varepsilon \in (0, \eta)$  for  $\eta > 0$  in Claim 5, one can conclude that

$$\begin{aligned} \text{dist}(\mathcal{P}, \mathcal{P}_\varepsilon) &\leq \max_{x \in \mathcal{P}_\varepsilon} \left\| \sum_{\xi \in \mathcal{I}} \lambda_\xi u_{\xi, \varepsilon} - \sum_{\xi \in \mathcal{I}} \lambda_\xi v_\xi \right\|_1 \\ &= \max_{x \in \mathcal{P}_\varepsilon} \varepsilon \left\| \sum_{\xi \in \mathcal{I}} \lambda_\xi A_\xi^{-1} \mathbf{1} \right\|_1 \\ &\leq \varepsilon \max_{\xi} \|A_\xi^{-1} \mathbf{1}\|_1, \end{aligned}$$

where we choose  $K = \max_{\xi} \|A_\xi^{-1} \mathbf{1}\|_1$ . This completes the proof of Lemma 3.

## 4 APPLICATIONS OF THEOREM 1 TO COMBINATORIAL OPTIMIZATION

In this section, we introduce concrete instances of LPs satisfying the conditions of Theorem 1 so that BP correctly converges to its optimal solution. Specifically, we consider LP formulations associated to several combinatorial optimization problems including shortest path, maximum weight perfect matching, traveling salesman, maximum weight disjoint vertex cycle packing and vertex cover. We note that the shortest path result, Corollary 6, is known (Ruozzi and Tatikonda, 2008), where we rediscover it as a corollary of Theorem 1. Our other results, Corollaries 7-11, are new and what we first establish in this paper.

### 4.1 SHORTEST PATH

Given directed graph  $G = (V, E)$  and non-negative edge weights  $w = [w_e : e \in E] \in \mathbb{R}_+^{|E|}$ , the shortest path problem is to find the shortest path from the source  $s$  to the destination  $t$ : it minimizes the sum of edge weights along the path. One can naturally design the following LP for this problem:

$$\begin{aligned} & \text{minimize} && w \cdot x \\ & \text{subject to} && \sum_{e \in \delta^o(v)} x_e - \sum_{e \in \delta^i(v)} x_e \\ & && = \begin{cases} 1 & \text{if } v = s \\ -1 & \text{if } v = t \\ 0 & \text{otherwise} \end{cases} \quad \forall v \in V \\ & && x = [x_e] \in [0, 1]^{|E|}. \end{aligned} \quad (11)$$

where  $\delta^i(v), \delta^o(v)$  are the set of incoming, outgoing edges of  $v$ . It is known that the above LP always has an integral solution, i.e., the shortest path from  $s$  to  $t$ . We consider the following GM for LP (11):

$$\Pr[X = x] \propto \prod_{e \in E} e^{-w_e x_e} \prod_{v \in V} \psi_v(x_{\delta(v)}), \quad (12)$$

where the factor function  $\psi_v$  is defined as

$$\psi_v(x_{\delta(v)}) = \begin{cases} 1 & \text{if } \sum_{e \in \delta^o(v)} x_e - \sum_{e \in \delta^i(v)} x_e \\ & = \begin{cases} 1 & \text{if } v = s \\ -1 & \text{if } v = t \\ 0 & \text{otherwise} \end{cases} \\ 0 & \text{otherwise} \end{cases}.$$

For the above GM (12), one can easily check Conditions C2, C3 of Theorem 1 hold and derive the following corollary whose formal proof is presented in the supplementary material due to the space constraint.

**Corollary 6** *If the shortest path from  $s$  to  $t$ , i.e., the solution of the shortest path LP (11), is unique, then the max-product BP on GM (12) converges to it.*

The uniqueness condition in the above corollary is easy to guarantee by adding small random noises to edge weights.

### 4.2 MAXIMUM WEIGHT PERFECT MATCHING

Given undirected graph  $G = (V, E)$  and non-negative edge weights  $w = [w_e : e \in E] \in \mathbb{R}_+^{|E|}$  on edges, the maximum weight perfect matching problem is to find a set of edges such that each vertex is connected to exactly one edge in the set and the sum of edge weights in the set is maximized. One can naturally design the following LP for this problem:

$$\begin{aligned} & \text{maximize} && w \cdot x \\ & \text{subject to} && \sum_{e \in \delta(v)} x_e = 1, \quad \forall v \in V \\ & && x = [x_e] \in [0, 1]^{|E|}. \end{aligned} \quad (13)$$

where  $\delta(v)$  is the set of edges connected to a vertex  $v$ . If the above LP has an integral solution, it corresponds to the solution of the maximum weight perfect matching problem.

It is known that the maximum weight matching LP (13) always has a half-integral solution  $x^* \in \{0, \frac{1}{2}, 1\}^{|E|}$ . We will design BP for obtaining the half-integral solution. To this end, duplicate each edge  $e$  to  $e_1, e_2$  and define a new graph  $G' = (V, E')$  where  $E' = \{e_1, e_2 : e \in E\}$ . Then, we suggest the following equivalent LP that always have an integral solution:

$$\begin{aligned} & \text{maximize} && w' \cdot x \\ & \text{subject to} && \sum_{e_i \in \delta(v)} x_{e_i} = 2 \quad \forall v \in V \\ & && x = [x_{e_i}] \in [0, 1]^{|E'|}. \end{aligned} \quad (14)$$

where  $w'_{e_1} = w'_{e_2} = w_e$ . One can easily observe that solving LP (14) is equivalent to solving LP (13) due to our construction of  $G'$  and  $w'$ . Now, construct the following GM for LP (14):

$$\Pr[X = x] \propto \prod_{e_i \in E'} e^{w'_{e_i} x_{e_i}} \prod_{v \in V} \psi_v(x_{\delta(v)}), \quad (15)$$

where the factor function  $\psi_v$  is defined as

$$\psi_v(x_{\delta(v)}) = \begin{cases} 1 & \text{if } \sum_{e_i \in \delta(v)} x_{e_i} = 2 \\ 0 & \text{otherwise} \end{cases}.$$

For the above GM (15), we derive the following corollary of Theorem 1 whose formal proof is presented in the supplementary material due to the space constraint.

**Corollary 7** *If the solution of the maximum weight perfect matching LP (14) is unique, then the max-product BP on GM (15) converges to it.*

Again, the uniqueness condition in the above corollary is easy to guarantee by adding small random noises to edge weights  $[w'_{e_i}]$ . We note that it is known (Bayati et al., 2011) that BP converges to the unique and integral solution of LP (13), while Corollary 7 implies that BP can solve it without the integrality condition. We note that one can easily obtain a similar result for the maximum weight (non-perfect) matching problem, where we omit the details in this paper.

### 4.3 MAXIMUM WEIGHT PERFECT MATCHING WITH ODD CYCLES

In previous section we prove that BP converges to the optimal (possibly, fractional) solution of LP (14), equivalently LP (13). One can add odd cycle (also called Blossom) constraints and make those LPs tight i.e. solves the maximum weight perfect matching problem:

$$\begin{aligned} & \text{maximize} && w \cdot x \\ & \text{subject to} && \sum_{e \in \delta(v)} x_e = 1, \quad \forall v \in V \\ & && \sum_{e \in C} x_e \leq \frac{|C| - 1}{2}, \quad \forall C \in \mathcal{C}, \\ & && x = [x_e] \in [0, 1]^{|E|}. \end{aligned} \quad (16)$$

where  $\mathcal{C}$  is a set of odd cycles in  $G$ . The authors (Shin et al., 2013) study BP for solving LP (16) by replacing  $\sum_{e \in \delta(v)} x_e = 1$  by  $\sum_{e \in \delta(v)} x_e \leq 1$ , i.e., for the maximum weight (non-perfect) matching problem. Using Theorem 1, one can extend the result to the maximum weight perfect matching problem, i.e., solving LP (16). To this end, we follow the approach (Shin et al., 2013) and construct the following graph  $G' = (V', E')$  and weight  $w' = [w'_e : e \in E'] \in \mathbb{R}^{|E'|}$  given set  $\mathcal{C}$  of disjoint odd cycles:

$$\begin{aligned} V' &= V \cup \{v_C : C \in \mathcal{C}\} \\ E' &= \{(u, v_C) : u \in C, C \in \mathcal{C}\} \cup E \setminus \{e \in C : C \in \mathcal{C}\} \end{aligned}$$

$$w'_e = \begin{cases} \frac{1}{2} \sum_{e' \in E(C)} (-1)^{d_C(u, e')} w_{e'} & \text{if } e = (u, v_C) \\ & \text{for some } C \in \mathcal{C}, \\ w_e & \text{otherwise} \end{cases}$$

where  $d_C(u, e')$  is the graph distance between  $u, e'$  in cycle  $C$ . Then, LP (16) is equivalent to the following LP:

$$\begin{aligned} & \text{maximize} && w' \cdot y \\ & \text{subject to} && \sum_{e \in \delta(v)} y_e = 1, \quad \forall v \in V \\ & && \sum_{u \in V(C)} (-1)^{d_C(u, e)} y_{(v_C, u)} \in [0, 2], \quad \forall e \in E(C) \\ & && \sum_{e \in \delta(v_C)} y_e \leq |C| - 1, \quad \forall C \in \mathcal{C} \\ & && y = [y_e] \in [0, 1]^{|E'|}. \end{aligned} \quad (17)$$

Now, we construct the following GM from the above LP:

$$\Pr[Y = y] \propto \prod_{e \in E} e^{w_e y_e} \prod_{v \in V} \psi_v(y_{\delta(v)}) \prod_{C \in \mathcal{C}} \psi_C(y_{\delta(v_C)}), \quad (18)$$

where the factor function  $\psi_v, \psi_C$  is defined as

$$\begin{aligned} \psi_v(y_{\delta(v)}) &= \begin{cases} 1 & \text{if } \sum_{e \in \delta(v)} y_e = 1 \\ 0 & \text{otherwise} \end{cases}, \\ \psi_C(y_{\delta(v_C)}) &= \begin{cases} 1 & \text{if } \sum_{u \in V(C)} (-1)^{d_C(u, e)} y_{(v_C, u)} \in \{0, 2\} \\ & \sum_{e \in \delta(v_C)} y_e \leq |C| - 1 \\ 0 & \text{otherwise} \end{cases}. \end{aligned}$$

For the above GM (18), we derive the following corollary of Theorem 1 whose formal proof is presented in the supplementary material due to the space constraint.

**Corollary 8** *If the solution of the maximum weight perfect matching with odd cycles LP (17) is unique and integral, then the max-product BP on GM (18) converges to it.*

We again emphasize that a similar result for the maximum weight (non-perfect) matching problem was established in (Shin et al., 2013). However, the proof technique in the paper does not extend to the perfect matching problem. This is in essence because presumably the perfect matching problem is harder than the non-perfect matching one. Under the proposed generic criteria of Theorem 1, we overcome the technical difficulty.

### 4.4 VERTEX COVER

Given undirected graph  $G = (V, E)$  and non-negative integer vertex weights  $b = [b_v : v \in V] \in \mathbb{Z}_+^{|V|}$ , the vertex cover problem is to find a set of vertices minimizes the sum of vertex weights in the set such that each edge is connected to at least one vertex in it. This problem is one of Karp's 21 NP-complete problems (Karp, 1972). The associated LP formulation to the vertex cover problem is as follows:

$$\begin{aligned} & \text{minimize} && b \cdot y \\ & \text{subject to} && y_u + y_v \geq 1, (u, v) \in E \\ & && y = [y_v] \in [0, 1]^{|V|}. \end{aligned} \quad (19)$$

However, if we design a GM from the above LP, it does not satisfy conditions in Theorem 1. Instead, we will show that BP can solve the following dual LP:

$$\begin{aligned} & \text{maximize} && \sum_{e \in E} x_e \\ & \text{subject to} && \sum_{e \in \delta(v)} x_e \leq b_v, \quad \forall v \in V \\ & && x = [x_e] \in \mathbb{R}_+^{|E|}. \end{aligned} \quad (20)$$

Note that the above LP always has a half-integral solution. As we did in Section 4.2, one can duplicate edges, i.e.,

$E' = \{e_1, \dots, e_{2b_{\max}} : e \in E\}$  with  $b_{\max} = \max_v b_v$ , and design the following equivalent LP having an integral solution:

$$\begin{aligned} & \text{maximize} && w' \cdot x \\ & \text{subject to} && \sum_{e_i \in \delta(v)} x_{e_i} \leq 2b_v, \quad \forall v \in V, \\ & && x = [x_{e_i}] \in [0, 1]^{|E'|} \end{aligned} \quad (21)$$

where  $w'_{e_i} = w_e$  for  $e \in E$  and its copy  $e_i \in E'$ . From the above LP, we can construct the following GM:

$$\Pr[X = x] \propto \prod_{e_i \in E'} e^{w'_{e_i} x_{e_i}} \prod_{v \in V} \psi_v(x_{\delta(v)}), \quad (22)$$

where the factor function  $\psi_v$  is defined as

$$\psi_v(x_{\delta(v)}) = \begin{cases} 1 & \text{if } \sum_{e_i \in \delta(v)} x_{e_i} \leq 2b_v \\ 0 & \text{otherwise} \end{cases}.$$

For the above GM (22), we derive the following corollary of Theorem 1 whose formal proof is presented in the supplementary material due to the space constraint.

**Corollary 9** *If the solution of the vertex cover dual LP (21) is unique, then the max-product BP on GM (22) converges it.*

Again, the uniqueness condition in the above corollary is easy to guarantee by adding small random noises to edge weights  $[w'_{e_i}]$ . We further remark that if the solution of the primal LP (19) is integral, then it can be easily found from the solution of the dual LP (21) using the strictly complementary slackness condition (Bertsimas and Tsitsiklis, 1997).

#### 4.5 TRAVELING SALESMAN

Given directed graph  $G = (V, E)$  and non-negative edge weights  $w = [w_e : e \in E] \in \mathbb{R}_+^{|E|}$ , the traveling salesman problem (TSP) is to find the minimum weight Hamiltonian cycle in  $G$ . The natural LP formulation to TSP is following:

$$\begin{aligned} & \text{minimize} && w \cdot x \\ & \text{subject to} && \sum_{e \in \delta(v)} x_e = 2 \\ & && x = [x_e] \in [0, 1]^{|E|}. \end{aligned} \quad (23)$$

From the above LP, one can construct the following GM:

$$\Pr[X = x] \propto \prod_{e \in E} e^{-w_e x_e} \prod_{v \in V} \psi_v(x_{\delta(v)}), \quad (24)$$

where the factor function  $\psi_v$  is defined as

$$\psi_v(x_{\delta(v)}) = \begin{cases} 1 & \text{if } \sum_{e \in \delta(v)} x_e = 2 \\ 0 & \text{otherwise} \end{cases}.$$

For the above GM (24), we derive the following corollary of Theorem 1 whose formal proof is presented in the supplementary material due to the space constraint.

**Corollary 10** *If the solution of the traveling salesman LP (23) is unique and integral, then the max-product BP on GM (24) converges it.*

Again, the uniqueness condition in the above corollary is easy to guarantee by adding small random noises to edge weights. In Section 5, we show the empirical performance of the max-product BP on GM (24) for solving TSP without relying on the integrality condition in Corollary 10.

#### 4.6 MAXIMUM WEIGHT CYCLE PACKING

Given undirected graph  $G = (V, E)$  and non-negative edge weights  $w = [w_e : e \in E] \in \mathbb{R}_+^{|E|}$ , the maximum weight vertex disjoint cycle packing problem is to find the maximum weight set of cycles with no common vertex. It is easy to observe that it is equivalent to find a subgraph maximizing the sum of edge weights on it such that each vertex of the subgraph has degree 2 or 0. The natural LP formulation to this problem is following:

$$\begin{aligned} & \text{maximize} && w \cdot x \\ & \text{subject to} && \sum_{e \in \delta(v)} x_e = 2y_v \\ & && x = [x_e] \in [0, 1]^{|E|}, y = [y_v] \in [0, 1]^{|V|}. \end{aligned} \quad (25)$$

From the above LP, one can construct the following GM:

$$\Pr[X = x, Y = y] \propto \prod_{e \in E} e^{w_e x_e} \prod_{v \in V} \psi_v(x_{\delta(v)}, y_v), \quad (26)$$

where the factor function  $\psi_v$  is defined as

$$\psi_v(x_{\delta(v)}, y_v) = \begin{cases} 1 & \text{if } \sum_{e \in \delta(v)} x_e = 2y_v \\ 0 & \text{otherwise} \end{cases}.$$

For the above GM (26), we derive the following corollary of Theorem 1 whose formal proof is presented in the supplementary material due to the space constraint.

**Corollary 11** *If the solution of maximum weight vertex disjoint cycle packing LP (25) is unique and integral, then the max-product BP on GM (26) converges it.*

Again, the uniqueness condition in the above corollary is easy to guarantee by adding small random noises to edge weights.

### 5 EXPERIMENTAL RESULTS FOR TRAVELING SALESMAN PROBLEM

In this section, we report empirical performances of BP on GM (24) for solving the traveling salesman problem (TSP)

Table 1: Experimental results for small size complete graph and each number is the average among 100 samples. For example, Greedy+BP means that the Greedy algorithm using edge weights as BP beliefs as we describe in Section 5. The left value is the approximation ratio, i.e., the average weight ratio between the heuristic solution and the exact solution. The right value is the average weight of the heuristic solutions. The last row is a ratio of tight TSP LP (23).

| Size            | 5           | 10          | 15          | 20          | 25          |
|-----------------|-------------|-------------|-------------|-------------|-------------|

| Tight LPs       | 62%           | 62.3%          | 63%            | 52.2%          | 55%            | 52.2%          |

that is presumably the most famous one in combinatorial optimization. In particular, we design the following BP-guided heuristic for solving TSP:

1. Run BP for a fixed number of iterations, say 100, and calculate the BP marginal beliefs (3).
2. Run the known TSP heuristic using edge weights as  $\log \frac{b_{[0]}}{b_{[1]}}$  using BP marginal beliefs instead of the original weights.

For TSP heuristic in Step 2, we use Greedy, Christofides, Insertion, N-Neighbor and 2-Opt provided by the LEMON graph library (Dezso et al., 2011). We first perform the experiments on the complete graphs of size 5, 10, 15, 20, 25 and random edge weight in  $(0, 1)$  to measure approximation qualities of heuristics, where it is reported in Table 1. Second, we consider the sparse Erdos-Renyi random graph of size 100, 200 and random edge weight in  $(0, 1)$ . Then, we make it a complete graph by adding non-existing edges with penalty edge weight 1000.<sup>2</sup> For these random in-

<sup>2</sup>This is to ensure that a Hamiltonian cycle always exists.

stances, we report performance of various heuristics in Table 2. Our experiments show that BP boosts performances of known TSP heuristics in overall, where BP is very easy to code and does not hurt the simplicity of heuristics.

## 6 CONCLUSION

The BP algorithm has been the most popular algorithm for solving inference problems arising graphical models, where its distributed implementation, associated ease of programming and strong parallelization potential are the main reasons for its growing popularity. In this paper, we aim for designing BP algorithms solving LPs, and provide sufficient conditions for its correctness and convergence. We believe that our results provide new interesting directions on designing efficient distributed (and parallel) solvers for large-scale LPs.

## Abstract

This paper addresses the computational issues of learning with long, and possibly all,  $N$ -grams in a document corpus. Our main result uses suffix trees to show that  $N$ -gram matrices require memory and time that is at worst *linear* (in the length of the underlying corpus) to store and to multiply a vector. Our algorithm can speed up any  $N$ -gram based machine learning algorithm which uses gradient descent or an optimization procedure that makes progress through multiplication. We also provide a linear running time and memory framework that screens  $N$ -gram features according to a multitude of statistical criteria and produces the data structure necessary for fast multiplication. Experiments on natural language and DNA sequence datasets demonstrate the computational savings of our framework; our multiplication algorithm is four orders of magnitude more efficient than naïve multiplication on the DNA data. We also show that prediction accuracy on large-scale sentiment analysis problems benefits from long  $N$ -grams.

## 1 Introduction

$N$ -gram models are indispensable in natural language processing (NLP), information retrieval, and, increasingly, computational biology. They have been applied successfully in sentiment analysis (Paskov, 2013), text categorization (Cavnar, 1994), author identification (Houvardas, 2006), DNA function prediction (Kähärä, 2013), and numerous other tasks. The allure of  $N$ -gram models comes from their simplicity, interpretability, and efficacy: a document corpus is represented by its  $N$ -gram matrix, where each row/column corresponds to a distinct document/ $N$ -gram respectively, and each entry counts the number of occurrences of that  $N$ -gram in the document. The  $N$ -gram matrix provides a feature representation for statistical mod-

elling and the coefficients of each  $N$ -gram can often be interpreted as a score indicating their relevance to the task.

At the simplest extreme, unigrams provide a summary of the word distribution in each document and serve as an effective baseline representation for a variety of NLP tasks. Higher order  $N$ -grams provide more nuance by capturing short-term positional information and can achieve state of the art results on a variety of tasks (Wang, 2012) (Paskov, 2013). A canonical example of the value of longer  $N$ -grams is given by the phrase "I don't like horror movies, but this was excellent," which fails to convey its positive sentiment when its words are scrambled. Unfortunately, this additional information comes at a cost: a document of  $n$  words may contain up to  $\Theta(Kn)$  *distinct*  $N$ -grams of length  $K$ <sup>1</sup>. This growth makes the memory and computational burden of training  $N$ -gram models beyond bigrams impractical for large natural language corpora. Statistically, these larger feature representations suffer from the curse of dimensionality (Hastie, 2001) and may lead the model to overfit, so careful regularization is necessary.

This paper ameliorates the computational burden of learning with long  $N$ -grams. We demonstrate how the structure of suffix trees can be used to store and multiply<sup>2</sup> any  $N$ -gram matrix in time and space that is at most *linear* in the length of the underlying corpus. As most learning algorithms rely on matrix-vector multiplication to learn and predict, our results equate the computational cost of learning with  $N$ -gram matrices to scanning through the original corpus. Our method can speed up *any* learning algorithm that exhibits such structure by simply replacing its multiplication routine with ours. Fast multiplication is possible by means of a specialized data structure that efficiently represents the algebraic structure of the  $N$ -gram matrix. In view of the statistical issues associated with long  $N$ -grams, we provide a linear running time and memory framework that not only computes this data structure, but also filters  $N$ -grams by various criteria and outputs necessary column

---

<sup>1</sup>We use  $N$ -grams of length  $K$  to mean  $N$ -grams of length *at most*  $K$  for brevity.

<sup>2</sup>Multiplication always refers to matrix-vector multiplication.

normalizations. The emphasis of this framework is minimality: by only storing the topological structure of the suffix tree we achieve memory requirements that are comparable to storing the original document corpus. As such, our framework can be used to permanently store the corpus in a format that is optimized for machine learning.

Our paper is organized as follows: section 2 derives the fast multiplication algorithm by showing that after redundant columns in the  $N$ -gram matrix are removed, the algebraic structure of the resulting submatrix is encoded by the suffix tree of the underlying corpus. We then investigate how this matrix can be used as a black-box in various common learning scenarios in section 3. Section 4 presents our preprocessing framework. Timing and memory benchmarks that demonstrate the efficacy of the multiplication algorithm are presented in section 5. We also find that high-order  $N$ -grams can improve prediction accuracy in large-scale sentiment analysis tasks.

### 1.1 Related Work

Suffix trees and arrays are used by (Vish., 2004), (Teo, 2006), and (Rieck, 2008) for kernels that efficiently compute pair-wise document similarities based on  $N$ -grams. Computing the similarity of all document pairs limits kernels to moderately sized datasets and the lack of explicit features prevents the use of sparsity inducing regularizers such as in the Lasso (Tibs., 1996). Next, (Zhang, 2006) use suffix trees to identify useful  $N$ -grams in a text corpus and to show that the all  $N$ -gram matrix may be pruned since it contains redundant columns. We show in section 2 that the resulting  $N$ -gram matrix may still have too many entries to be practical for large corpora and observe this experimentally. Suffix trees are also used by (Wood, 2011) to efficiently represent and perform inference with a hierarchical process for text. Finally, while (Abou., 2004) and (Kasai, 2001) provide space efficient frameworks for working with suffix arrays, our framework is specialized to statistical processing and achieves greater memory efficiency.

### 1.2 Multiplication in Machine Learning

We briefly discuss the importance of matrix-vector multiplication for learning. Let  $\mathbf{x}_1, \dots, \mathbf{x}_N \in \mathbb{R}^d$  be  $N$  data points with corresponding labels  $y_1, \dots, y_N \in \mathcal{Y}$  and let  $X \in \mathbb{R}^{N \times d}$  be the feature matrix that stores  $\mathbf{x}_i$  as its  $i^{\text{th}}$  row. Matrix-vector multiplication operations abound in all phases of supervised and unsupervised learning: basic preprocessing that computes normalizing factors of the form  $X^T \mathbf{1}$  (or  $X \mathbf{1}$ ) for every feature (or data point); screening rules that use  $|X^T y|$  (when  $\mathcal{Y} \subset \mathbb{R}$ ) to exclude uninformative features (Tibs., 2010); or predictions of the form  $f(Xw)$  where  $w$  is a learned vector of weights.

Multiplication is also essential for many of the optimization techniques that lie at the core of these learning algo-

rithms. A variety of learning problems can be expressed as optimization problems of the form

$$\underset{w \in \mathbb{R}^d, \beta \in \mathbb{R}^p}{\text{minimize}} L_y(Xw, \beta) + \lambda R(w) \quad (1)$$

where  $w, \beta$  are the learning parameters,  $L_y$  is a loss function that encodes the  $y_i$  labels (if the problem is supervised), and  $R$  is a regularization penalty. It is important to remember that this framework captures a number of *unsupervised* learning problems as well, such as Principle Component Analysis, which is useful directly and as a preprocessing step for clustering, deep learning, and other techniques (Hastie, 2001). Any (sub)gradient<sup>3</sup> of (1) with respect to  $w$  is given by

$$g_w \in X^T \partial_{Xw} L(Xw, \beta) + \lambda \partial_w R(w). \quad (2)$$

where  $\partial_z f(z)$  is the subdifferential of  $f$  with respect to  $z$ .

Since every (sub)gradient descent method (Parikh, 2013) or accelerated variant critically relies on  $g_w$  as a search direction, computing  $Xw$  and then  $X^T[\partial_{Xw} L(Xw, \beta)]$  is essential and often the most costly part of the optimization. A number of other popular large-scale optimization methods also reduce to multiplying  $X$  repeatedly. These include Krylov subspace algorithms such as the conjugate gradient method, and various quasi-Newton methods including BFGS and its limited memory variant (Nocedal, 2006).

### 1.3 Background and Notation

Let  $\Sigma$  be a finite vocabulary with a strict total ordering  $\prec$  over its elements. A *document*  $D = x_1 x_2 \dots x_n$  of length  $n$  is a list of  $n$  characters drawn from  $\Sigma$  and an  $N$ -gram is any string of characters drawn from  $\Sigma$ . We will refer to each of the  $n$  suffixes in  $D$  via  $D[i] = x_i x_{i+1} \dots x_n$ . We denote the set of all substrings in  $D$  by  $D^* = \{x_i \dots x_{i+k} \mid 1 \leq i \leq n, 0 \leq k \leq n - i\}$  and the set of all substrings in a document corpus of  $N$  documents  $\mathcal{C} = \{D_1, \dots, D_N\}$  as  $\mathcal{C}^* = \bigcup_{i=1}^N D_i^*$ .

Given a subset  $\mathcal{S} \subseteq \mathcal{C}^*$  of the set of substrings in (any of) the documents, entry  $X_{is}$  of the  $N$ -gram matrix  $X \in \mathbb{Z}_+^{N \times |\mathcal{S}|}$  counts how many times substring  $s \in \mathcal{S}$  appears in document  $D_i$ . We use  $M_i$  to indicate the  $i^{\text{th}}$  column of matrix  $M$ ; when each column pertains to a specific mathematical object, such as an  $N$ -gram or tree node, we may use that object as an index (to avoid imposing a particular ordering over the objects). We will *always* take  $X$  to be an  $N$ -gram matrix for an implicitly given corpus.

A *compact tree*  $\mathcal{T} = (V, E)$  is a tree with nodes  $V$  and edges  $E$  where every internal node is required to have at least 2 children. This ensures that if  $\mathcal{T}$  has  $n$  leaves, then there are at most  $n - 1$  internal nodes. We use  $\text{ch}(v) \subset V$  and  $\text{p}(v) \in V$  to denote the children and parent of  $v \in V$ ,

<sup>3</sup>To handle non-differentiable objectives, see (Parikh, 2013).

respectively. The root node is given by  $\text{root}(\mathcal{T})$ , the depth of any node  $v \in V$  is  $d(v)$  (with  $d(\text{root}(\mathcal{T})) = 1$ ), and  $\text{depth}(T)$  is the maximum depth of any node in  $V$ . Finally, a *branch* of  $\mathcal{T}$  is a path starting at the root and ending at a leaf; we will use the terminal leaf to identify branches. We will also be concerned with subtrees  $\hat{\mathcal{T}} = (\hat{V}, \hat{E})$  of  $\mathcal{T}$  which contain a subset  $\hat{V} \subset V$  of its nodes. We allow the new edge set  $\hat{E}$  to be arbitrary and add a second argument to  $\text{ch}(v, \hat{E})$  and  $\text{p}(v, \hat{E})$  to indicate that parent/child relationships are taken with respect to this new edge set.

### 1.3.1 Suffix Trees

Given a document  $D = x_1x_2\dots x_n$  whose characters belong to an alphabet  $\Sigma$ , the *suffix tree*  $\mathcal{T}_D = (V, E)$  for  $D$  is a compact tree with  $n$  leaves, each of which corresponds to a distinct suffix of  $D$  and is numbered according to the starting position of the suffix  $1, \dots, n$ . The edges along branch  $i$  are labelled with non-empty substrings that partition  $D[i]$ : suffix  $D[i]$  can be recovered by concatenating the edge labels from the root to leaf  $i$ . Let  $l(e)$  for  $e \in E$  be the label of edge  $e$  and define the *node character*  $c(v)$  of any non-root node  $v \in V$  to be the first character of  $l(\text{p}(v), v)$ . The nodes of  $\mathcal{T}_D$  are constrained so that siblings may not have the same node character and are ordered according to the  $<$  relation on these characters. These constraints ensure that every node has at most  $|\Sigma|$  children and they allow for well-defined traversals of  $\mathcal{T}_D$ . Moreover, every substring  $s \in D^*$  is represented by a unique path in  $\mathcal{T}_D$  that starts at the root node and terminates in — possibly the middle of — an edge. Similarly to suffixes,  $s$  equals the concatenation of all characters encountered along edges from the root to the path's terminus (only a prefix of the final edge will be concatenated if the path ends in the middle of an edge).

Remarkably,  $\mathcal{T}_D$  can be constructed in  $O(n)$  time (Gusfield, 1997) and has  $n$  leaves and at most  $n - 1$  internal nodes, yet it represents all  $O(n^2)$  distinct substrings of  $D$ . This is possible because any substrings whose path representation in  $\mathcal{T}$  ends at the same edge belong to the same *equivalence class*. In particular, for  $v \in V \setminus \{\text{root}(\mathcal{T}_D)\}$  suppose that edge  $(\text{p}(v), v)$  has a label  $t = x_i \dots x_{i+k}$  and let  $s$  be the string obtained by concatenating the edge labels on the path from  $\text{root}(\mathcal{T}_D)$  down to  $v$ . Then the strings  $S(v) = \{sx_i, sx_{i+1}, \dots, sx_{i+k}\}$  belong to the same equivalence class because they occur in the same locations, i.e. if  $sx_i$  starts at location  $l$  in  $D$ , then so do all members of  $S(v)$ . For example, in the string "xaxaba" the substrings "x" and "xa" belong to the same equivalence class.

The *generalized suffix tree*  $\mathcal{T}_C$  for a document corpus  $C$  of  $n$  words compactly represents the set of all substrings in  $C^*$  and has  $n$  leaves pertaining to every suffix of every document in  $C$ . Leaves are also annotated with the document they belong to and  $\mathcal{T}_C$  inherits all of the linear-time storage and computational guarantees of the regular suffix tree (with respect to the corpus length  $n$ ).

### 1.3.2 Tree Traversals and Storage

The majority of algorithms in this paper can be expressed as a bottom-up or top-down traversal of a tree  $T = (V, E)$  (typically the suffix tree or one of its subtrees) in which information is only exchanged between a parent and its children. Given a fixed ordering of  $V$ , the necessary information for a traversal is the topology of  $T$ , i.e. its parent-child relationships, as well as any node annotations necessary for the computation. We use two formats which efficiently store this information and make traversals easy: the *breadth-first format* (BFF) and *preorder depth-first format* (DFF). In both cases we distinguish between the internal nodes and leaves of  $T$  and divide them into their respective sets  $I \cup L = V$ . In the BFF we order the nodes of  $I$  according to their *breadth-first traversal* whereas in the DFF we order the nodes of  $I$  according to their *preorder depth first traversal*; both formats assign indices  $[0, \dots, |I|]$  to the nodes in  $I$ . Note that for these traversals to be well defined we assume that the children of each node are ordered in some (arbitrary) but fixed manner. Next, the leaves of  $T$ , i.e.  $L$ , are assigned indices  $[|I|, \dots, |V|]$  so that if  $u, v \in L$  and  $p(u)$  comes before  $p(v)$  — note that both parents must be in  $I$  — then  $u$  comes before  $v$ . This ordering ensures that leaves are ordered into contiguous blocks with respect to their parent and that the blocks are in the same order as  $I$ .

A pair of arrays  $(\text{ch}^I, \text{ch}^L)$ , each of size  $|I|$ , capture the topology of  $T$ : for all  $v \in I$ ,  $\text{ch}_v^I = |\text{ch}(v) \cap I|$  stores the number of internal children of  $v$  and  $\text{ch}_v^L = |\text{ch}(v) \cap L|$  stores the number of leaf children of  $v$ . The number of bits needed to store this topology is

$$|I|(\lceil \log_2 U(I) \rceil + \lceil \log_2 U(L) \rceil) \quad (3)$$

where  $U(I), U(L)$  are the largest values in  $\text{ch}^I, \text{ch}^L$  respectively, i.e. the largest number of internal/leaf children for any node. Given node annotations in the same order as the BFF or DFF, top-down/bottom-up traversals are easy to perform by a linear sweep of the annotations and  $\text{ch}^I, \text{ch}^L$  arrays. All memory access is sequential and can be performed efficiently by standard (i.e. desktop) memory and processors.

A speed/memory tradeoff exists for the two formats. The amount of random access memory necessary for a traversal is proportional to the *depth* of  $T$  for DFF versus the *width* of  $T$  for the BFF. As we discuss in section 4, the former is likely to be smaller than the latter for our purposes. The space savings of the DFF are achieved by maintaining a stack of active nodes pertaining to the current branch being processed. The additional logic required for this book-keeping makes the DFF slightly slower than the BFF for the traversal. As such, the DFF is useful for more complicated computations in which the amount of information stored per node may be large, whereas the BFF is useful for simple computations that will be performed many times.

## 2 Fast Multiplication

This section presents our fast multiplication algorithm. Let  $\mathcal{T}_C = (V, E)$  be the suffix tree for a document corpus  $\mathcal{C} = \{D_1, \dots, D_N\}$  and let  $X$  be an  $N$ -gram matrix containing a column for every  $s \in \mathcal{S} \subseteq \mathcal{C}^*$ , i.e. the  $N$ -grams we are interested in. In order to uncover the necessary algebraic structure for our algorithm we must first remove redundant columns in  $X$ . As observed in (Zhang, 2006), redundant columns occur whenever strings in  $\mathcal{S}$  belong to the same equivalence class. This implies the following lemma:

**Lemma 1.** *For any  $v \in V$ , any  $s, s' \in \mathcal{S} \cap S(v)$  have the same distribution among the documents in  $\mathcal{C}$  so  $X_s = X_{s'}$ .*

We remove this redundancy by working with the *node matrix*  $\mathcal{X} \in \mathbb{Z}_+^{N \times M}$ , a submatrix of  $X$  that contains a single column for the  $M$  equivalence classes present in  $\mathcal{S}$ . Formally, node  $v \in V$  is present in  $X$  if  $S(v) \cap \mathcal{S} \neq \emptyset$  and we define  $\mathcal{V} \subset V$  to be the set of all nodes present in  $X$ . Column  $\mathcal{X}_v$  for  $v \in \mathcal{V}$  is obtained by picking an arbitrary  $s \in S(v) \cap \mathcal{S}$  and setting  $\mathcal{X}_v = X_s$ . We can also reconstruct  $X$  from  $\mathcal{X}$  by replicating column  $\mathcal{X}_v$   $|S(v) \cap \mathcal{S}|$  times; this underscores the inefficiency in the  $N$ -gram matrix.

### 2.1 Linear Dependencies in the Node Matrix

We are now ready to show how the topology of  $\mathcal{T}_C$  determines the linear dependencies among the columns of  $\mathcal{X}$ . Central to our analysis is the lemma below, which shows that the document frequency of any node is determined entirely by the leaves of its subtree:

**Lemma 2.** *The number of times node  $v \in V \setminus \{\text{root}(\mathcal{T}_C)\}$  appears in document  $D_i \in \mathcal{C}$  equals the number of leaves that belong to  $D_i$  in the subtree rooted at  $v$ .*

The simplest case occurs when  $\mathcal{V} = V \setminus \{\text{root}(\mathcal{T}_C)\}$ , i.e. every node in  $\mathcal{T}_C$  (except for the root) has a corresponding column in  $\mathcal{X}$ . In this case lemma 2 directly establishes a recursive definition for the columns of  $\mathcal{X}$ :

$$\mathcal{X}_v = \begin{cases} \mathbf{e}_{\text{doc}(v)}^N & \text{if } v \text{ is a leaf} \\ \sum_{u \in \text{ch}(v)} \mathcal{X}_u & \text{otherwise.} \end{cases} \quad (4)$$

Here  $\mathbf{e}_i^N$  is the  $i^{\text{th}}$  canonical basis vector for  $\mathbb{R}^N$  and  $\text{doc}(v)$  indicates the document index leaf  $v$  is labelled with. Importantly, (4) shows that the column corresponding to any internal node can be expressed as a simple linear combination of the columns of its children. This basic property lies at the core of our fast multiplication algorithm.

We now show how to apply the reasoning behind (4) to the more general case when  $\mathcal{V}$  is an arbitrary subset of  $V$ , i.e. a node's children may be partly missing. Define  $\mathcal{T}_C(\mathcal{V}) = (\hat{V}, \hat{E})$ , the *restriction* of  $\mathcal{T}_C$  to  $\mathcal{V}$ , to be a tree

with nodes  $\hat{V} = \mathcal{V} \cup \{\text{root}(\mathcal{T}_C)\}$ . In addition, for any  $v \in V \setminus \{\text{root}(\mathcal{T}_C)\}$  let  $\text{la}(v, \hat{V}) \in \hat{V}$  be the closest *proper ancestor* of  $v$  in  $\mathcal{T}_C$  that is also in  $\hat{V}$ ; since  $\text{root}(\mathcal{T}_C) \in \hat{V}$ , this mapping is always well defined. The edge set  $\hat{E}$  preserves the ancestor relationships among the nodes in  $\hat{V}$ : every  $v \in \mathcal{V}$  is connected to  $\text{la}(v, \hat{V})$  as a child. An inductive argument shows that if  $u, v \in \hat{V}$ , then  $u$  is an ancestor of  $v$  in  $\mathcal{T}_C$  if and only if  $u$  is also an ancestor of  $v$  in  $\mathcal{T}_C(\mathcal{V})$ .

Associated with  $\mathcal{T}_C(\mathcal{V})$  is a matrix  $\Phi \in \mathbb{Z}_+^{N \times |\mathcal{V}|}$  that subsumes the role of leaf document labels.  $\Phi$  contains a column for every node  $v \in \mathcal{V}$  and accounts for all of the leaves in  $\mathcal{T}_C$ . When  $v$  is a leaf in  $\mathcal{T}_C$  and  $v$  is included in  $\mathcal{V}$  we set  $\Phi_v = \mathbf{e}_{\text{doc}(v)}^N$ . Otherwise,  $v$  is accounted for in  $\Phi_{\text{la}(v, \hat{V})}$ , the column pertaining to  $v$ 's closest ancestor in  $\mathcal{V}$ . In particular, if  $u \in \mathcal{V}$  is *not* a leaf in  $\mathcal{T}_C$ , then

$$\Phi_u = \sum_{\substack{v \in \text{leaves}(\mathcal{T}_C) \setminus \mathcal{V} \\ \text{la}(v, \hat{V}) = u}} \mathbf{e}_{\text{doc}(v)}^N. \quad (5)$$

This bookkeeping allows us to relate the columns of  $\mathcal{X}$  when  $\mathcal{V}$  is any subset of  $V$ :

**Theorem 1.** *The columns of the node matrix  $\mathcal{X}$  for  $\mathcal{V} \subseteq V \setminus \{\text{root}(\mathcal{T}_C)\}$  are given recursively by*

$$\mathcal{X}_v = \Phi_v + \sum_{u \in \text{ch}(v; \hat{E})} \mathcal{X}_u$$

where  $\Phi$  and  $\mathcal{T}_C(\mathcal{V}) = (\hat{V}, \hat{E})$  are defined above.

This theorem shows that  $\mathcal{X}_v$  is a simple linear combination of the columns of its children in  $\mathcal{T}_C(\mathcal{V})$  plus a correction term in  $\Phi$ . We utilize this structure below to give a fast matrix-vector multiplication algorithm for node matrices.

### 2.2 Fast Multiplication Algorithm

A simple application of Theorem 1 shows that the matrix-vector product  $\mathcal{X}w$  for  $w \in \mathbb{R}^{|\mathcal{V}|}$  can be obtained by recursively collecting entries of  $w$  into a vector  $\beta \in \mathbb{R}^{|\mathcal{V}|}$ :

$$\beta_v = w_v + \beta_{\text{p}(v; \hat{E})} \quad (6a)$$

$$\mathcal{X}w = \Phi\beta \quad (6b)$$

Here we use the convention  $\beta_{\text{root}(\mathcal{T}_C(\mathcal{V}))} = 0$ . The transposed operation  $\mathcal{X}^T y$  for  $y \in \mathbb{R}^N$  can also be written recursively by expressing each entry as

$$(\mathcal{X}^T y)_v = \Phi_v^T y + \sum_{u \in \text{ch}(v; \hat{E})} (\mathcal{X}^T y)_u. \quad (7)$$

Equations (6-7) lead to the following theorem, for which we provide a proof sketch:

<sup>4</sup>Note that  $\mathcal{V}$  never includes the root node.

**Theorem 2.** *Let  $\mathcal{C}$  be a document corpus of  $n$  words and let  $\mathcal{X}$  be any node matrix derived from this corpus. Then  $\mathcal{X}$  requires  $O(n)$  memory to store. Multiplying a vector with  $\mathcal{X}$  or  $\mathcal{X}^T$  requires  $O(n)$  operations.*

*Proof.* Vector  $\beta$  in equation (6) can be computed in  $O(|\mathcal{V}|) \in O(n)$  operations by a top-down traversal that computes each of its entries in constant time. The matrix  $\Phi$  is a sparse matrix with *at most* one entry per leaf of the suffix tree  $\mathcal{T}_{\mathcal{C}}$ , i.e. at most  $n$  entries. It follows that the product  $\Phi\beta$  requires  $O(n)$  operations which proves the theorem for multiplication with  $\mathcal{X}$ . The transposed case follows similarly by noting that we must compute a matrix-vector product with  $\Phi^T$  and perform a bottom-up traversal that performs constant time operations for every node in  $\mathcal{V}$ .  $\square$

### 2.2.1 Efficiency Gains

We use naïve multiplication to mean sparse matrix-vector multiplication in what follows. The supplementary material discusses examples which show that naïve multiplication with the  $N$ -gram matrix  $X$  can be asymptotically slower than naïve multiplication with  $\mathcal{X}$ , which in turn can be asymptotically slower than multiplication with our recursive algorithm. These examples establish the following complexity separation result:

**Theorem 3.** *There exists documents of  $n$  words for which*

1. *The all  $N$ -grams matrix  $X$  requires  $\Theta(n^2)$  storage and operations to multiply naïvely.*
2. *The all  $N$ -grams node matrix  $\mathcal{X}$  requires  $\Theta(n\sqrt{n})$  storage and operations to multiply naïvely.*
3. *In all cases recursive multiplication of the node matrix requires  $O(n)$  storage and operations.*

### 2.3 Matrix Data Structure

The fast multiplication algorithm can be performed directly on the suffix tree derived from  $\mathcal{C}$ , but it is faster to use a dedicated data structure optimized for the algorithm’s memory access patterns. The breadth-first multiplication tree (BFMT) stores the topology of  $\mathcal{T}_{\mathcal{C}}(\mathcal{V})$  in the BFF (discussed in section 1.3.2) and the frequency information in  $\Phi$  as a sparse matrix in a modified compressed sparse column (csc) format (see the supplementary material) whose columns are ordered according to the order of the BFF. We chose this format because executing equations (6) and (7) requires a simple linear sweep of the BFMT. We expect that the vectors being multiplied can be stored in memory and therefore opted for the speed afforded by the BFF instead of the memory savings of the DFF.

The total number of bits necessary to store the BFMT is given by equation (3) along with the total number of bits

necessary to store  $\Phi$ , which is

$$|\mathcal{V}| \lceil \log_2 U^\Phi \rceil + \text{nz}(\lceil \log_2 M \rceil + \lceil \log_2 N \rceil). \quad (8)$$

Here  $U^\Phi = \max_{v \in \mathcal{V}} \|\Phi_v\|_0$  is the largest number of non-zero elements in a column of  $\Phi$ ,  $\text{nz}$  is the total number of non-zero elements in  $\Phi$ , and  $M$  is the largest entry in  $\Phi$ . It is easy to verify that  $|\mathcal{I}| \leq |\mathcal{V}| \leq \text{nz} \leq n$  and the term involving  $\text{nz}$  typically dominates the memory requirements.

## 3 Common Usage Patterns

We now discuss how several common machine learning scenarios can be adapted to use our representation of the node matrix or preferably, to treat multiplication with  $\mathcal{X}$  as a black-box routine. The most straightforward use case is to replace the original  $N$ -gram matrix with the more succinct node matrix. Moreover, mean centering and column normalization can be performed *implicitly*, without modifying  $\mathcal{X}$ , by premultiplying and adding a correction term:

$$((\mathcal{X} - \mathbf{1}\mu^T)\Sigma)w = \mathcal{X}(\Sigma w) - (\mu^T \Sigma w)\mathbf{1}$$

Here  $\mu$  is a vector of column means and  $\Sigma$  is a diagonal matrix of column normalizing factors. Analogous formulas exist for row centering and normalization.

### 3.1 Problem Reformulation

A variety of optimization problems can also be reformulated so that they are *equivalent* to using the original  $N$ -gram matrix. A simple example of such a conversion comes from using ridge regression to model label  $y_i \in \mathbb{R}$  based on the  $i^{\text{th}}$  row of the  $N$ -gram matrix  $X$ . We wish to solve

$$\underset{w \in \mathbb{R}^d}{\text{minimize}} \frac{1}{2} \|y - Xw\|_2^2 + \frac{\lambda}{2} \|w\|_2^2. \quad (9)$$

It is easy to show that if  $\lambda > 0$  and  $N$ -grams  $s, t$  belong to the same equivalence class, then  $w_s = w_t$ . We can simulate the effect of these duplicated variables by collecting terms. Let  $\mathcal{S}$  be the set of  $N$ -grams present in  $X$ ,  $\mathcal{V}$  the set of suffix tree nodes present in  $X$ , and define  $\mathcal{S}(v) = \mathcal{S}(v) \cap \mathcal{S}$  for brevity. For all  $v \in \mathcal{V}$  let  $z_v = |\mathcal{S}(v)|w_s$  for some  $s \in \mathcal{S}(v)$ . Then  $\sum_{s \in \mathcal{S}(v)} X_s w_s = \mathcal{X}_v z_v$  and  $\sum_{s \in \mathcal{S}(v)} w_s^2 = |\mathcal{S}(v)|^{-1} z_v^2$  so problem (9) is equivalent to a *smaller* weighted ridge regression using  $\mathcal{X}$ :

$$\underset{z \in \mathbb{R}^{|\mathcal{V}|}}{\text{minimize}} \frac{1}{2} \|y - \mathcal{X}z\|_2^2 + \frac{\lambda}{2} \sum_{v \in \mathcal{V}} \frac{z_v^2}{|\mathcal{S}(v)|}. \quad (10)$$

Note that this also shows that representations using the  $N$ -gram matrix downweight the ridge penalty of each equivalence class in proportion to its size.

We can characterize the set of optimization problems that have an equivalent problem where the  $N$ -gram matrix can

be replaced with the node matrix. Define a partition  $\mathcal{J}$  of the integer set  $\{1, \dots, d\}$  to be a set of  $m$  integral intervals  $\zeta_k = \{i, \dots, j\}$  such that  $\bigcup_{k=1}^m \zeta_k = \{1, \dots, d\}$  and  $\zeta_k \cap \zeta_j = \emptyset$  if  $k \neq j$ . A function  $f : \mathbb{R}^d \rightarrow \mathbb{R}^p$  is *permutation invariant* with respect to  $\mathcal{J}$  (abbrev.  $\mathcal{J}$ -PI) if for all  $x \in \mathbb{R}^d$ ,  $f(x) = f(\pi[x])$  where  $\pi : \mathbb{R}^d \rightarrow \mathbb{R}^d$  is any permutation that only permutes indices within the same interval  $\zeta_k \in \mathcal{J}$ . For our purposes it is important to note that  $L_p$ -norms are  $\mathcal{J}$ -PI as are affine functions  $Ax + b$  whenever columns  $A_i = A_j \forall i, j \in \zeta_k, \forall \zeta_k \in \mathcal{J}$ . It is straightforward to show that if  $f, g : \mathbb{R}^d \rightarrow \mathbb{R}^p$  are both  $\mathcal{J}$ -PI and  $c : \mathbb{R}^p \rightarrow \mathbb{R}^q$  then  $f(x) + g(x)$  and  $c(f(x))$  are also  $\mathcal{J}$ -PI.

We prove the following theorem in the supplementary material to connect permutation invariance to optimization:

**Theorem 4.** *Let  $f : \mathbb{R}^d \rightarrow \mathbb{R}$  be any convex function that is  $\mathcal{J}$ -PI where  $m = |\mathcal{J}|$ . Then there exists a convex function  $g : \mathbb{R}^m \rightarrow \mathbb{R}$  over  $m$  variables such that the problem  $\min_{x \in \mathbb{R}^d} f(x)$  is equivalent to  $\min_{z \in \mathbb{R}^m} g(z)$ . If  $z^*$  is optimal for the second problem, then  $x_i = z_k^* \forall i \in \zeta_k, \forall \zeta_k \in \mathcal{J}$  is optimal for the first problem.*

This theorem establishes that any convex loss of the form  $L(Xw, b)$ ; e.g. SVM, logistic regression, least squares; added to any  $L_p$  norm, e.g.  $L_2$  ridge or  $L_1$  lasso penalty, can be simplified to an equivalent learning problem that uses the node matrix instead of the  $N$ -gram matrix.

### 3.2 Holding Out Data

Oftentimes the document corpus is organized into  $T$  (possibly overlapping) integral sets  $\mathcal{Q}_1, \dots, \mathcal{Q}_T$  indexing the documents. For instance, splitting documents into training and testing sets yields  $T = 2$  index sets, and further subdividing the training set for  $K$ -fold crossvalidation introduces  $2K$  additional sets (indicating the hold out and training data for each split). In this case we are not interested in multiplying all of  $\mathcal{X}$ , but only the submatrix whose rows' indices are in the given  $\mathcal{Q}_i$ . This matrix-vector product can be computed by calling the recursive multiplication algorithm with the topology information in  $\mathcal{T}_C(\mathcal{V})$  (derived from the full corpus) and with the submatrix of  $\Phi$  whose rows' indices are in  $\mathcal{Q}_i$ . Also note that if only a subset of the documents will ever be used for training, we can ignore any nodes in  $\mathcal{T}_C$  that do not appear in the training set since they (should) be ignored by any learning algorithm; we discuss this further in section 4.2.

## 4 Preprocessing

We use an intermediary data structure, the depth-first preprocessing tree (DFPT), to output the BFMT. The DFPT is computed from a corpus  $\mathcal{C}$  and stores the *minimal* information in  $\mathcal{T}_C = (V, E)$  necessary to produce any BFMT and to prune the nodes in  $V$ . It can be computed once and used to store  $\mathcal{C}$  in a format that is amenable for arbitrary machine

learning tasks. Given a new learning problem the DFPT proceeds in two stages: 1) it identifies useful  $N$ -grams in  $V$  and calculates relevant column normalizations, and 2) it emits a BFMT tailored to that task. Construction of the DFPT, as well as its processing stages, requires  $O(n)$  time and memory with respect to the corpus length  $n$ .

As suggested by its name, the DFPT stores the topology of  $\mathcal{T}_C$  in DFF, its leaf-document annotations, and if filtering by  $N$ -gram length, the edge label length for each internal node of  $V$ . Its processing stages are a sequence of top-down/bottom-up traversals of  $\mathcal{T}_C$  that are individually more sophisticated than those required by our multiplication algorithm, so we opted for the memory savings afforded by the DFF. Indeed,  $\text{depth}(\mathcal{T}_C)$  is bounded by the length of the longest document in  $\mathcal{C}$  while the tree width is bounded by the corpus length; the memory savings of the DFF over the BFF are substantial. Importantly, the traversals stream through the DFPT so it is reasonable to operate on it via external memory, e.g. a hard drive, if memory is limited.

In detail, the DFPT requires  $2|I| \lceil \log_2 |\Sigma| \rceil + n \lceil \log_2 N \rceil$  bits to store the topology and leaf-document annotations, where  $I$  is the set of internal nodes of  $V$ ,  $N$  the number of documents in  $\mathcal{C}$ , and  $\Sigma$  the alphabet. For reference storing  $\mathcal{C}$  requires  $n \lceil \log_2 |\Sigma| \rceil + N \lceil \log_2 n \rceil$  bits and  $|I| < n$ . An additional  $|I| \lceil \log_2 \frac{n}{N} \rceil$  bits are used to store edge labels lengths, but this information is only necessary when pruning by maximum  $N$ -gram length.

### 4.1 Computing the Depth-First Suffix Tree

Computing the DFPT from  $\mathcal{C}$  represents the least memory efficient part of our framework as we first compute a suffix array (SA) (Gusfield, 1997) from the text and then convert the SA into the DFPT. The process requires  $3n \lceil \log_2 n \rceil + n \lceil \log_2 (|\Sigma| + N) \rceil$  bits and  $O(n)$  time. We emphasize that our framework is completely modular so the DFPT only needs to be computed once. We leave it as an open problem to determine if a more memory efficient algorithm exists that directly computes the DFPT.

Recalling that each leaf of  $\mathcal{T}_C$  is numbered according to the suffix it corresponds to, the SA is a permutation of the integers  $[0, \dots, n)$  that stores the leaves of  $\mathcal{T}_C$  in a *pre-order depth-first traversal*. We use an SA rather than a suffix tree because the former typically requires 4 times less memory than a suffix tree and can also be constructed in  $O(n)$  time and memory. We use the implementation of (Mori, 2015), which requires  $m = 3n \lceil \log_2 n \rceil + n \lceil \log_2 (|\Sigma| + N) \rceil$  bits to construct the SA, where the second term corresponds to a modified copy of  $\mathcal{C}$ . This was the most memory efficient linear-time suffix array construction algorithm we could find; asymptotically slower but more memory efficient algorithms may be preferable for DNA sequence data.

The details of how we compute the DFPT from a suffix

array are rather involved and will be discussed in an extended version of this paper. The framework of (Kasai, 2001) is instrumental in our conversion as it allows us to simulate a *post-order depth-first traversal* of  $\mathcal{T}_C$  using the SA. By carefully managing memory and off-loading unused information to external storage, each step of the conversion requires at most  $m - n\lceil\log_2 n\rceil$  bits to be stored in main memory at any time. The *total* memory requirements, including storing the DFPT while it is constructed, never exceed the maximum of  $m - n\lceil\log_2 n\rceil$  and  $2n\lceil\log_2 n\rceil + (n + |I|)\lceil\log_2 N\rceil$  bits; both are less than  $m$ .

## 4.2 Filtering and Normalizations

The first stage of the DFPT’s processing determines which nodes in  $\mathcal{T}_C$  should be present in the final BFMT. It also computes any required normalizations, such as the column mean or norm, of the node matrix  $\mathcal{X}$  the BFMT represents. We assume that only the internal nodes  $I \subset V$  of  $\mathcal{T}_C$  will ever be used; each leaf appears in only a single document and is unlikely to carry useful information. We model the screening process as a sequence of filters that are applied to  $I$ : associated with  $I$  is a boolean array  $b \in \{0, 1\}^{|I|}$  where  $b_v = 1$  indicates that node  $v \in I$  is useful and  $b_v = 1 \forall v \in I$  initially. Each filter takes as input the DFPT and  $b$ , and updates  $b$  (in place) with its own criteria. All of our filters are memory efficient and only need to store  $|I| + O(\text{depth}(\mathcal{T}_C))$  bits in memory as the BFMT can reasonably be streamed from slower external storage. With the exception of the unique document filter, all of the filters listed below run in  $O(n)$  time:

**$N$ -gram length:** removes nodes whose shortest corresponding  $N$ -gram is longer than a given threshold.

**Training set:** removes nodes that do not appear in any documents designated as the training set.

**Unique document frequency:** removes nodes that do not appear in at least some number of *distinct* documents. We use an algorithm given in (Paskov, 2015) which runs in  $O(n\alpha^{-1}(n))$  time, where  $\alpha^{-1}$  is the inverse Ackermann function ( $\alpha^{-1}(10^{80}) = 4$ ) and is essentially linear-time. A  $O(n)$  algorithm (Gusfield, 1997) is possible, but it requires complicated pre-processing and an additional  $n\lceil\log_2 n\rceil$  bits of memory.

**Strong rules:** given *mean centered* document labels  $y \in \mathbb{R}^N$ , removes all nodes  $v$  for which  $|\mathcal{X}_v^T y| < \lambda$  for a threshold  $\lambda$ . This implements the strong rules of (Tibs., 2010) and can be applied to a subset of the documents  $\mathcal{I}_r \subset \{1, \dots, N\}$  (e.g. training data) by mean centering only  $y_{\mathcal{I}_r}$  and setting  $y_i = 0$  for all  $i \notin \mathcal{I}_r$ . Column normalizations are achieved by checking  $\eta_v^{-1}|\mathcal{X}_v^T y| < \lambda$ , where  $\eta_v^{-1}$  is the normalization for column  $v$ . This filter essentially multiplies  $\mathcal{X}^T y$  using the DFPT and the normalization can be computed on the fly (see discussion below).

Once we know which nodes will be used in the BFMT we typically require the column mean  $\mu = \frac{1}{N}\mathcal{X}^T \mathbf{1}$  and some kind of normalization  $\eta_v^{-1}$  for each column of  $\mathcal{X}$ . Noting that all entries of  $\mathcal{X}$  are non-negative, the  $L_1$ -norm of each column is  $\eta = \mathcal{X}^T \mathbf{1}$ . Each of these quantities is a matrix-vector multiply that we perform using the DFPT. These quantities can be specialized to training data by setting appropriate entries of the  $\mathbf{1}$  vector to 0. We can also compute the  $L_2$ -norm of each column of  $\mathcal{X}$  or the  $L_1/L_2$ -norm of each column of  $\mathcal{X} - \mathbf{1}\mu^T$ , the mean centered node matrix. These normalizations however require  $O(N|I|)$  time and  $O(N\text{depth}(\mathcal{T}_C))$  memory; the space savings of the DFF are critical for the memory bound. These running times are tolerable if performed only once, especially on the short and wide trees that tend to occur with natural language.

## 4.3 Producing the Matrix Structure

The final stage in our pipeline produces the BFMT using the DFPT and filter  $b$ . The following lemma follows from the definitions of breadth-first and depth-first traversals and is essential for easy conversion between the two formats:

**Lemma 3.** *Given a tree  $T = (V, E)$ , let  $\beta$  be an (ordered) list of the nodes in  $V$  in breadth-first order and define  $\delta$  to be a list of  $V$  in depth-first preorder. Define  $\beta(d)$  and  $\delta(d)$  to be the (sub) lists of  $\beta$  and  $\delta$  respectively containing only nodes at depth  $d$ . Then  $\beta(d) = \delta(d) \forall d = 1, \dots, \text{depth}(T)$ .*

This lemma states that the breadth-first and depth-first preorder traversals list nodes in the same order if we only consider the nodes of a tree at a specific depth. We thus allocate memory for the BFMT by counting the number of nodes with  $b_v = 1$  at each depth in the DFPT. The lemma then allows us to copy the relevant nodes in the DFPT into the BFMT skeleton by maintaining a stack of size  $\text{depth}(\mathcal{T}_C)$  that keeps track of how many nodes have been written to the BFMT at each depth. The depth-first traversal also makes it is easy to determine edges by keeping track of each node’s nearest ancestor (in  $\mathcal{T}_C$ ) that is in the BFMT. The copying process streams through the DFPT and  $b$  in a single linear sweep and requires storing the BFMT and  $O(\text{depth}(\mathcal{T}_C))$  bits in memory.

## 5 Experiments

This section provides benchmarks for our multiplication algorithm and applies it to solve several large-scale sentiment analysis tasks. We implemented our framework in  $C^5$  and compiled it used the GCC compiler version 4.4.7 for an x86-64 architecture. Our reference machine uses an Intel Xeon E5-2687W processor with 8 cores running at 3.1 GHz and has 128 Gb of RAM.

<sup>5</sup>Please contact the first author for source code.

## 5.1 Memory and Timing Benchmarks

We evaluate our multiplication algorithm on three kinds of data to investigate its performance in a variety of scenarios: short natural language articles, long technical papers, and DNA sequence data. The first is the BeerAdvocate dataset (McAuley, 2013), a corpus of 1,586,088 beer reviews totalling 1 Gb of plaintext and each consisting of a median of 126 words. The second is a collection of 70,728 journal articles collected from NCBI (U.S. National Library, 2015) with a median length of 6955 words and totalling 3 Gb of plaintext<sup>6</sup>. Our third dataset is derived from the 1000 Genomes Project (1000 Genomes Project, 2008) and it consists of 6,196,151 biallelic markers, i.e. binary values, along chromosome 1 for 250 people.

Our preprocessing framework required at most 3.5 times the memory of the original datasets for the natural language data. The third dataset however presents a worst case scenario for our framework and suffix tree/arrays in general. It requires 185 megabytes to store because of its small alphabet size, yet its suffix array requires  $n \lceil \log_2 n \rceil$  bits, i.e. 31 times more memory, and several times this amount to compute. While the DFPT ameliorates this memory usage, it still requires 10 times more memory than the original data and total memory usage went up to 18 gigabytes when computing it from the suffix array.

Figure 1 compares the memory requirements of the BFMT to explicitly storing the node and  $N$ -gram matrices for all  $N$ -grams up to length  $K$  that appear in at least 2 documents. We show space requirements for our modified sparse matrix format (MSF) as well as the standard sparse format (SSF), e.g. used in Matlab. The top two graphs correspond to the natural language datasets and have similar patterns: memory usage for the explicit representations rises quickly for up to  $K = 7$  and then tapers off as overly long  $N$ -grams are unlikely to appear in multiple documents. In all cases the BFMT is superior, requiring approximately 3 times less memory than the MSF and up to 14 times less memory than its floating-point counterpart. While there is some separation between the node matrix and naïve all  $N$ -gram matrix, the gap – which is more pronounced in the journal articles – is mitigated by filtering  $N$ -grams that do not appear in multiple documents.

The third graph presents a striking difference between the representations: the BFMT requires up to 41 times less memory than the MSF node matrix and over 4,600 times less memory than the naïve  $N$ -gram matrix. The floating point counterparts for these matrices accentuate the differences by a factor of 5. Interestingly, the size of the BMFT decreases as  $K$  increases from  $10^3$  to  $10^4$ . This occurs because when  $K \geq 10^4$ , the BFMT behaves as if all  $N$ -grams are included so that all entries in the frequency matrix  $\Phi$  are

<sup>6</sup>This data was graciously made available by the Saccharomyces Genome Database at Stanford.

Figure 1: Memory utilization for the BFMT, node, and all  $N$ -gram matrices as a function of maximum  $N$ -gram length  $K$  on the BeerAdvocate data (top), journal data (middle) and 1000 genomes data (bottom).

0 or 1. When  $K \approx 10^3$ , most of the entries are bounded by 1, but a few large entries exist and force additional bits to be used for *all* non-zero frequencies in  $\Phi$ .

Next, figure 2 compares the average multiplication time for the BFMT to ordinary sparse multiplication with the node matrix. The top figure presents results for the BeerAdvocate data; we did not include timings for the journal data since they are essentially the same. We were unable to provide timing results for the node matrix on the DNA data because it quickly exceeded our computer’s memory. All trials were performed using a single core for fairness of comparison. The difference between the BFMT and the node matrix closely follows the memory requirement differences. This is to be expected as both multiplication routines make a single pass over the data so running time is proportional to the amount of data that must be scanned. We also note that the BFMT running time scales gracefully

Figure 2: Average time to perform one matrix-vector multiplication with the BFMT and node matrices as a function of maximum  $N$ -gram length  $K$  on the BeerAdvocate data (top) and 1000 Genomes Data (bottom). Node matrix times are missing for the latter because it was impractical to store.

on the DNA data; time increases at a logarithmic rate with respect to  $K$  since the  $x$ -axis is logarithmic.

## 5.2 Sentiment Analysis Tasks

We applied our framework to sentiment analysis tasks on three large datasets: the BeerAdvocate dataset, a set of 6,396,350 music reviews from Amazon (McAuley, 2013) (4.6 Gb of text), and a set of 7,850,072 movie reviews also from Amazon (McAuley, 2013) (7.4 Gb of text). Each review’s sentiment is a value between 1 and 5 (indicating negative or positive) and we tried to predict this sentiment using a ridge regression model on features provided by the node matrix. Each dataset was randomly split into training, validation, and testing sets comprised of 75%, 12.5%, and 12.5% of the total data; all parameters discussed below were selected based on their validation set performance.

We solved the regression by implementing a conjugate gradient solver in C that uses our fast multiplication routine. The ridge parameter  $\lambda$  was tuned on a grid of up to 100 values. We stopped tuning once the validation error increased for 5 consecutive  $\lambda$  values and the procedure typically terminated after trying 60 values.  $N$ -grams were pruned by maximum  $N$ -gram length and were required to appear in at least 20 distinct documents – we experimented with several document frequency thresholds. We also used the strong rules to select a subset of the features for each  $\lambda$  value and used  $\alpha\lambda$  as the threshold;  $\alpha = 1$  always gave the best performance. Finally, all columns were mean centered and normalized by their  $L_2$  norm. Our framework computed this normalization in 2.5 minutes for the larger movie dataset. The largest and most time intensive feature set contained 19.4 million features and occurred for  $K = 5$  on the movie dataset. It took 26 hours to solve for and evaluate 69 lambda values while running on a *single* core. We

were able to effectively run all  $N$ -gram trials in parallel.

Table 1: Mean Squared Error for Sentiment Analysis

| K | Beer         | Music        | Movies       |
|---|--------------|--------------|--------------|
| 1 | 0.286        | 0.766        | 0.765        |
| 2 | 0.254        | 0.481        | 0.237        |
| 3 | 0.245        | 0.366        | 0.140        |
| 4 | <b>0.244</b> | 0.333        | 0.121        |
| 5 | <b>0.244</b> | <b>0.325</b> | <b>0.115</b> |

Table 1 summarizes the mean-squared error of our regression model on the testing set. All three datasets benefit from longer  $N$ -grams, but we note that the longer datasets seem to benefit more (size increases from left to right). Confounding this potential effect are peculiarities specific to the tasks and specific to BeerAdvocate versus Amazon reviews (recall that the music and movie reviews both come from the same data source). Nonetheless, it is also possible that larger datasets are better equipped to utilize long  $N$ -grams: they provide enough examples to counter the variance incurred from estimating coefficients for long, and therefore relatively infrequent,  $N$ -grams. It will be interesting to verify this potential effect with more experiments.

## 6 Conclusion

This paper shows that learning with long  $N$ -grams on large corpora is tractable because of the rich structure in  $N$ -gram matrices. We provide a framework that can be used to permanently store a document corpus in a format optimized for machine learning. Given a particular learning task, our framework finds helpful  $N$ -grams and emits a data structure that is tailored to the problem and allows for fast matrix-vector multiplication – an operation that lies at the heart of many popular learning algorithms.

Our work suggests a number of extensions. While our multiplication algorithm is single-threaded, the underlying data structure is a tree and the necessary traversals are easy to parallelize. Finding an efficient algorithm to directly compute the DFPT without using a suffix array will also be useful. Finally, our framework provides considerable computational savings for DNA sequence data over naïve representations (up to 4 orders of magnitude). We hope that our algorithm will inspire additional research into long  $N$ -gram models for this kind of data.

## Abstract

Covariate adjustment is a widely used approach to estimate total causal effects from observational data. Several graphical criteria have been developed in recent years to identify valid covariates for adjustment from graphical causal models. These criteria can handle multiple causes, latent confounding, or partial knowledge of the causal structure; however, their diversity is confusing and some of them are only sufficient, but not necessary. In this paper, we present a criterion that is necessary and sufficient for four different classes of graphical causal models: directed acyclic graphs (DAGs), maximum ancestral graphs (MAGs), completed partially directed acyclic graphs (CPDAGs), and partial ancestral graphs (PAGs). Our criterion subsumes the existing ones and in this way unifies adjustment set construction for a large set of graph classes.

## 1 INTRODUCTION

Which covariates do we need to adjust for when estimating total causal effects from observational data? Graphical causal modeling allows to answer this question constructively, and contributed fundamental insights to the theory of adjustment in general. For instance, a simple example known as the “M-bias graph” shows that it is not always appropriate to adjust for all observed (pre-treatment) covariates (Shrier, 2008; Rubin, 2008). A few small graphs also suffice to refute the “Table 2 fallacy” (Westreich and Greenland, 2013), which is the belief that the coefficients in multiple regression models are “mutually adjusted”. Thus, causal graphs had substantial impact on theory and practice of covariate adjustment (Shrier and Platt, 2008).

The practical importance of covariate adjustment has inspired a growing body of theoretical work on graphical criteria that are sufficient and/or necessary for adjustment.

Pearl’s back-door criterion (Pearl, 1993) is probably the most well-known, and is sufficient but not necessary for adjustment in DAGs. Shpitser et al. (2012) adapted the back-door criterion to a necessary and sufficient graphical criterion for adjustment in DAGs. Others considered graph classes other than DAGs, which can represent structural uncertainty. van der Zander et al. (2014) gave necessary and sufficient graphical criteria for MAGs that allow for unobserved variables (latent confounding). Maathuis and Colombo (2015) presented a generalized back-door criterion for DAGs, MAGs, CPDAGs and PAGs, where CPDAGs and PAGs represent Markov equivalence classes of DAGs or MAGs, respectively, and can be inferred directly from data (see, e.g., Spirtes et al., 2000; Chickering, 2003; Colombo et al., 2012; Claassen et al., 2013; Colombo and Maathuis, 2014). The generalized back-door criterion is sufficient but not necessary for adjustment.

In this paper, we extend the results of Shpitser et al. (2012), van der Zander et al. (2014) and Maathuis and Colombo (2015) to derive a single necessary and sufficient adjustment criterion that holds for all four graph classes: DAGs, CPDAGs, MAGs and PAGs.

To illustrate the use of our generalized adjustment criterion, suppose we are given the CPDAG in Figure 1a and we want to estimate the total causal effect of  $X$  on  $Y$ . Our criterion will inform us that the set  $\{A, Z\}$  is an adjustment set for this CPDAG, which means that it is an adjustment set in every DAG that the CPDAG represents (Figure 1b). Hence, we can estimate the causal effect without knowledge of the full causal structure. In a similar manner, by applying our criterion to a MAG or a PAG, we find adjustment sets that are valid for all DAGs represented by this MAG or PAG. Our criterion finds such adjustment sets whenever they exist; else, our knowledge of the model structure is insufficient to compute the desired causal effect by covariate adjustment. We hope that this ability to allow for incomplete structural knowledge or latent confounding or both will help address concerns that graphical causal modelling “assumes that all [...] DAGs have been properly specified” (West and Koch, 2014).

Figure 1: (a) A CPDAG in which, according to our criterion,  $\{A, Z\}$  is an adjustment set for the total causal effect of  $X$  on  $Y$ . (b) The Markov equivalence class of (a), with node labels removed for simplicity and varying edges highlighted. An adjustment set for a CPDAG (PAG) is one that works in all DAGs (MAGs) of the Markov equivalence class.

We note that, although we can find all causal effects that are identifiable by covariate adjustment, we generally do not find all identifiable causal effects, since some effects may be identifiable by other means, such as Pearl’s front-door criterion (Pearl, 2009, Section 3.3.2) or the ID algorithm (Tian and Pearl, 2002; Shpitser and Pearl, 2006). We also point out that MAGs and PAGs are in principle not only able to represent unobserved confounding, but can also account for unobserved selection variables. However, in this paper we assume that there are no unobserved selection variables. This restriction is mainly due to the fact that selection bias often renders it impossible to identify causal effects using just covariate adjustment. Bareinboim et al. (2014) discuss these problems and present creative approaches to work around them, e.g., by combining data from different sources. We leave the question whether adjustment could be combined with such auxiliary methods aside for future research.

## 2 PRELIMINARIES

Throughout the paper we denote sets in bold uppercase letters (e.g.,  $\mathbf{S}$ ), graphs in calligraphic font (e.g.,  $\mathcal{G}$ ) and nodes in a graph in uppercase letters (e.g.,  $X$ )

**Nodes and edges.** A graph  $\mathcal{G} = (\mathbf{V}, \mathbf{E})$  consists of a set of nodes (variables)  $\mathbf{V} = \{X_1, \dots, X_p\}$  and a set of edges  $\mathbf{E}$ .

There is at most one edge between any pair of nodes, and nodes are called *adjacent* if they are connected by an edge. Every edge has two edge marks that can be arrowheads, tails or circles. Edges can be *directed*  $\rightarrow$ , *bidirected*  $\leftrightarrow$ , *non-directed*  $\circ\text{--}\circ$  or *partially directed*  $\circ\text{--}\rightarrow$ . We use  $\bullet$  as a stand in for any of the allowed edge marks. An edge is *into* (*out of*) a node  $X$  if the edge has an arrowhead (tail) at  $X$ . A *directed graph* contains only directed edges. A

*mixed graph* may contain directed and bi-directed edges. A *partial mixed graph* may contain any of the described edges. Unless stated otherwise, all definitions apply for partial mixed graphs.

**Paths.** A *path*  $p$  from  $X$  to  $Y$  in  $\mathcal{G}$  is a sequence of distinct nodes  $\langle X, \dots, Y \rangle$  in which every pair of successive nodes is adjacent in  $\mathcal{G}$ . A node  $V$  *lies on a path*  $p$  if  $V$  occurs in the sequence of nodes. The *length* of a path equals the number of edges on the path. A *directed path* from  $X$  to  $Y$  is a path from  $X$  to  $Y$  in which all edges are directed towards  $Y$ , i.e.,  $X \rightarrow \dots \rightarrow Y$ . A directed path is also called a *causal path*. A *possibly directed path* (*possibly causal path*) from  $X$  to  $Y$  is a path from  $X$  to  $Y$  that has no arrowhead pointing to  $X$ . A path from  $X$  to  $Y$  that is not possibly causal is called a *non-causal path* from  $X$  to  $Y$ . A directed path from  $X$  to  $Y$  together with an edge  $Y \rightarrow X$  ( $Y \leftrightarrow X$ ) forms an (*almost*) *directed cycle*. For two disjoint subsets  $\mathbf{X}$  and  $\mathbf{Y}$  of  $\mathbf{V}$ , a path from  $\mathbf{X}$  to  $\mathbf{Y}$  is a path from some  $X \in \mathbf{X}$  to some  $Y \in \mathbf{Y}$ . A path from  $\mathbf{X}$  to  $\mathbf{Y}$  is *proper* if only its first node is in  $\mathbf{X}$ .

**Subsequences and subpaths.** A *subsequence* of a path  $p$  is a sequence of nodes obtained by deleting some nodes from  $p$  without changing the order of the remaining nodes. A subsequence of a path is not necessarily a path. For a path  $p = \langle X_1, X_2, \dots, X_m \rangle$ , the *subpath* from  $X_i$  to  $X_k$  ( $1 \leq i \leq k \leq m$ ) is the path  $p(X_i, X_k) = \langle X_i, X_{i+1}, \dots, X_k \rangle$ . We denote the concatenation of paths by  $\oplus$ , so that for example  $p = p(X_1, X_k) \oplus p(X_k, X_m)$ . We use the convention that we remove any loops that may occur due to the concatenation, so that the result is again a path.

**Ancestral relationships.** If  $X \rightarrow Y$ , then  $X$  is a *parent* of  $Y$ . If there is a (possibly) directed path from  $X$  to  $Y$ , then  $X$  is a (*possible*) *ancestor* of  $Y$ , and  $Y$  is a (*possible*) *descendant* of  $X$ . Every node is also a descendant and an ancestor of itself. The sets of parents and (possible) descendants of  $X$  in  $\mathcal{G}$  are denoted by  $\text{Pa}(X, \mathcal{G})$  and  $(\text{Poss})\text{De}(X, \mathcal{G})$  respectively. For a set of nodes  $\mathbf{X} \subseteq \mathbf{V}$ , we have  $\text{Pa}(\mathbf{X}, \mathcal{G}) = \cup_{X \in \mathbf{X}} \text{Pa}(X, \mathcal{G})$ , with analogous definitions for  $(\text{Poss})\text{De}(\mathbf{X}, \mathcal{G})$ .

**Colliders and shields.** If a path  $p$  contains  $X_i \bullet \rightarrow X_j \leftarrow \bullet X_k$  as a subpath, then  $X_j$  is a *collider* on  $p$ . A *collider path* is a path on which every non-endpoint node is a collider. A path of length one is a trivial collider path. A path  $\langle X_i, X_j, X_k \rangle$  is an (*un*)*shielded triple* if  $X_i$  and  $X_k$  are (not) adjacent. A path is *unshielded* if all successive triples on the path are unshielded. Otherwise the path is *shielded*. A node  $X_j$  is a *definite non-collider* on a path  $p$  if there is at least one edge out of  $X_j$  on  $p$ , or if  $X_i \bullet \circ X_j \circ \bullet X_k$  is a subpath of  $p$  and  $\langle X_i, X_j, X_k \rangle$  is an unshielded triple. A node is of *definite status* on a path if it is a collider or a definite non-collider on the path. A path  $p$  is of definite status if every non-endpoint node on  $p$  is of definite status. An unshielded path is always of definite

status, but a definite status path is not always unshielded.

**m-separation and m-connection.** A definite status path  $p$  between nodes  $X$  and  $Y$  is *m-connecting* given a set of nodes  $\mathbf{Z}$  ( $X, Y \notin \mathbf{Z}$ ) if every definite non-collider on  $p$  is not in  $\mathbf{Z}$ , and every collider on  $p$  has a descendant in  $\mathbf{Z}$ . Otherwise  $\mathbf{Z}$  blocks  $p$ . If  $\mathbf{Z}$  blocks all definite status paths between  $X$  and  $Y$ , we say that  $X$  and  $Y$  are m-separated given  $\mathbf{Z}$ . Otherwise,  $X$  and  $Y$  are m-connected given  $\mathbf{Z}$ . For pairwise disjoint subsets  $\mathbf{X}, \mathbf{Y}, \mathbf{Z}$  of  $\mathbf{V}$ ,  $\mathbf{X}$  and  $\mathbf{Y}$  are m-separated given  $\mathbf{Z}$  if  $X$  and  $Y$  are m-separated by  $\mathbf{Z}$  for any  $X \in \mathbf{X}$  and  $Y \in \mathbf{Y}$ . Otherwise,  $\mathbf{X}$  and  $\mathbf{Y}$  are m-connected given  $\mathbf{Z}$ .

**Causal Bayesian networks.** A directed graph without directed cycles is a *directed acyclic graph* (DAG). A Bayesian network for a set of variables  $\mathbf{V} = \{X_1, \dots, X_p\}$  is a pair  $(\mathcal{G}, f)$ , where  $\mathcal{G}$  is a DAG, and  $f$  is a joint probability density for  $\mathbf{V}$  that factorizes according to the conditional independence relationships described via m-separation, that is  $f(\mathbf{V}) = \prod_{i=1}^p f(X_i | Pa(X_i, \mathcal{G}))$  (Pearl, 2009). We call a DAG causal when every edge  $X_i \rightarrow X_j$  in  $\mathcal{G}$  represents a direct causal effect of  $X_i$  on  $X_j$ . A Bayesian network  $(\mathcal{G}, f)$  is a *causal Bayesian network* if  $\mathcal{G}$  is a causal DAG. If a causal Bayesian network is given and all variables are observed one can easily derive post-intervention densities. In particular, we consider interventions  $do(\mathbf{X} = \mathbf{x})$  ( $\mathbf{X} \subseteq \mathbf{V}$ ), which represent outside interventions that set  $\mathbf{X}$  to  $\mathbf{x}$  (Pearl, 2009):

$$f(\mathbf{v} | do(\mathbf{X} = \mathbf{x})) = \begin{cases} \prod_{X_i \in \mathbf{V} \setminus \mathbf{X}} f(x_i | Pa(x_i, \mathcal{G})), & \text{for values of } \mathbf{V} \\ & \text{consistent with } \mathbf{x}, \\ 0, & \text{otherwise.} \end{cases} \quad (1)$$

Equation (1) is known as the truncated factorization formula (Pearl, 2009) or the g-formula (Robins, 1986).

**Maximal ancestral graph.** A mixed graph  $\mathcal{G}$  without directed cycles and almost directed cycles is called *ancestral*. A *maximal ancestral graph* (MAG) is an ancestral graph  $\mathcal{G} = (\mathbf{V}, \mathbf{E})$  where every two non-adjacent nodes  $X$  and  $Y$  in  $\mathcal{G}$  can be m-separated by a set  $\mathbf{Z} \subseteq \mathbf{V} \setminus \{X, Y\}$ . A DAG with unobserved variables can be uniquely represented by a MAG that preserves the ancestral and m-separation relationships among the observed variables (Richardson and Spirtes, 2002). The MAG of a causal DAG is a *causal MAG*.

**Markov equivalence.** Several DAGs can encode the same conditional independence information via m-separation. Such DAGs form a *Markov equivalence class* which can be described uniquely by a *completed partially directed acyclic graph* (CPDAG). Several MAGs can also encode the same conditional independence information. Such MAGs form a Markov equivalence class which can be

Figure 2: Two configurations where the edge  $X \rightarrow Y$  is visible.

described uniquely by a *partial ancestral graph* (PAG) (Richardson and Spirtes, 2002; Ali et al., 2009). We denote all DAGs (MAGs) in the Markov equivalence class described by a CPDAG (PAG)  $\mathcal{G}$  by  $[\mathcal{G}]$ .

**Consistent density.** A density  $f$  is *consistent* with a causal DAG  $\mathcal{D}$  if the pair  $(\mathcal{D}, f)$  forms a causal Bayesian network. A density  $f$  is consistent with a causal MAG  $\mathcal{M}$  if there exists a causal Bayesian network  $(\mathcal{D}', f')$ , such that  $\mathcal{M}$  represents  $\mathcal{D}'$  and  $f$  is the observed marginal of  $f'$ . A density  $f$  is consistent with a CPDAG (PAG)  $\mathcal{G}$  if it is consistent with a DAG (MAG) in  $[\mathcal{G}]$ .

**Visible and invisible edges.** All directed edges in DAGs and CPDAGs are said to be visible. Given a MAG  $\mathcal{M}$  or a PAG  $\mathcal{G}$ , a directed edge  $X \rightarrow Y$  is *visible* if there is a node  $V$  not adjacent to  $Y$  such that there is an edge between  $V$  and  $X$  that is into  $X$ , or if there is a collider path from  $V$  to  $X$  that is into  $X$  and every non-endpoint node on the path is a parent of  $Y$ . Otherwise,  $X \rightarrow Y$  is said to be *invisible* (Zhang, 2006; Maathuis and Colombo, 2015).

A directed visible edge  $X \rightarrow Y$  means that there are no latent confounders between  $X$  and  $Y$ .

### 3 MAIN RESULT

Throughout, let  $\mathcal{G} = (\mathbf{V}, \mathbf{E})$  represent a DAG, CPDAG, MAG or PAG, and let  $\mathbf{X}, \mathbf{Y}$  and  $\mathbf{Z}$  be pairwise disjoint subsets of  $\mathbf{V}$ , with  $\mathbf{X} \neq \emptyset$  and  $\mathbf{Y} \neq \emptyset$ . Here  $\mathbf{X}$  represents the intervention variables and  $\mathbf{Y}$  represents the set of response variables, i.e., we are interested in the causal effect of  $\mathbf{X}$  on  $\mathbf{Y}$ .

We define sound and complete graphical conditions for adjustment sets relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$ . Thus, if a set  $\mathbf{Z}$  satisfies our conditions relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$  (Definition 3.3), then it is a valid adjustment set for calculating the causal effect of  $\mathbf{X}$  on  $\mathbf{Y}$  (Definition 3.1), and every existing valid adjustment set satisfies our conditions (see Theorem 3.4). First, we define what we mean by an adjustment set.

**Definition 3.1. (Adjustment set; Maathuis and Colombo, 2015)** Let  $\mathcal{G}$  represent a DAG, CPDAG, MAG or PAG. Then  $\mathbf{Z}$  is an adjustment set relative to  $(\mathbf{X}, \mathbf{Y})$

in  $\mathcal{G}$  if for any density  $f$  consistent with  $\mathcal{G}$  we have  $f(\mathbf{y}|do(\mathbf{x})) = \begin{cases} f(\mathbf{y}|\mathbf{x}) & \text{if } \mathbf{Z} = \emptyset, \\ \int_{\mathbf{Z}} f(\mathbf{y}|\mathbf{x}, \mathbf{z})f(\mathbf{z})d\mathbf{z} = E_{\mathbf{Z}}\{f(\mathbf{y}|\mathbf{z}, \mathbf{x})\} & \text{otherwise.} \end{cases}$  If  $\mathbf{X} = \{X\}$  and  $\mathbf{Y} = \{Y\}$ , we call  $\mathbf{Z}$  an adjustment set relative to  $(X, Y)$  in the given graph.

To define our generalized adjustment criterion, we introduce the concept of amenability:

**Definition 3.2. (Amenability for DAGs, CPDAGs, MAGs and PAGs)** A DAG, CPDAG, MAG or PAG  $\mathcal{G}$  is said to be adjustment amenable, relative to  $(\mathbf{X}, \mathbf{Y})$  if every possibly directed proper path from  $\mathbf{X}$  to  $\mathbf{Y}$  in  $\mathcal{G}$  starts with a visible edge out of  $\mathbf{X}$ .

For conciseness, we will also write “amenable” instead of “adjustment amenable”. The intuition behind the concept of amenability is the following. In MAGs and PAGs, directed edges  $X \rightarrow Y$  can represent causal effects, but also mixtures of causal effects and latent confounding; in CPDAGs and PAGs, there are edges with unknown direction. This complicates adjustment because paths containing such edges can correspond to causal paths in some represented DAGs and to non-causal paths in others. For instance, when the graph  $X \rightarrow Y$  is interpreted as a DAG, the empty set is a valid adjustment set with respect to  $(X, Y)$  because there is only one path from  $X$  to  $Y$ , which is causal. When the same graph is however interpreted as a MAG, it can still represent the DAG  $X \rightarrow Y$ , but also for example the DAG  $X \leftarrow L \rightarrow Y$  where  $L$  is latent. A similar problem arises in the CPDAG  $X \circ - \circ Y$ .

We will show that for a graph  $\mathcal{G}$  that is not amenable relative to  $(\mathbf{X}, \mathbf{Y})$ , there is no adjustment set relative to  $(\mathbf{X}, \mathbf{Y})$  in the sense of Definition 3.1 (see Lemma 5.2). Note that every DAG is amenable, since all edges in a DAG are visible and directed. For MAGs, our notion of amenability reduces to the one defined by van der Zander et al. (2014).

We now introduce our Generalized Adjustment Criterion (GAC) for DAGs, CPDAGs, MAGs and PAGs.

**Definition 3.3. (Generalized Adjustment Criterion (GAC))** Let  $\mathcal{G}$  represent a DAG, CPDAG, MAG or PAG. Then  $\mathbf{Z}$  satisfies the generalized adjustment criterion relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$  if the following three conditions hold:

- (0)  $\mathcal{G}$  is adjustment amenable relative to  $(\mathbf{X}, \mathbf{Y})$ , and
- (1) no element in  $\mathbf{Z}$  is a possible descendant in  $\mathcal{G}$  of any  $W \in \mathbf{V} \setminus \mathbf{X}$  which lies on a proper possibly causal path from  $\mathbf{X}$  to  $\mathbf{Y}$ , and
- (2) all proper definite status non-causal paths in  $\mathcal{G}$  from  $\mathbf{X}$  to  $\mathbf{Y}$  are blocked by  $\mathbf{Z}$ .

Figure 3: (a) PAG  $\mathcal{P}$ , (b) MAG  $\mathcal{M}_1$ , (c) MAG  $\mathcal{M}_2$  used in Example 4.2.

Note that condition (0) does not depend on  $\mathbf{Z}$ . In other words, if condition (0) is violated, then there is no set  $\mathbf{Z}' \subseteq \mathbf{V} \setminus (\mathbf{X} \cup \mathbf{Y})$  that satisfies the generalized adjustment criterion relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$ .

Condition (1) defines a set of nodes that cannot be used in an adjustment set. Denoting this set of forbidden nodes by

$$\mathbf{F}_{\mathcal{G}}(\mathbf{X}, \mathbf{Y}) = \{W' \in \mathbf{V} : W' \in \text{PossDe}(W, \mathcal{G}) \text{ for some } W \notin \mathbf{X} \text{ which lies on a proper possibly causal path from } \mathbf{X} \text{ to } \mathbf{Y}\}, \quad (2)$$

condition (1) can be stated as:  $\mathbf{Z} \cap \mathbf{F}_{\mathcal{G}}(\mathbf{X}, \mathbf{Y}) = \emptyset$ . We will sometimes use this notation in examples and proofs.

We now give the main theorem of this paper.

**Theorem 3.4.** Let  $\mathcal{G}$  represent a DAG, CPDAG, MAG or PAG. Then  $\mathbf{Z}$  is an adjustment set relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$  (Definition 3.1) if and only if  $\mathbf{Z}$  satisfies the generalized adjustment criterion relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$  (Definition 3.3).

## 4 EXAMPLES

We now provide some examples that illustrate how the generalized adjustment criterion can be applied.

**Example 4.1.** We first return to the example of the Introduction. Consider the CPDAG  $\mathcal{C}$  in Figure 1a. Note that  $\mathcal{C}$  is amenable relative to  $(X, Y)$  and that  $\mathbf{F}_{\mathcal{C}}(X, Y) = \{Y\}$ . Hence, any node other than  $X$  and  $Y$  can be used in an adjustment set. Note that every definite status non-causal path  $p$  from  $X$  to  $Y$  has one of the following paths as a subsequence:  $p_1 = \langle X, Z, Y \rangle$  and  $p_2 = \langle X, A, B, Y \rangle$ , and nodes on  $p$  that are not on  $p_1$  or  $p_2$  are non-colliders on  $p$ . Hence, if we block  $p_1$  and  $p_2$ , then we block all definite status non-causal paths from  $X$  to  $Y$ . This implies that any superset of  $\{Z, A\}$  and  $\{Z, B\}$  is an adjustment set relative to  $(X, Y)$  in  $\mathcal{C}$ , and all adjustment sets are given by:  $\{Z, A\}$ ,  $\{Z, B\}$ ,  $\{Z, A, I\}$ ,  $\{Z, B, I\}$ ,  $\{Z, A, B\}$  and  $\{Z, A, B, I\}$ .

**Example 4.2.** To illustrate the concept of amenability, consider Figure 3 with a PAG  $\mathcal{P}$  in (a), and two MAGs  $\mathcal{M}_1$  and  $\mathcal{M}_2$  in  $[\mathcal{P}]$  in (b) and (c). Note that  $\mathcal{P}$  and  $\mathcal{M}_1$  are not amenable relative to  $(X, Y)$ . For  $\mathcal{P}$  this is due to the

Figure 4: (a) PAG  $\mathcal{P}_1$ , (b) PAG  $\mathcal{P}_2$  used in Example 4.3.

Figure 5: (a) CPDAG  $\mathcal{C}$ , (b) PAG  $\mathcal{P}$  used in Example 4.4.

path  $X \circ - \circ Y$ , and for  $\mathcal{M}_1$  this is due to the invisible edge  $X \rightarrow Y$ . On the other hand,  $\mathcal{M}_2$  is amenable relative to  $(X, Y)$ , since the edges  $X \rightarrow Y$  and  $X \rightarrow V_2$  are visible due to the edge  $V_1 \rightarrow X$  and the fact that  $V_1$  is not adjacent to  $Y$  or  $V_2$ . Since there are no proper definite status non-causal paths from  $X$  to  $Y$  in  $\mathcal{M}_2$ , it follows that the empty set satisfies the generalized adjustment criterion relative to  $(X, Y)$  in  $\mathcal{M}_2$ . Finally, note that  $\mathcal{M}_1$  could also be interpreted as a DAG. In that case it would be amenable relative to  $(X, Y)$ . This shows that amenability depends crucially on the interpretation of the graph.

**Example 4.3.** Let  $\mathcal{P}_1$  and  $\mathcal{P}_2$  be the PAGs in Figure 4(a) and Figure 4(b), respectively. Both PAGs are amenable relative to  $(X, Y)$ . We will show that there is an adjustment set relative to  $(X, Y)$  in  $\mathcal{P}_1$  but not in  $\mathcal{P}_2$ . This illustrates that amenability is not a sufficient criterion for the existence of an adjustment set.

We first consider  $\mathcal{P}_1$ . Note that  $\mathbf{F}_{\mathcal{P}_1}(X, Y) = \{V_4, Y\}$  is the set of nodes that cannot be used for adjustment. There are two proper definite status non-causal paths from  $X$  to  $Y$  in  $\mathcal{P}_1$ :  $X \leftarrow \circ V_3 \rightarrow Y$  and  $X \rightarrow V_4 \leftarrow V_3 \rightarrow Y$ . These are blocked by any set containing  $V_3$ . Hence, all sets satisfying the GAC relative to  $(X, Y)$  in  $\mathcal{P}_1$  are:  $\{V_3\}$ ,  $\{V_1, V_3\}$ ,  $\{V_2, V_3\}$  and  $\{V_1, V_2, V_3\}$ .

We now consider  $\mathcal{P}_2$ . Note that  $\mathbf{F}_{\mathcal{P}_2}(X, Y) = \mathbf{F}_{\mathcal{P}_1}(X, Y) = \{V_4, Y\}$ . There are three proper definite status non-causal paths from  $X$  to  $Y$  in  $\mathcal{P}_2$ :  $p_1 = X \leftrightarrow V_3 \rightarrow Y$ ,  $p_2 = X \leftrightarrow V_3 \leftrightarrow V_4 \rightarrow Y$  and  $p_3 = X \rightarrow V_4 \leftrightarrow V_3 \rightarrow Y$ . To block  $p_1$ , we must also use  $V_3$ . This implies that we must use  $V_4$  to block  $p_2$ . But  $V_4 \in \mathbf{F}_{\mathcal{P}_2}(X, Y)$ . Hence, there is no set  $\mathbf{Z}$  that satisfies the GAC relative to  $(X, Y)$  in  $\mathcal{P}_2$ .

**Example 4.4.** Let  $\mathbf{X} = \{X_1, X_2\}$  and  $\mathbf{Y} = \{Y\}$  and consider the CPDAG  $\mathcal{C}$  and the PAG  $\mathcal{P}$  in Figures 5(a) and 5(b). We will show that for both graphs there is no set that satisfies the generalized back-door criterion of Maathuis and Colombo (2015) relative to  $(\mathbf{X}, \mathbf{Y})$ , but there are sets that satisfy the generalized adjustment criterion relative to  $(\mathbf{X}, \mathbf{Y})$  in these graphs.

Recall that a set  $\mathbf{Z}$  satisfies the generalized back-door criterion relative to  $(\mathbf{X}, \mathbf{Y})$  and a CPDAG (PAG)  $\mathcal{G}$  if  $\mathbf{Z}$  contains no possible descendants of  $\mathbf{X}$  in  $\mathcal{G}$  and if for every  $X \in \mathbf{X}$  the set  $\mathbf{Z} \cup \mathbf{X} \setminus \{X\}$  blocks every definite status path from  $X$  to every  $Y \in \mathbf{Y}$  in  $\mathcal{G}$  that does not start with a visible edge out of  $X$ .

We first consider the CPDAG  $\mathcal{C}$ . To block the path  $X_2 \leftarrow V_2 \leftarrow Y$ , we must use node  $V_2$ , but  $V_2 \in \text{PossDe}(X_1, \mathcal{C})$ . Hence, no set  $\mathbf{Z}$  can satisfy the generalized back-door criterion relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{C}$ . However,  $\{V_1, V_2\}$  satisfies the generalized adjustment criterion relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{C}$ .

We now consider  $\mathcal{P}$ . To block the path  $X_2 \leftarrow V_2 \leftrightarrow Y$ , we must use node  $V_2$ . But,  $V_2 \in \text{De}(X_1, \mathcal{P})$  and thus there is no set satisfying the generalized back-door criterion relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{P}$ . However, sets  $\{V_1, V_2\}$ ,  $\{V_1, V_2, V_3\}$ ,  $\{V_1, V_2, V_4\}$ ,  $\{V_1, V_2, V_3, V_4\}$  all satisfy the generalized adjustment criterion relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{P}$ .

## 5 PROOF OF THEOREM 3.4

For DAGs and MAGs, our generalized adjustment criterion reduces to the following adjustment criterion:

**Definition 5.1. (Adjustment Criterion (AC))** Let  $\mathcal{G} = (\mathbf{V}, \mathbf{E})$  represent a DAG or MAG. Then  $\mathbf{Z}$  satisfies the adjustment criterion relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$  if the following three conditions hold:

- (0\*)  $\mathcal{G}$  is adjustment amenable with respect to  $(\mathbf{X}, \mathbf{Y})$ , and
  - (a) no element in  $\mathbf{Z}$  is a descendant in  $\mathcal{G}$  of any  $W \in \mathbf{V} \setminus \mathbf{X}$  which lies on a proper causal path from  $\mathbf{X}$  to  $\mathbf{Y}$ , and
  - (b) all proper non-causal paths in  $\mathcal{G}$  from  $\mathbf{X}$  to  $\mathbf{Y}$  are blocked by  $\mathbf{Z}$ .

This adjustment criterion is a slightly reformulated but equivalent version of the adjustment criterion of Shpitser et al. (2012) for DAGs and of van der Zander et al. (2014) for MAGs, with amenability directly included in the criterion. This adjustment criterion was shown to be sound and complete for DAGs (Shpitser et al., 2012; Shpitser, 2012) and MAGs (van der Zander et al., 2014). We therefore only need to prove Theorem 3.4 for CPDAGs and PAGs.

To this end, we need three main lemmas, given below. Throughout, we let  $\mathcal{G} = (\mathbf{V}, \mathbf{E})$  represent a CPDAG or

Figure 6: Proof structure of Theorem 3.4.

a PAG, and we let  $\mathbf{X}$ ,  $\mathbf{Y}$  and  $\mathbf{Z}$  be pairwise disjoint subsets of  $\mathbf{V}$ , with  $\mathbf{X} \neq \emptyset$  and  $\mathbf{Y} \neq \emptyset$ . We use GAC and AC to refer to the generalized adjustment criterion (Definition 3.3) and adjustment criterion (Definition 5.1), respectively.

Lemma 5.2 is about condition (0) of the GAC:

**Lemma 5.2.** *If a CPDAG (PAG)  $\mathcal{G}$  satisfies condition (0) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$ , then every DAG (MAG) in  $[\mathcal{G}]$  satisfies condition (0\*) of the AC relative to  $(\mathbf{X}, \mathbf{Y})$ . On the other hand, if  $\mathcal{G}$  violates condition (0) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$ , then there exists no set  $\mathbf{Z}' \subseteq \mathbf{V} \setminus (\mathbf{X} \cup \mathbf{Y})$  that is an adjustment set relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$  (see Definition 3.1).*

Next, we assume that  $\mathcal{G}$  satisfies condition (0) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$ . Under this assumption, we show that  $\mathbf{Z}$  satisfies conditions (1) and (2) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$  if and only if  $\mathbf{Z}$  satisfies conditions (a) and (b) of the AC relative to  $(\mathbf{X}, \mathbf{Y})$  in every DAG (MAG) in  $[\mathcal{G}]$ . This is shown in two separate lemmas:

**Lemma 5.3.** *Let condition (0) of the GAC be satisfied relative to  $(\mathbf{X}, \mathbf{Y})$  in a CPDAG (PAG)  $\mathcal{G}$ . Then the following two statements are equivalent:*

- $\mathbf{Z}$  satisfies condition (1) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$ .
- $\mathbf{Z}$  satisfies condition (a) of the AC relative to  $(\mathbf{X}, \mathbf{Y})$  in every DAG (MAG) in  $[\mathcal{G}]$ .

**Lemma 5.4.** *Let condition (0) of the GAC be satisfied relative to  $(\mathbf{X}, \mathbf{Y})$  in a CPDAG (PAG)  $\mathcal{G}$ , and let  $\mathbf{Z}$  satisfy condition (1) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$ . Then the following two statements are equivalent:*

- $\mathbf{Z}$  satisfies condition (2) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$ .
- $\mathbf{Z}$  satisfies condition (b) of the AC relative to  $(\mathbf{X}, \mathbf{Y})$  in every DAG (MAG) in  $[\mathcal{G}]$ .

The proofs of Lemmas 5.2, 5.3 and 5.4 are discussed in Sections 5.1, 5.2 and 5.3, respectively. Some proofs require additional lemmas that can be found in the supplement. The proof of Lemma 5.4 is the most technical, and builds on the work of Zhang (2006).

Figure 6 shows how all lemmas fit together to prove Theorem 3.4.

**Proof of Theorem 3.4:** First, suppose that the CPDAG (PAG)  $\mathcal{G}$  and the sets  $\mathbf{X}$ ,  $\mathbf{Y}$  and  $\mathbf{Z}$  satisfy all conditions of the GAC. By applying Lemmas 5.2, 5.3 and 5.4 in turn, it directly follows that all conditions of the AC are satisfied by  $\mathbf{X}$ ,  $\mathbf{Y}$  and  $\mathbf{Z}$  and any DAG (MAG) in  $[\mathcal{G}]$ .

To prove the other direction, suppose that the tuple  $\mathcal{G}$ ,  $\mathbf{X}$ ,  $\mathbf{Y}$ ,  $\mathbf{Z}$  does not satisfy all conditions of the GAC. First, suppose that  $\mathcal{G}$  violates condition (0) relative to  $(\mathbf{X}, \mathbf{Y})$ . Then by Lemma 5.2, there is no adjustment set relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$ , and hence  $\mathbf{Z}$  is certainly not an adjustment set.

Otherwise,  $\mathbf{Z}$  must violate condition (1) or (2) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$ . By applying Lemmas 5.3 and 5.4 in turn, this implies that there is a DAG  $\mathcal{D}$  (MAG  $\mathcal{M}$ ) in  $[\mathcal{G}]$  such that  $\mathbf{Z}$  violates conditions (a) or (b) of the AC relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{D}$  ( $\mathcal{M}$ ). Since the AC is sound and complete for DAGs and MAGs, this implies that  $\mathbf{Z}$  is not an adjustment set relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{D}$  ( $\mathcal{M}$ ), so that  $\mathbf{Z}$  is certainly not an adjustment set relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$ . □

## 5.1 PROOF OF LEMMA 5.2

The proof of Lemma 5.2 is based on the following lemma:

**Lemma 5.5.** *Let  $X$  and  $Y$  be nodes in a PAG  $\mathcal{P}$ , such that there is a possibly directed path  $p^*$  from  $X$  to  $Y$  in  $\mathcal{P}$  that does not start with a visible edge out of  $X$ . Then there is a MAG  $\mathcal{M}$  in  $[\mathcal{P}]$  such that the path  $p$  in  $\mathcal{M}$ , consisting of the same sequence of nodes as  $p^*$  in  $\mathcal{P}$ , contains a subsequence that is a directed path from  $X$  to  $Y$  starting with an invisible edge in  $\mathcal{M}$ .*

The proof of Lemma 5.5 is given in the supplement.

**Proof of Lemma 5.2:** First suppose that  $\mathcal{G}$  satisfies condition (0) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$ , meaning that every proper possibly directed path from  $\mathbf{X}$  to  $\mathbf{Y}$  in  $\mathcal{G}$  starts with a visible edge out of  $\mathbf{X}$ . Any visible edge in  $\mathcal{G}$  is visible in all DAGs (MAGs) in  $[\mathcal{G}]$ , and any proper directed path in a DAG (MAG) in  $[\mathcal{G}]$  corresponds to a proper possibly directed path in  $\mathcal{G}$ . Hence, any proper directed path from  $\mathbf{X}$  to  $\mathbf{Y}$  in any DAG (MAG) in  $[\mathcal{G}]$  starts with a visible edge out of  $\mathbf{X}$ . This shows that all DAGs (MAGs) in  $[\mathcal{G}]$  satisfy condition (0\*) of the AC relative to  $(\mathbf{X}, \mathbf{Y})$ .

Next, suppose that  $\mathcal{G}$  violates condition (0) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$ . We will show that this implies that there is no set  $\mathbf{Z}' \subseteq \mathbf{V} \setminus (\mathbf{X} \cup \mathbf{Y})$  that is an adjustment set relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$ . We give separate proofs for CPDAGs and PAGs.

Thus, let  $\mathcal{G}$  represent a CPDAG and suppose that there is a proper possibly directed path  $p$  from a node  $X \in \mathbf{X}$  to a node  $Y \in \mathbf{Y}$  that starts with a non-directed edge ( $\circ \rightarrow \circ$ ).

Let  $p' = \langle X, V_1, \dots, Y \rangle$  (where  $V_1 = Y$  is allowed) be a shortest subsequence of  $p$  such that  $p'$  is also a proper possibly directed path from  $X$  to  $Y$  starting with a non-directed edge in  $\mathcal{G}$ . We first show that  $p'$  is a definite status path, by contradiction. Thus, suppose that  $p'$  is not a definite status path. Then the length of  $p'$  is at least 2, and we write  $p' = \langle X, V_1, \dots, V_k = Y \rangle$  for  $k \geq 2$ . Since the subpath  $p'(V_1, Y)$  is a definite status path (otherwise we can choose a shorter path), this means that  $V_1$  is not of a definite status on  $p'$ . This implies the existence of an edge between  $X$  and  $V_2$ . This edge must be of the form  $X \rightarrow V_2$ , since  $X \circ\text{-} V_2$  implies that we can choose a shorter path, and  $X \leftarrow V_2$  together with  $X \circ\text{-} V_1$  implies  $V_1 \leftarrow V_2$  by Lemma 1 from Meek (1995) (see Section 1 of the supplement), so that  $p'$  is not possibly directed from  $X$  to  $Y$ . But the edge  $X \rightarrow V_2$  implies that  $V_1 \rightarrow V_2$ , since otherwise Lemma 1 from Meek (1995) implies  $X \rightarrow V_1$ . But then  $V_1$  is a definite non-collider on  $p'$ , which contradicts that  $V_1$  is not of definite status.

Hence,  $p'$  is a proper possibly directed definite status path from  $X$  to  $Y$ . By Lemma 7.6 from Maathuis and Colombo (2015) (see Section 1 of the supplement), there is a DAG  $\mathcal{D}_1$  in  $[\mathcal{G}]$  such that there are no additional arrowheads into  $X$ , as well as a DAG  $\mathcal{D}_2$  in  $[\mathcal{G}]$  such that there are no additional arrowheads into  $V_1$ . This means that the paths corresponding to  $p'$  are oriented as  $p'_1 = X \rightarrow V_1 \rightarrow \dots \rightarrow Y$  and  $p'_2 = X \leftarrow V_1 \rightarrow \dots \rightarrow Y$  in  $\mathcal{D}_1$  and  $\mathcal{D}_2$ . An adjustment set relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{D}_2$  must block the non-causal path  $p'_2$ , by using at least one of the non-endpoints nodes on this path. But all these nodes are in  $\mathbf{F}_{\mathcal{D}_1}(\mathbf{X}, \mathbf{Y})$  (see (2)). Hence, there is no set  $\mathbf{Z}' \subseteq \mathbf{V} \setminus (\mathbf{X} \cup \mathbf{Y})$  that satisfies the AC relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{D}_1$  and  $\mathcal{D}_2$  simultaneously. Since the AC is sound and complete for DAGs, this implies that there is no  $\mathbf{Z}' \subseteq \mathbf{V} \setminus (\mathbf{X} \cup \mathbf{Y})$  that is an adjustment set relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$ .

Finally, let  $\mathcal{G}$  represent a PAG and suppose that there is a proper possibly directed path  $p$  from some  $X \in \mathbf{X}$  to some  $Y \in \mathbf{Y}$  that does not start with a visible edge out of  $X$  in  $\mathcal{G}$ .

By Lemma 5.5, there is a subsequence  $p'$  of  $p$  such that there is a MAG  $\mathcal{M}$  in  $[\mathcal{G}]$  where the corresponding path is directed from  $X$  to  $Y$  and starts with an invisible edge. Then  $\mathcal{M}$  is not amenable relative to  $(\mathbf{X}, \mathbf{Y})$ . By Lemma 5.7 from van der Zander et al. (2014) (see Section 1 of the supplement) this means that there is no set  $\mathbf{Z}' \subseteq \mathbf{V} \setminus (\mathbf{X} \cup \mathbf{Y})$  that is an adjustment set relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{M}$ . Hence, there is no set  $\mathbf{Z}' \subseteq \mathbf{V} \setminus (\mathbf{X} \cup \mathbf{Y})$  that is an adjustment set relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$ .  $\square$

## 5.2 PROOF OF LEMMA 5.3

**Proof of Lemma 5.3:** First, suppose that  $\mathbf{Z}$  satisfies condition (1) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$ . Then  $\mathbf{Z} \cap \mathbf{F}_{\mathcal{G}}(\mathbf{X}, \mathbf{Y}) = \emptyset$ . Since  $\mathbf{F}_{\mathcal{D}}(\mathbf{X}, \mathbf{Y}) \subseteq \mathbf{F}_{\mathcal{G}}(\mathbf{X}, \mathbf{Y})$

( $\mathbf{F}_{\mathcal{M}}(\mathbf{X}, \mathbf{Y}) \subseteq \mathbf{F}_{\mathcal{G}}(\mathbf{X}, \mathbf{Y})$ ) for any DAG  $\mathcal{D}$  (MAG  $\mathcal{M}$ ) in  $[\mathcal{G}]$ , it follows directly that  $\mathbf{Z}$  satisfies condition (a) of the AC relative to  $(\mathbf{X}, \mathbf{Y})$  in all DAGs (MAGs) in  $[\mathcal{G}]$ .

To prove the other direction, suppose that  $\mathcal{G}$  satisfies condition (0) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$ , but that  $\mathbf{Z}$  does not satisfy condition (1) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$ . Then there is a node  $V \in \mathbf{Z} \cap \mathbf{F}_{\mathcal{G}}(\mathbf{X}, \mathbf{Y})$ , i.e.,  $V \in \mathbf{Z}$  and  $V$  is a possible descendant of a node  $W$  on a proper possibly directed path from some  $X \in \mathbf{X}$  to some  $Y \in \mathbf{Y}$  in  $\mathcal{G}$ . We denote this path by  $p = \langle X, V_1, \dots, V_k, Y \rangle$ , where  $k \geq 1$  and  $W \in \{V_1, \dots, V_k\}$ . Then the subpaths  $q = p(X, W)$  and  $r = p(W, Y)$  are also proper possibly directed paths. Moreover, there is a possibly directed path  $s$  from  $W$  to  $V$ , where this path is allowed to be of zero length (if  $W = V$ ). We will show that the existence of these paths implies that there is a DAG  $\mathcal{D}$  (MAG  $\mathcal{M}$ ) in  $[\mathcal{G}]$  such that  $\mathbf{Z}$  violates condition (a) of the AC relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{D}$  ( $\mathcal{M}$ ).

By Lemma B.1 from Zhang (2008) (see Section 1 of the supplement), there are subsequences  $q'$ ,  $r'$  and  $s'$  of  $q$ ,  $r$  and  $s$  that are unshielded proper possibly directed paths (again  $s'$  is allowed to be a path of zero length). Moreover,  $q'$  must start with a directed (visible) edge, since otherwise the concatenated path  $q' \oplus r'$ , which is again a proper possibly directed path from  $X$  to  $Y$ , would violate condition (0) of the GAC.

Lemma B.1 from Zhang (2008) then implies that  $q'$  is a directed path from  $X$  to  $W$  in  $\mathcal{G}$ . Hence, the path corresponding to  $q'$  is a directed path from  $X$  to  $W$  in any DAG (MAG) in  $[\mathcal{G}]$ .

By Lemma 7.6 from Maathuis and Colombo (2015), there is at least one DAG  $\mathcal{D}$  (MAG  $\mathcal{M}$ ) in  $[\mathcal{G}]$  that has no additional arrowheads into  $W$ . In this graph  $\mathcal{D}$  ( $\mathcal{M}$ ), the path corresponding to  $r'$  is a directed path from  $W$  to  $Y$ , and the path corresponding to  $s'$  is a directed path  $W$  to  $V$ . Hence,  $V \in \mathbf{F}_{\mathcal{D}}(\mathbf{X}, \mathbf{Y})$  ( $V \in \mathbf{F}_{\mathcal{M}}(\mathbf{X}, \mathbf{Y})$ ), so that  $\mathbf{Z}$  does not satisfy condition (a) of the AC relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{D}$  ( $\mathcal{M}$ ).  $\square$

## 5.3 PROOF OF LEMMA 5.4

We first define a distance between a path and a set in Definition 5.6. We then give the proof of Lemma 5.4. This proof relies on Lemma 5.7 and Lemma 5.8 which are given later in this section.

**Definition 5.6. (Distance-from- $\mathbf{Z}$ ; Zhang, 2006)** Given a path  $p$  from  $\mathbf{X}$  to  $\mathbf{Y}$  that is  $m$ -connecting given  $\mathbf{Z}$  in a DAG or MAG, for every collider  $Q$  on  $p$ , there is a directed path (possibly of zero length) from  $Q$  to a member of  $\mathbf{Z}$ . Define the distance-from- $\mathbf{Z}$  of  $Q$  to be the length of a shortest directed path (possibly of length 0) from  $Q$  to  $\mathbf{Z}$ , and define the distance-from- $\mathbf{Z}$  of  $p$  to be the sum of the distances from  $\mathbf{Z}$  of the colliders on  $p$ .

**Proof of Lemma 5.4:** Let  $\mathcal{G}$  represent an amenable

CPDAG (PAG) that satisfies condition (0) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$ , and let  $\mathbf{Z}$  satisfy condition (1) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$ .

We first prove that if  $\mathbf{Z}$  does not satisfy condition (2) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$ , then  $\mathbf{Z}$  does not satisfy condition (b) of the AC relative to  $(\mathbf{X}, \mathbf{Y})$  in any DAG (MAG) in  $[\mathcal{G}]$ . Thus, assume that there is a proper definite status non-causal path  $p$  from  $X \in \mathbf{X}$  to  $Y \in \mathbf{Y}$  that is m-connecting given  $\mathbf{Z}$  in  $\mathcal{G}$ . Consider any DAG  $\mathcal{D}$  (MAG  $\mathcal{M}$ ) in  $[\mathcal{G}]$ . Then the path corresponding to  $p$  in  $\mathcal{D}$  ( $\mathcal{M}$ ) is a proper non-causal m-connecting path from  $\mathbf{X}$  to  $\mathbf{Y}$  given  $\mathbf{Z}$ . Hence,  $\mathbf{Z}$  violates condition (b) of the AC relative to  $(\mathbf{X}, \mathbf{Y})$  and  $\mathcal{D}$  ( $\mathcal{M}$ ).

Next, we prove that if  $\mathbf{Z}$  violates condition (b) of the AC relative to  $(\mathbf{X}, \mathbf{Y})$  in some DAG (MAG) in  $[\mathcal{G}]$ , then  $\mathbf{Z}$  violates condition (2) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$ . Thus, assume that there is a DAG  $\mathcal{D}$  (MAG  $\mathcal{M}$ ) in  $[\mathcal{G}]$  such that there is a proper non-causal m-connecting path from  $\mathbf{X}$  to  $\mathbf{Y}$  in  $\mathcal{D}$  ( $\mathcal{M}$ ) given  $\mathbf{Z}$ . We choose a shortest such path  $p$ , such that no equally short proper non-causal m-connecting path has a shorter distance-from- $\mathbf{Z}$  than  $p$ . By Lemma 5.8 below, the corresponding path  $p^*$  in  $\mathcal{G}$  is an m-connecting proper definite status non-causal path from  $\mathbf{X}$  to  $\mathbf{Y}$  given  $\mathbf{Z}$ . Hence  $\mathbf{Z}$  violates condition (b) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{G}$ .  $\square$

**Lemma 5.7.** *Let  $\mathcal{M}$  represent a MAG (DAG) and let  $\mathcal{P}$  be the PAG (CPDAG) of  $\mathcal{M}$ . Let  $\mathcal{P}$  satisfy condition (0) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$ , and let  $\mathbf{Z}$  satisfy condition (1) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{P}$ . Let  $p$  be a shortest proper non-causal path from  $\mathbf{X}$  to  $\mathbf{Y}$  that is m-connecting given  $\mathbf{Z}$  in  $\mathcal{M}$  and let  $p^*$  denote the corresponding path constituted by the same sequence of variables in  $\mathcal{P}$ . Then  $p^*$  is a proper definite status non-causal path in  $\mathcal{P}$ .*

Lemma 5.7 is related to Lemma 1 from Zhang (2006). The proof of Lemma 5.7 is given in the supplement.

**Lemma 5.8.** *Let  $\mathcal{M}$  represent a MAG (DAG) and let  $\mathcal{P}$  be the PAG (CPDAG) of  $\mathcal{M}$ . Let  $\mathcal{P}$  satisfy condition (0) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$ , and let  $\mathbf{Z}$  satisfy condition (1) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{P}$ . Let  $p$  be a shortest proper non-causal path from  $\mathbf{X}$  to  $\mathbf{Y}$  that is m-connecting given  $\mathbf{Z}$  in  $\mathcal{M}$ , such that no equally short such path has a shorter distance-from- $\mathbf{Z}$  than  $p$ . Let  $p^*$  denote the corresponding path constituted by the same sequence of variables in  $\mathcal{P}$ . Then  $p^*$  is a proper definite status non-causal path from  $\mathbf{X}$  to  $\mathbf{Y}$  that is m-connecting given  $\mathbf{Z}$  in  $\mathcal{P}$ .*

Lemma 5.8 is related to Lemma 2 from Zhang (2006).

**Proof of Lemma 5.8.** By Lemma 5.7,  $p^*$  is a proper definite status non-causal path in  $\mathcal{P}$ . It is only left to prove that  $p^*$  is m-connecting given  $\mathbf{Z}$  in  $\mathcal{P}$ .

Every definite non-collider on  $p^*$  in  $\mathcal{P}$  corresponds to a non-collider on  $p$  in  $\mathcal{M}$ , and every collider on  $p^*$  is also

a collider on  $p$ . Since  $p$  is m-connecting given  $\mathbf{Z}$ , no non-collider is in  $\mathbf{Z}$  and every collider has a descendant in  $\mathbf{Z}$ . Let  $Q$  be an arbitrary collider (if there is one). Then there is a directed path (possibly of zero length) from  $Q$  to a node in  $\mathbf{Z}$  in  $\mathcal{M}$ . Let  $d$  be a shortest such path from  $Q$  to a node  $Z \in \mathbf{Z}$ . Let  $d^*$  denote the corresponding path in  $\mathcal{P}$ , constituted by the same sequence of variables. Then  $d^*$  is an unshielded possibly directed path from  $Q$  to  $Z$  in  $\mathcal{P}$  (Lemma B.1 from Zhang (2008)).

It is only left to show that  $d^*$  is a directed path. If  $d^*$  is of zero length, this is trivially true. Otherwise, suppose for contradiction that there is a circle mark on  $d^*$ . Then  $d^*$  must start with a circle mark at  $Q$  (cf. Lemma B.2 from Zhang, 2008 and Lemma 7.2 from Maathuis and Colombo, 2015; see Section 1 of the supplement).

Let  $S$  be the first node on  $d$  after  $Q$ . If  $S$  is not a node on  $p$ , then following the proof of Lemma 2 from Zhang (2006) there is a path  $p' = p(X, W) \oplus W \bullet \rightarrow S \leftarrow \bullet V \oplus p(V, Y)$ , where  $W$  and  $V$  are nodes distinct from  $Q$  on  $p(X, Q)$  and  $p(Q, Y)$  respectively and  $p'$  is m-connecting given  $\mathbf{Z}$  in  $\mathcal{M}$ . Since  $p'$  is non-causal and shorter than  $p$ , or as long as  $p$  but with a shorter distance-from- $\mathbf{Z}$  than  $p$ , the path  $p'$  must be non-proper, i.e.  $S \in \mathbf{X}$ . But, in that case the path  $\langle S, V \rangle \oplus p(V, Y)$  is a proper non-causal m-connecting path from  $\mathbf{X}$  to  $\mathbf{Y}$  given  $\mathbf{Z}$  that is shorter than  $p$  in  $\mathcal{M}$ . This contradicts our assumption about  $p$ .

If  $S$  is a node on  $p$ , then it lies either on  $p(X, Q)$  or  $p(Q, Y)$ . Assume without loss of generality that  $S$  is on  $p(Q, Y)$ . Following the proof of Lemma 2 from Zhang (2006), there exists a path  $p' = p(X, W) \oplus W \bullet \rightarrow S \oplus p(S, Y)$  in  $\mathcal{M}$ , where  $W$  is a node on  $p(X, Q)$  distinct from  $Q$  that is m-connecting given  $\mathbf{Z}$  in  $\mathcal{M}$ . Since  $p'$  is proper, and shorter than  $p$ , or as long as  $p$  but with a shorter distance-from- $\mathbf{Z}$  than  $p$ , the path  $p'$  must be causal in  $\mathcal{M}$ . Let  $p'^*$  denote the corresponding path constituted by the same sequence of variables in  $\mathcal{P}$ . Then  $p'^*$  is a possibly causal path and  $Z \in \text{PossDe}(S, \mathcal{P})$ , so  $Z \in \mathbf{F}_{\mathcal{P}}(\mathbf{X}, \mathbf{Y}) \cap \mathbf{Z}$ . This is in contradiction with our assumption of  $\mathbf{Z}$  satisfying condition (1) of the GAC relative to  $(\mathbf{X}, \mathbf{Y})$  in  $\mathcal{P}$ .

Thus, the path  $d^*$  is directed and  $Q$  is an ancestor of  $\mathbf{Z}$  in  $\mathcal{P}$ . This proves that  $p^*$  is a proper definite status non-causal path from  $\mathbf{X}$  to  $\mathbf{Y}$  that is m-connecting given  $\mathbf{Z}$  in  $\mathcal{M}$ .  $\square$

## 6 DISCUSSION

We have derived a generalized adjustment criterion that is necessary and sufficient for adjustment in DAGs, MAGs, CPDAGs and PAGs. Our criterion unifies existing criteria for DAGs and MAGs, and provides a new result for CPDAGs and PAGs, where only a sufficient criterion ex-

isted until now. This is relevant in practice, in particular in combination with algorithms that can learn CPDAGs or PAGs from observational data.

Our generalized adjustment criterion is stated in terms of paths that need to be blocked, which is intuitively appealing. A logical next step for future research would be to transform our criterion into an algorithmically constructive version that could be used to efficiently perform tasks like enumeration of all minimal adjustment sets for a given graph. This has already been done for DAGs and MAGs by van der Zander et al. (2014), and we strongly suspect that their results can be extended to CPDAGs and PAGs as well. In a similar spirit, it would be desirable to have an easily checkable condition to determine if there exists any adjustment set at all, as done for the generalized back-door criterion for single interventions by Maathuis and Colombo (2015). In turn, these results could then be used to characterize distances between graphs, as done by Peters and Bühlmann (2015). Future work might also explore under which circumstances our restriction to not allow for latent selection variables might be relaxed, or whether our criterion could be combined with methods to recover from selection bias (Bareinboim et al., 2014).

As pointed out in Section 4, our criterion sometimes has to interpret PAGs or MAGs differently than DAGs or CPDAGs. This is the case precisely when the first edge on some proper possibly causal path in a MAG or PAG is not visible. However, this difference in interpretation is irrelevant for DAGs or CPDAGs that would be amenable when viewed as a MAG or PAG. For instance, if we are given a DAG  $\mathcal{D}$  that is amenable when interpreted as a MAG  $\mathcal{M}$ , then its adjustment sets also work for every DAG that the MAG  $\mathcal{M}$  represents, many of which could contain latent confounding variables. Reading a DAG as a MAG (or a CPDAG as a PAG) can thus allow computing adjustment sets that are to some extent invariant to confounding.

We note that an adjustment set relative to  $(\mathbf{X}, \mathbf{Y})$  in a given graph can only exist if the total causal effect of  $\mathbf{X}$  on  $\mathbf{Y}$  is identifiable in the graph. If the effect of  $\mathbf{X}$  on  $\mathbf{Y}$  is not identifiable, one may be interested in computing all possible total causal effects of  $\mathbf{X}$  on  $\mathbf{Y}$  for DAGs represented by the given graph. Such an approach is used in the IDA algorithm of Maathuis et al. (2009, 2010), by considering all DAGs represented by a CPDAG and applying back-door adjustment to each of these DAGs. Similar ideas could be used for MAGs and PAGs, but listing all relevant DAGs described by a MAG or PAG seems rather non-trivial.

There is also an interesting connection between amenability and instrumental variables: a MAG or PAG  $\mathcal{G}$  with  $\mathbf{X} = \{X\}$  is amenable with respect to  $(\mathbf{X}, \mathbf{Y})$  whenever it contains an *instrument*  $I$ , i.e. there exists a variable that is a parent of  $X$  but not a parent of any child of  $X$  (e.g.,  $I$  in Figure 1a). Thus, instruments are useful to find adjustment

sets in nonparametric graphical models that allow for latent confounding. This connection is perhaps surprising given that the notion of instruments originates from causal effect identifications in linear models (Angrist et al., 1996).

In summary, our generalized adjustment criterion exhaustively characterizes the options to identify total causal effects by covariate adjustment in DAGs, MAGs, CPDAGs, and PAGs. Our results entail several existing, less general or less powerful ones (Pearl, 1993; Shpitser et al., 2012; Textor and Liškiewicz, 2011; van der Zander et al., 2014; Maathuis and Colombo, 2015) as special cases.

## Abstract

Energy arbitrage has the potential to make electric grids more efficient and reliable. Batteries hold great promise for energy storage in arbitrage but can degrade rapidly with use. In this paper, we analyze the impact of storage degradation on the structure of optimal policies in energy arbitrage. We derive properties of the battery degradation response that are sufficient for the existence of optimal threshold policies, which are easy to interpret and compute. Our experimental results suggest that explicitly considering battery degradation in optimizing energy arbitrage significantly improves solution quality.

## 1 INTRODUCTION

Energy storage and arbitrage play an important role in numerous domains including hybrid vehicle propulsion or electric grids [Walawalkar et al., 2007]. An important challenge in this domain is to decide how much energy to store or release based on current and expected future prices. Related resource efficiency optimization problems have been recently studied, among others, in the computational sustainability research area [Gomes, 2009, Petrik and Zilberstein, 2011, Ermon et al., 2011, Ermon et al., 2013]. Since computing an energy arbitrage policy is a difficult sequential *stochastic* optimization problem subject to significant uncertainty, it is particularly relevant to the computational sustainability community.

In this paper, we are concerned with optimizing energy arbitrage under stochastically varying energy prices. The goal of the decision maker is to maximize profits by charging an energy storage device when the price of energy is low and discharging it when it is high. We show that optimal policies have a threshold structure even when *battery degradation* is considered and use this structure to develop a practical algorithm.

Our optimal threshold policy has two price-dependent thresholds  $l$  and  $u$  ( $l \leq u$ ). If the current state of charge is less than  $l$ , then the battery is charged up to  $l$ . If the current state of charge is greater than  $u$ , then the battery is discharged to  $u$ . For any state of charge between  $l$  and  $u$ , no action is taken. Such threshold structure makes charging policies easy to compute, analyze, and interpret.

The structure of optimal policies in energy arbitrage has been analyzed previously without accounting for battery degradation [Lifshitz and Weiss, 2014, Nadarajah, 2014, Van de Ven et al., 2011, Harsha and Dahleh, 2011]. In case of batteries—an important energy storage device—the degradation can be significant and often represents an important limitation due to the high cost of batteries.

Batteries degrade most noticeably by losing capacity to hold charge. Modeling how usage patterns affect different battery types (e.g. NiMH and Li-ion) is an important research problem [Ramadass et al., 2003, Aurbach, 2000]. In Li-ion batteries, the degradation is predominantly influenced by 1) the state of charge, 2) the rate of charge and discharge, and 3) the ambient temperature. We aim, in this work, to minimize the battery’s capacity loss as it is influenced by the state of charge.

Battery degradation has been explicitly considered in optimizing energy storage in hybrid vehicles [Bashash et al., 2011, Serrao et al., 2005, Hoke et al., 2011, Moura et al., 2011]. These methods solve a discretized dynamic program. The drawback of this approach is that the computed policies are complex, hard to implement and interpret. In addition, the discretization and sampling issues can significantly degrade solution quality as we show experimentally. On the other hand, the optimality of threshold policies has been studied widely in the inventory management literature [Porteus, 2002]. There is, however, no concept of storage degradation in traditional inventory management domains.

The existence of an optimal threshold policy in our setting is somewhat surprising. The standard threshold policy results rely on the fact that the optimal value function is convex or  $k$ -convex. The optimal value function for non-trivial battery degradation functions, as we show, may be

non-convex. Yet, we establish the existence of a threshold policy through the convexity of an auxiliary optimization function.

The remainder of the paper is organized as follows. Section 2 describes the overall arbitrage model. We primarily study models that faithfully capture the energy arbitrage setting in electric grids. Section 3 describes the model of battery degradation and derives some basic properties of the degradation function. Then, we show sufficient conditions for the existence of threshold policies in Section 4 and describe how the structure can be used in computing an optimized policy in Section 5. Section 6 describes an application of the methodology with the analysis of the results and a comparison to discretization-based methods.

## 2 ENERGY STORAGE MODEL

This section describes the model of energy arbitrage and storage. We assume multiple finite *known* price levels and a stochastic evolution given a limited storage capacity. In particular, the storage is assumed to be an electrical battery that degrades when energy is stored or retrieved.

The underlying model is a Markov decision process. We assume a discrete-time problem with either a finite horizon  $T$  or a discounted infinite horizon. Prices are governed by a Markov process with states  $\Theta$ . There are two energy prices in each time step:  $p^i : \Theta \rightarrow \mathbb{R}_+$  is the purchase (or input) price and  $p^o : \Theta \rightarrow \mathbb{R}_+$  is the selling (or output) price. To simplify notation, the difference in these prices is also used to model the energy loss in the charging and discharging processes. In other words, the prices measure the cost of energy as added or subtracted from the storage and may not actually be sold or purchased.

We use  $s$  to denote the available battery capacity with  $s_0$  denoting the initial capacity. The current state of charge is denoted as  $x$  or  $y$  and must satisfy that  $0 \leq x_t \leq s_t$  at any time step  $t$ . The action is the amount of energy to charge or discharge, which is denoted by  $u$ . Positive  $u$  indicates that energy is purchased to charge the battery; negative  $u$  indicates the sale of energy.

We will make the following assumption regarding the purchase and selling prices.

**Assumption 1.** Purchase price is higher than the selling price per unit in a time step:

$$p_\theta^i \geq p_\theta^o \quad \forall \theta \in \Theta.$$

Assumption 1 is virtually always satisfied in practice. If violated, direct arbitrage by simultaneously purchasing and selling energy in a single time step would then equalize the prices. In addition, the purchase price  $p^i$  will be greater than the selling price  $p^o$  due to the inefficiencies involved in charging and discharging.

As mentioned above, the focus of the paper is on degradation of battery capacity as a function of its use. In particular, we model the degradation as a function of the battery

capacity when charged or discharged. We use a general model of battery degradation with a specific focus on Li-ion batteries. The degradation function  $d(x, u) \in \mathbb{R}_+$  represents the battery capacity loss after starting at the state of charge  $x \geq 0$  and charging (discharging if negative) by  $u$  with  $-x \leq u \leq s_0 - x$ . This function indicates the loss of capacity, such that:

$$s_{t+1} = s_t - d(x_t, u_t)$$

We discuss the degradation function in more detail in Section 3.

Our model makes several simplifying assumptions that are reasonable in an electric grid scenario, but may not apply to other scenarios such as a hybrid vehicle battery storage. In particular, we assume that the purchase and selling prices are independent of the energy quantity sold or purchased and battery degradation is independent of current and temperature.

The state set in the Markov decision problem is composed of  $(x, s, \theta)$  where  $x$  is the state of charge,  $s$  is the battery capacity, and  $\theta \in \Theta$  is the state of the price process. The available actions in a state  $(x, s, \theta)$  are  $u$  such that  $-x \leq u \leq s - x$ . The transition is from  $(x_t, s_t, \theta_t)$  to  $(x_{t+1}, s_{t+1}, \theta_{t+1})$  given action  $u_t$  is:

$$\begin{aligned} x_{t+1} &= x_t + u_t \\ s_{t+1} &= s_t - d(x_t, u_t) \end{aligned}$$

The probability of this transition is given by  $\mathbb{P}[\theta_{t+1}|\theta_t]$ . The reward for this transition is:

$$r((x_t, s_t, \theta_t), u_t) = \begin{cases} -u_t \cdot p^i - c^d \cdot d(x_t, u_t) & \text{if } u_t \geq 0 \\ -u_t \cdot p^o - c^d \cdot d(x_t, u_t) & \text{if } u_t < 0 \end{cases}$$

That is, the reward captures the monetary value of the transaction minus a penalty for degradation of the battery. Here,  $c^d$  represents the cost of a unit of lost battery capacity.

The solution of the Markov decision process is a policy  $\pi$ , which can be computed from a value function  $v$  and a post-decision (or state-action) value function  $q$ . We focus on both the discounted infinite horizon with a discount factor  $\lambda \in (0, 1)$  and the finite horizon with the undiscounted total return criterion.

The Bellman optimality equations for this problem are:

$$\begin{aligned} q_T(x, s, \theta_T) &= 0 \\ v_t(x, s, \theta_t) &= \min\{p_{\theta_t}^i [u]_+ + p_{\theta_t}^o [u]_- + \\ &\quad + c^d d(x, u) + \\ &\quad + q_t(x + u, s - d(x, u), \theta_t) : \\ &\quad : u \in [-x, s - x]\} \\ q_t(x, s, \theta_t) &= \lambda \cdot \mathbb{E}[v_{t+1}(x, s, \theta_{t+1})] \end{aligned} \quad (2.1)$$

where  $[u]_+ = \max\{u, 0\}$  and  $[u]_- = \min\{u, 0\}$  and the expectation is taken over  $P(\theta_{t+1}|\theta_t)$ . For finite horizon case,  $\lambda = 1$ .

For the purpose of our theoretical analysis, we assume that the lost capacity is immediately replaced and therefore the battery capacity does not actually change ( $s_{t+1} = s_t = s_0$ ). Instead, the degradation induces a penalty in the form of capacity replacement cost governed by  $c_d$ . In that case, the capacity  $s$  can be omitted from the definition of  $v$  in (2.1). The experimental results, however, study the setting in which the capacity is not immediately replaced.

### 3 BATTERY DEGRADATION FUNCTION

This section describes properties of the degradation function  $d(x, u)$  that can capture the behavior of Li-ion batteries [Aurbach, 2000, Ramadass et al., 2003] and can guarantee the existence of an optimal threshold policy. We focus on Li-ion batteries because of their ubiquity and considerable promise in future applications [Peterson et al., 2010]. The chemical processes in other battery types—such as NiMH and NiCd—are often quite different [Serrao et al., 2005].

As noted above, we consider the dependence of the degradation only on the state of charge because the other variables, such as the temperature and the current, can be efficiently controlled in an electric grid energy application.

In broad terms, a Li-ion battery degrades significantly while the state of charge is either very low or very high. A naive policy that minimizes battery degradation will therefore attempt to use the battery as close to approximately 50% state of charge as possible.

Instead of considering a single degradation function, we define a class of functions  $d(x, u)$ , *continuous* in  $u$  for  $x \in [0, s_0]$ , that in addition satisfy the following properties.

- A1 *Convexity*: function  $d(x, u)$  is convex in  $u$  for all  $x \in [0, s_0]$ .
- A2 *Memorylessness*:  $d(x, u_1 + u_2) = d(x, u_1) + d(x, u_2)$  when  $\text{sgn}(u_1) = \text{sgn}(u_2)$ .
- A3 *Cycle linearity*: function  $d(0, u) + d(u, -u)$  is linear in  $u$ .

Next we informally describe the meaning of the properties above; a more detailed analysis of functions that satisfy these properties follows later. The property A1 is generally satisfied in Li-ion batteries in which the degradation is more severe near the extreme range of the state of charge. The property A2 requires that the degradation due to the charging is independent of the amount charged, but instead depends only on the current state of charge. Finally, the property A3 requires that the degradation due to charging an arbitrary amount from the state of charge 0 and subsequently fully discharging is linear in the amount charged.

The assumptions above, unfortunately, are hard to grasp intuitively and therefore difficult to justify. To elucidate the definitions, consider the alternative definition of

Figure 1: Example degradation function with  $\delta_+(x) = x^2$  and  $\delta_-(x) = 1 - x^2$ .

$d(x, u)$  based on the degradation at any state of charge for an infinitesimally small amount of energy charged  $\delta_+ : [0, s_0] \rightarrow \mathbb{R}_+$  or discharged  $\delta_- : [0, s_0] \rightarrow \mathbb{R}_+$ . The degradation function is then simply defined as the following integral:

$$d(x, u) = \begin{cases} \int_x^{x+u} \delta_+(y) dy & \text{if } u \geq 0 \\ \int_{x+u}^x \delta_-(y) dy & \text{if } u < 0 \end{cases}. \quad (3.1)$$

Fig. 1 depicts an example of the immediate degradation functions  $\delta_+$  and  $\delta_-$  and the corresponding degradation function  $d$  for two values of the current state of charge.

The following proposition describes how the properties of  $\delta_+$  and  $\delta_-$  translate to properties of  $d(x, u)$ .

**Proposition 3.1.** *When  $d$  is defined as in (3.1) and*

- (i) *both  $\delta_-$  and  $\delta_+$  are continuous on  $[0, s_0]$*
- (ii)  *$\delta_+$  is nondecreasing and  $\delta_-$  is nonincreasing*
- (iii)  *$\delta_+(y) + \delta_-(y)$  is a constant for any  $y \in [0, s_0]$*

*Then, the battery degradation function  $d(x, u)$  satisfies the properties of A1, A2 and A3.*

*Proof.* The property (i) implies that there exist anti-derivatives  $D_+$  and  $D_-$  to  $\delta_+$  and  $\delta_-$  on the appropriate intervals. Then:

$$d(x, u) = \begin{cases} D_+(x+u) - D_+(x) & \text{if } u \geq 0 \\ D_-(x) - D_-(x+u) & \text{if } u < 0 \end{cases}$$

We prove each property individually.

A1: *Convexity.* The convexity for a fixed  $x$  and  $u \neq 0$  follows directly from the convexity of  $D_+$  and  $-D_-$ . The functions  $D_+(x, u)$  and  $D_-(x, u)$  are convex because their first derivatives  $\delta_+$  and  $-\delta_-$  are nondecreasing [Boyd and Vandenberghe, 2004]. Since both  $D_+$  and  $D_-$  are non-negative functions and  $d(x, 0) = 0$ , we have

Figure 2: Example degradation function with  $\delta_+(x) = 0.01 \cdot x^6$  and  $\delta_-(x) = 0.005 \cdot (1-x)^3$ .

that  $u = 0$  is the minimum of  $d(x, u)$  and therefore it satisfies the convexity condition.

A2: Memorylessness. If  $u_1 > 0$  and  $u_2 > 0$ ,

$$\begin{aligned} d(x, u_1 + u_2) &= \int_x^{x+u_1+u_2} \delta_+(y) dy \\ &= \int_x^{x+u_1} \delta_+(y) dy + \int_{x+u_1}^{x+u_1+u_2} \delta_+(y) dy \\ &= d(x, u_1) + d(x + u_1, u_2). \end{aligned}$$

The property holds similarly when  $u_1 < 0$  and  $u_2 < 0$ .

A3: Cycle linearity. Let  $u > 0$ ,

$$d(0, u) + d(u, -u) = \int_0^u \delta_+(y) dy + \int_0^u \delta_-(y) dy$$

since  $\delta_+(y) + \delta_-(y)$  is a constant, the cycle linearity is satisfied.  $\square$

Note that the degradation function in Fig. 1 satisfies the properties A1–A3. This can be easily seen since  $\delta_+(x) + \delta_-(x) = 1$ . However, the degradation of Li-ion batteries may not always satisfies these properties. Fig. 2 illustrates an example, based on real Li-ion behavior [Bashash et al., 2011], which violates A3. The precise form of the degradation function for any particular battery design can be obtained either experimentally or by simulation [Ramadesigan et al., 2012].

## 4 STRUCTURE OF OPTIMAL POLICIES

In this section, we show the existence of an optimal threshold policy in the battery storage problem if properties A1–A3 are satisfied. The analysis is based on a finite-horizon version of the problem and we discuss how this structure generalizes to discounted infinite horizon problems later in the section.

A two-threshold charge policy is defined as follows:

Figure 3: Example of a threshold policy. The upper (red) line represents  $C(\theta)$ ; the lower (green) line represents  $c(\theta)$ .

**Definition 4.1.** A two-threshold charge policy with thresholds  $(c_{t,\theta}, C_{t,\theta})$  with  $c_{t,\theta} \leq C_{t,\theta}$  for some  $\theta \in \Theta$  and  $t = 1 \dots T$  is defined as:

$$u_t = \begin{cases} c_{t,\theta} - x_t & \text{when } x_t \leq c_{t,\theta} \\ C_{t,\theta} - x_t & \text{when } x_t \geq C_{t,\theta} \\ 0 & \text{otherwise} \end{cases} \quad (4.1)$$

where  $t$  is the current time step,  $x_t$  is the current battery charge,  $\theta_t$  is the price level state, and  $u_t$  is the change in the state of charge.

One of the main appealing properties of a threshold policy is its simplicity and interpretability. Fig. 3 depicts an example of a threshold policy. The  $x$ -axis represents the state of the price process  $\theta$ . In this example, the price of energy grows linearly with  $\theta$  and the price transitions behave as a martingale. If the current state of charge is in the red region, the next step is to discharge the battery to the red line. Similarly, states in the green region are charged up to the green line.

Note that the policy in Fig. 3 behaves very intuitively. When the price of energy is low (small  $\theta$ ), the battery is charged to a high level. It is not charged fully, however, to prevent excessive degradation of capacity. No action is taken for the medium energy price. When the energy price increases to its maximum level, the battery is fully discharged.

We are now ready to state the main theoretical result of the paper.

**Theorem 4.2.** Assume that the battery degradation function satisfies properties A1, A2, and A3 and  $\lambda = 1$ . Then, there exists an optimal two-threshold charge policy for the finite horizon problem with some time-dependent thresholds  $(c(t, \theta), C(t, \theta))$ .

To prove the theorem, we need to show several auxiliary properties. The following lemma describes the properties of the degradation function induced by the assumptions above.

Figure 4: Degradation function in Example 4.4.

**Lemma 4.3.** A degradation function  $d$  that satisfies property A2 also satisfies:

- (i)  $d(x, 0) = 0$
- (ii)  $d(x, y - x) = d(0, y) - d(0, x)$  when  $y \geq x$
- (iii)  $d(x, y - x) = d(x, -x) - d(y, -y)$  when  $y \leq x$

In addition, when  $d$  satisfies property A1, then:

- (iv)  $d(x, -x)$  is concave in  $x$
- (v)  $d(x, y - x) = \max\{d(0, y) - d(0, x), d(x, -x) - d(y, -y)\}$

*Proof.* The lemma follows by simple algebraic manipulation for the individual cases as follows.

Case (i):

$$d(x, u + 0) = d(x, 0) + d(x + 0, u).$$

Case (ii):

$$d(0, y) = d(0, x + (y - x)) = d(0, x) + d(x, y - x).$$

Case (iii):

$$d(x, -x) = d(x, (y - x) - y) = d(x, y - x) + d(y, -y).$$

Case (iv): by rewriting  $d(s_0, -s_0) = d(s_0, -(s_0 - x) - x)$  we get:

$$d(x, -x) = d(s_0, -s_0) - d(s_0, x - s_0).$$

Function  $d(x, -x)$  is concave because  $d(s_0, x - s_0)$  is convex.

Case (v): Note that  $d(0, x)$  is non-decreasing, and  $d(x, -x)$  is non-increasing. The proof then readily follows from properties (ii) and (iii).  $\square$

We are now ready to prove the main result. The typical proof of the threshold property in inventory management settings is based on convexity of the value function. Unfortunately, as the example described below in Example 4.4

Figure 5: Example of functions in the proof of Theorem 4.2. The current charge is  $x$  and the optimal action is to discharge to  $y_o^*$ .

Figure 6: Example of functions in the proof of Theorem 4.2. The current charge is  $x$  and the optimal action is to leave the charge unchanged.

demonstrates, the value function in our setting may be non-convex. Instead, we use property A3 to establish the convexity of the post-decision value function (the concept is similar to  $q$ -function in reinforcement learning). In particular, the linearity required by A1 can be used to cancel out the value function non-convexities due to the battery degradation.

*Proof of Theorem 4.2.* Like most structural proofs in dynamic programming, the proof is based a backward induction on time steps. But first, we need to derive a more convenient representation of the optimality equation (2.1). To that effect, rewrite the term  $p_\theta^i [u]_+ + p_\theta^o [u]_-$  in (2.1) as a maximum over two functions:

$$p_\theta^i [u]_+ + p_\theta^o [u]_- = \max\{p_\theta^i u, p_\theta^o u\}.$$

This holds from Assumption 1. It will be more convenient to change the optimization variable in (2.1) from the charge difference  $u$  to the new state of charge  $y = x + u$ . Also using property (v) from Lemma 4.3 to express the degradation function, the optimality expression for  $v_t(x, \theta)$  now reads as:

$$\min_{y \in [0, s_0]} \max \left\{ p_\theta^i(y - x), p_\theta^o(y - x) \right\} + q_t(y, \theta) + c^d \cdot \max \left\{ d(0, y) - d(0, x), d(x, -x) - d(y, -y) \right\}.$$

Properties (ii) and (iii) from Lemma 4.3 and Assumption 1 imply that the two max operators attain their respective first terms if and only if  $y \geq x$  and therefore can be merged:

$$\min_{y \in [0, s_0]} \max \left\{ p_\theta^i(y - x) + c^d(d(0, y) - d(0, x)) + q_t(y, \theta), p_\theta^o(y - x) + c^d(d(x, -x) - d(y, -y)) + q_t(y, \theta) \right\}$$

Then we replace  $\max\{a, b\}$  by  $\max_{\xi \in [0, 1]} \{\xi a, (1 - \xi)b\}$ . Thus the Bellman optimality conditions become:

$$v_t(x, \theta) = \min_{y \in [0, s_0]} \max_{\xi \in [0, 1]} \phi_t(y, \xi, x, \theta),$$

where the main objective function  $\phi$  is defined as:

$$\phi_t(y, \xi, x, \theta) = \xi(f_t^i(y, \theta) + g_t^i(x, \theta)) + (1 - \xi)(f_t^o(y, \theta) + g_t^o(x, \theta)).$$

The functions  $g^i$  and  $g^o$  represent terms that are constant with respect to the optimization variable  $y$ :

$$g_t^i(x, \theta) = -p_\theta^i x - c^d d(0, x) \\ g_t^o(x, \theta) = -p_\theta^o x + c^d d(x, -x).$$

On the other hand, the functions  $f^i$  and  $f^o$  represent terms that depend on the optimization variable  $y$ :

$$f_t^i(y, \theta) = p_\theta^i y + c^d d(0, y) + q_t(y, \theta) \\ f_t^o(y, \theta) = p_\theta^o y - c^d d(y, -y) + q_t(y, \theta).$$

The remainder of the proof focuses on showing that  $f^i$  and  $f^o$  are convex and using this convexity to show the optimality of a threshold policy in computing the minimization over  $y$ .

We next show by induction on  $t$  from  $t = T$  to  $t = 0$  that the functions  $f_t^i$  and  $f_t^o$  are *convex* even if  $q_t$  is not. To prove the base case  $t = T$  recall that  $q_T = 0$ . The convexity of  $f_t^i$  and  $f_t^o$  then follows from property (iv) in Lemma 4.3.

To prove the inductive step, assume that the functions  $f_{t+1}^i$  and  $f_{t+1}^o$  are *convex*. Our focus is on showing convexity of  $f_t^i$ ; the derivation of convexity of  $f_t^o$  is analogous. Recall that:

$$f_t^i(y, \theta) = p_\theta^i y + c^d d(0, y) + \mathbb{E}[v_{t+1}(x, \theta_{t+1})]$$

Since given a fixed  $x$ , the function  $\phi(y, \xi, x)$  is convex-concave, continuous, and optimized on convex compact sets we have by a generalized minimax theorem (e.g. [Sion, 1958]) and further algebraic manipulation that:

$$v_{t+1}(x, \theta) = \min_{y \in [0, s_0]} \max_{\xi \in [0, 1]} \phi_{t+1}(y, \xi, x, \theta) \\ = \max_{\xi \in [0, 1]} \min_{y \in [0, s_0]} \phi_{t+1}(y, \xi, x, \theta) \\ = \max \left\{ g_{t+1}^i(x, \theta) + \min_{y \in [0, s_0]} f_{t+1}^i(y, \theta), g_{t+1}^o(x, \theta) + \min_{y \in [0, s_0]} f_{t+1}^o(y, \theta) \right\},$$

Note that the functions  $g_{t+1}^i$  and  $g_{t+1}^o$  may not be convex, but taking the maximum outside of the minimization will help to establish the convexity of  $f_t^i$ .

Next, plug in the above expression for  $v_{t+1}$  and the definitions of  $g_{t+1}^i$  and  $g_{t+1}^o$  to  $f_t^i(y, \theta)$ . Further algebraic simplification yields:

$$f_t^i(y, \theta) = c^d d(0, y) + \mathbb{E} \left[ \max \left\{ -c^d d(0, y) + L_1(y), c^d d(y, -y) + L_2(y) \right\} \right] \\ = \mathbb{E} \left[ \max \left\{ L_3(y), c^d d(0, y) + c^d d(y, -y) + L_4(y) \right\} \right]$$

where  $L_1(y) \dots L_4(y)$  represent functions that are linear or constant in  $y$ . Now, recall from Lemma 4.3 that the function  $d(y, -y)$  is concave. However, Assumption A3 implies that  $d(0, y) + d(y, -y)$  is a linear (convex) term. Point-wise maximization and expectation preserve convexity and thus the function  $f_t^i$  is convex. The analogous proof for  $f_t^o$  requires that  $d(0, y) + d(y, -y)$  is concave (or linear) and thus the linearity required by A3.

The final step in the proof is to show the two-threshold structure in the solution to the action optimization problem:

$$\min_{y \in [0, s_0]} \max \left\{ f_t^i(y, \theta) + g_t^i(x, \theta), f_t^o(y, \theta) + g_t^o(x, \theta) \right\}. \quad (4.2)$$

Figs. 5 and 6 depict examples of functions in (4.2) for two different values of the current state of charge  $x$ . The horizontal axis represents the next state of charge  $y$  and the bold dashed line highlights the maximum of the two functions. Note that the change in the current state of charge  $x$  only shifts the two functions without changing their shape.

Now, recall that from Lemma 4.3 and from the construction of (4.2), the following inequalities hold:

$$y > x \Rightarrow f_t^i(y, \theta) + g_t^i(x, \theta) \geq f_t^o(y, \theta) + g_t^o(x, \theta) \\ y < x \Rightarrow f_t^i(y, \theta) + g_t^i(x, \theta) \leq f_t^o(y, \theta) + g_t^o(x, \theta) \\ y = x \Rightarrow f_t^i(y, \theta) + g_t^i(x, \theta) = f_t^o(y, \theta) + g_t^o(x, \theta)$$

Now let  $e_i(y) = f_t^i(y, \theta) + g_t^i(x, \theta)$  and  $y_i^* \in \arg \min_{y \in [0, s_0]} e_i(y)$ . Also let  $e_o(y) = f_t^o(y, \theta) + g_t^o(x, \theta)$

Figure 7: Value function at time  $t = 1$ .

and  $y_o^* \in \arg \min_{y \in [0, s_0]} e_o(y)$ . We will show below that the optimal solution to (4.2) can be either at  $y_i^*$ ,  $y_o^*$ , or at  $x$ . There are three possible cases:

1. If  $y_i^* > x$  then  $y_i^*$  is optimal in (4.2) because  $f_i^i(y, \theta) + g_i^i(x, \theta) \leq f_i^o(y, \theta) + g_i^o(x, \theta)$  for any  $y < x$ .
2. If  $y_o^* < x$  then  $y_o^*$  is optimal in (4.2) as above.
3. If  $y_i^* \leq x$  and  $y_o^* \geq x$  then  $x$  is optimal in (4.2). Barring the trivial case  $y_i^* = x$ , for any  $y > x$ , we have  $\frac{e_i(y) - e_i(x)}{y - x} \geq \frac{e_i(x) - e_i(y_i^*)}{x - y_i^*} \geq 0$  since  $e_i(y)$  is convex. Therefore  $e_i(y) \geq e_i(x)$  for any  $y > x$ . A similar argument for any  $y < x$  shows that  $e_o(y) \geq e_o(x)$  which proves the desired optimality of  $x$  in (4.2).

These cases correspond to the threshold policy as described in Definition 4.1.  $\square$

The following example illustrates that even when the conditions A1–A3 are satisfied, the optimal value function may not be convex.

**Example 4.4.** Consider a two stage problem with the sale price  $p^i = p^o = 2$ , the degradation cost  $c^d = 1$  and the degradation function being:

$$d(x, u) = \max\{(x + u)^2 - x^2, (s_0 - x - u)^2 - (s_0 - x)^2\}.$$

The degradation function at  $x = 0.2$  and  $x = 0.8$  is depicted in Fig. 4.

The battery capacity is  $s_0 = 1$ . It is easy to show that the optimal policy in the last stage is simply to fully discharge the battery. Then  $v_1(x) = -p^o \cdot x + c^d \cdot d(x, -x)$ . By Lemma 4.3, the function  $v_1$  is concave as illustrated in Fig. 7.

Note that the degradation function in Example 4.4 satisfies the property A3 and, therefore, this property is insufficient

to guarantee the convexity of a value function. In fact, the value function will only be convex only if  $d(x, -x)$  is linear—the degradation function is linear only when the degradation is independent of the battery charge.

Finally, note that Theorem 4.2 does not apply to discounted problems. To apply to discounted problems, we require a modified A3 that states that both functions  $d(0, u) + \lambda d(u, -u)$  and  $-\lambda d(0, u) - d(u, -u)$  are convex.

**Corollary 4.5.** Assume that the battery degradation function satisfies properties A1, A2, and modified A3. Then there exists an optimal two-threshold charge policy for the discounted infinite horizon problem with time-independent thresholds  $(c(\theta), C(\theta))$ .

The proof of Corollary 4.5 follows the same steps as the proof of Theorem 4.2 and is provided in the appendix. The stationarity follows using the standard argument for the existence of an optimal stationary policy, e.g. Theorem 6.2.7 in [Puterman, 2005].

The modified condition A3 is however more difficult to satisfy and verify than the original A3. However, it may be sufficient to satisfy either one of these properties approximately in order for a threshold policy be close to optimal. This analysis is, however, beyond the scope of the present paper.

## 5 OPTIMIZATION ALGORITHM

So far we described the structure of the optimal policy. It is important to also develop an algorithm that can take advantage of this structure and efficiently compute the optimal policy. In this section, we describe such an algorithm and prove its optimality. We focus on the infinite horizon problem which is more relevant in practice.

A naive approach to optimizing threshold policies is to iteratively evaluate a given set of thresholds by simulation and then optimize the threshold values. This class of methods is known as simulation-optimization or policy search [Carson and Maria, 1997]. Simply searching over all sets of thresholds is intractable because the number of threshold values that need to be computed is  $2^{|\Theta|}$ . As we show below this search can be decomposed by the states of the price process  $\theta$  leading to Algorithm 1. The algorithm optimizes each pair of thresholds independently for each state of the price process.

The evaluation function  $\tilde{f}(c_{\theta_1}, C_{\theta_1}, \dots, c_{\theta_k}, C_{\theta_k}, \dots, c_{\theta_n}, C_{\theta_n})$  is computed by simulating the execution. Using common random numbers when optimizing a value by simulation in this setting can significantly reduce sample variance and speed up the algorithm [Glasserman and Yao, 1992]. To model the discount factor, we assume a termination probability of  $1 - \lambda$  in every step. The function  $\tilde{f}$  is computed as a sample average.

In the remainder of the section, assume that the function  $\tilde{f}$  can be evaluated precisely. The result readily generalizes to

// Initialize thresholds
1  $(c_\theta, C_\theta) \leftarrow (0, 1) \quad \forall \theta \in \Theta$ ;
// Initialize step counter
2  $k \leftarrow 1$ ;
3  $g_0 \leftarrow \inf, g_{-1} \leftarrow \inf$ ;
4 while  $g_{k-1} < g_{k-2} + \epsilon$  do
5   for  $\theta \in \Theta$  do
6     // Optimize thresholds for  $\theta$ 
7      $c_\theta, C_\theta \leftarrow \arg \min_{\bar{c}_\theta, \bar{C}_\theta} \tilde{f}(\dots, \bar{c}_\theta, \bar{C}_\theta, \dots)$ ;
8     //  $\tilde{f}$  is sampled mean return
9      $g_k \leftarrow \tilde{f}(c_{\theta_1}, C_{\theta_1}, \dots, c_{\theta_n}, C_{\theta_n})$ ;
10     $k \leftarrow k + 1$ ;
// Return computed thresholds
9 return  $\{(\theta, c_\theta, C_\theta) : \theta \in \Theta\}$ 

```

---

the sampled setting by considering appropriate Hoeffding or Bernstein concentration inequalities.

**Proposition 5.1.** *Consider an energy arbitrage problem that satisfies the properties A1, A2, and modified A3 sufficient for the optimality of a threshold policy. Then Algorithm 1 converges to the optimal solution in a finite number of iterations.*

*Proof.* We argue that Algorithm 1 corresponds to a variant of the simplex algorithm implementation on the dual MDP formulation (e.g., [Puterman, 2005]). First, note that using the same argument as in the proof of Theorem 4.2 we can show that the optimal solution to the minimization in Algorithm 1 is also a threshold policy. Therefore, the algorithm corresponds to a coordinate descent on the linear program formulation of the MDP. The result then follows from the finite number of coordinate blocks.  $\square$

## 6 NUMERICAL RESULTS

This section numerically evaluates Algorithm 1 in an idealized, but realistic, model of daily energy price evolution and a degradable Li-ion battery. First, we analyze the properties of the computed solution and study the impact of the battery degradation on the quality of the computed policy. Then, we compare the solution based on a threshold policy to directly solving a discretized version of the problem.

The experimental setting assumes that energy is traded daily in a large exchange market that is not influenced by the trading policy. We compute policies for a discount factor of 0.9999 and report results of simulations of energy arbitrage throughout 5 years (1825 days).

Our energy prices are based on data from the Intercontinental Exchange (IEC) [IEC, 2015] for New England for years 2001 through 2013. The price per MW h in this period ranges between \$24 and \$312. Numerous papers have focused on building predictive models of energy

Figure 8: Optimal threshold policy  $\pi_{\text{non}}$  which does not consider battery degradation. The price state  $\theta$  represents the average price of energy in \$/MW h.

prices, most auto-regressive or latent [Mateo et al., 2005, Aggarwal et al., 2009]. Since the prediction problem is not the main focus of this work, we simply use a Markov model with quantized price data in \$25 intervals. The model is described in detail in Appendix A.1. More accurate models of the energy price, such as ones that include seasonal effects, may lead to significantly greater returns. In addition, to model transmission and battery inefficiencies, we use  $p^i$  that is 5% higher and  $p^o$  that is 5% lower than the spot market price.

The battery degradation process is based on a generic behavior of a Li-ion battery depicted in Fig. 2. The actual degradation will depend on the specific construction of the particular battery [Ramadesigan et al., 2012]. We assume a battery of size 1 MW h; using a larger battery would simply linearly scale the results. We assume a low price of Li-ion batteries at about \$20 per kW h, which translates to a degradation cost of  $c^d = 20000$ . While the current price of Li-ion batteries is considerably higher, it is expected to decrease in the future.

Policies are computed using 10 iterations of Algorithm 1. We first compute a policy  $\pi_{\text{non}}$  that ignores the effects of battery degradation. This is the approach taken by some previous relevant work [Harsha and Dahleh, 2011, Van de Ven et al., 2011]. This policy is depicted in Fig. 9. Second, we compute the policy that considers the degradation  $\pi_{\text{deg}}$  and show it in Fig. 9.

Both policies  $\pi_{\text{non}}$  and  $\pi_{\text{deg}}$  charge the battery to a relatively high level when the energy price is low and discharge it when the energy price is high. However, note that  $\pi_{\text{deg}}$  charges the battery to a lower maximal level, and also is more conservative in discharging the battery completely, unless the price of energy is especially high. This behavior decreases some potential trading revenues but minimizes battery degradation.

Fig. 10 compares the capacity loss of the two policies as a function of the trading day averaged over 10 runs. It is no-

Figure 9: Optimal threshold policy  $\pi_{deg}$  which considers battery degradation. The price state  $\theta$  represents the average price of energy in \$/MWh.

Figure 10: Cost of the capacity loss as a function of the trading day. The final capacity loss corresponds to about 10% of the initial capacity for  $\pi_{non}$ .

Figure 11: Cost of the capacity loss as a function of the trading day. The final capacity loss corresponds to about 10% of the initial capacity for  $\pi_{non}$ .

ticeable that the policy that does not consider ends up leading to battery degradation that is more than double of the policy that is optimized for battery loss. Fig. 11 shows the cumulative gains from the arbitrage less the cost of the lost battery capacity. Note that the policy that does not consider battery degradation ends up with negative returns. That is the cost of the lost capacity is greater than the profits earned from trading.

One note on practicality of using Li-ion batteries for energy storage is in order. Although we assumed a very low cost of Li-ion batteries, it does not appear that the return that we obtained is sufficient to offset the capital invested in the battery. However, when the capacity is already available for a different purpose, such as with an plug-in electric vehicle, energy arbitrage using the battery may be viable [Yudovina and Michailidis, 2014, Peterson et al., 2010].

## 7 CONCLUSION

We described sufficient conditions that guarantee the existence of an optimal threshold policy for energy arbitrage with a degradable battery storage. Threshold policies in this setting are very appealing for several reasons. They are relatively easy to compute and are simple to analyze, interpret, and implement. Our experimental results indicate that it is necessary to consider battery degradation in realistic scenarios since the battery cost is significant in comparison with energy prices. In addition, even when the degradation function does not satisfy the threshold policy assumptions, the proposed algorithm can compute very good solutions that in fact outperform a dynamic programming solution of the discretized problem.

Future work should characterize the structure of policies for problems that violate A3. In addition, the threshold policy property could be combine with a dynamic programming approach instead of simulation optimization. Such approach may lead to more efficient algorithms in terms of computational and sampling complexities.

## Abstract

Standard time series structure learning algorithms assume that the measurement timescale is approximately the same as the timescale of the underlying (causal) system. In many scientific contexts, however, this assumption is violated: the measurement timescale can be substantially slower than the system timescale (so intermediate time series datapoints will be missing). This assumption violation can lead to significant learning errors. In this paper, we provide a novel learning algorithm to extract system-timescale structure from measurement data that undersample the underlying system. We employ multiple algorithmic optimizations that exploit the problem structure in order to achieve computational tractability. The resulting algorithm is highly reliable at extracting system-timescale structure from undersampled data.

## 1 INTRODUCTION

In many domains, measurement speed can be significantly slower than the causal or communication speeds in the underlying system. For example, fMRI experiments typically measure brain activity roughly every two seconds, but the causal and communication connections between neuronal layers operate much faster [8]. Similar observations can be made about systems in ecology, climatology, economics, genomics and proteomics, and cognitive science. Moreover, a discrepancy between the measurement timescale  $\tau_M$  and the system timescale  $\tau_S$  can make a difference: an apparent  $A \rightarrow B$  connection at  $\tau_M$  can be consistent with any possible connection at  $\tau_S$ :  $A \rightarrow B$ ,  $A \leftarrow B$ , or no connection at all. Thus, it is critical that we not simply restrict our attention to learning connections at  $\tau_M$ .

In this paper, we address the problem of learning the causal structure at  $\tau_S$  from measurements taken at a slower sam-

pling rate, also called “undersampled” data.<sup>1</sup> We focus on cases in which the underlying system structure can be represented as a directed graphical model (without simultaneous influence). There has been very little prior work on the problem of structure learning from undersampled time series data, though there have been important prior explorations of learning when the measurement and system timescales diverge, or when causal influences operate on multiple timescales [3, 5, 9]. There are multiple algorithms for learning graphical structure from time series data [6, 7, 11, 14, 15], but they all assume that  $\tau_M$  is at least as fast as  $\tau_S$ . Undersampling was explicitly addressed in [2], but they focused on the “forward” problem of undersampling: given a structure at  $\tau_S$ , what structure will be realized at  $\tau_M$ ? That paper provided some preliminary theorems (used below) to characterize the backward problem, but not a usable algorithm for actually learning structure at  $\tau_S$  from measurements at  $\tau_M$ . In this paper, we introduce such an algorithm: the *Mesochronal Structure Learning* (MSL) algorithm (from Greek μέσω (*mésō*) for “through” and χρόνος (*chrónos*) for “time”) (Section 3); and show that it can often learn significant  $\tau_S$  structure from  $\tau_M$  data (Section 4). First, however, we provide a precise statement of the problem.

## 2 REPRESENTATION AND FORMALISM

We use a compressed graph representation of the underlying system structure.<sup>2</sup> We assume that the system is first-order Markov,<sup>3</sup> and so temporal information can be encoded directly in the graphical edges. This assumption also implies a form of “causal sufficiency”: specifically,

---

<sup>1</sup>Measurements taken at a faster sampling rate pose a computational challenge, but not a distinctive theoretical problem.

<sup>2</sup>This framework is mathematically equivalent to dynamic Bayesian networks [4, 12], so all results could instead be expressed using DBNs [2]. However, compressed graphs provide significant computational advantages for this particular problem domain.

<sup>3</sup>That is, the system-state at  $t$  is independent of all system-states at  $t - n$  for  $n > 1$ , conditional on the system-state at  $t - 1$ .

there cannot be unobserved variables such that nodes in the current timestep (at the causal timescale) are conditionally associated once the variable values at the previous timestep are known. Let  $\mathcal{G}$  be a directed graphical model over variables  $\mathbf{V}$  such that  $V_i \rightarrow V_j$  means  $V_i^{t-1} \rightarrow V_j^t$ , where superscripts denote (relative) time index. We exclude contemporaneous connections because  $\tau_S$  can be arbitrarily fast.  $\mathcal{G}$  can be cyclic, including self-loops, but the underlying system structure will be acyclic when “unrolled” through time. Let  $P(2\mathbf{V})$  be a joint probability distribution over  $\mathbf{V}^t$  and  $\mathbf{V}^{t-1}$ . We connect  $\mathcal{G}$  and  $P(2\mathbf{V})$  through standard assumptions, though adjusted for this setting. Specifically, let  $\text{pa}(V_i)$  denote the parents of  $V_i$  in  $\mathcal{G}$ . The Markov assumption requires:  $V_i^t$  is independent of  $[\mathbf{V}^t \setminus V_i^t] \cup [\mathbf{V}^{t-1} \setminus \text{pa}(V_i)^{t-1}]$  conditional on  $\text{pa}(V_i)^{t-1}$ . The Faithfulness assumption requires that these be the only independencies involving some  $V_i^t$ .

Let  $\{t^0, t^1, \dots, t^k, \dots\}$  denote the timesteps at the system timescale. We say that the system is *sampled at rate  $u$*  when the measured timesteps are  $\{t^0, t^u, \dots, t^{ku}, \dots\}$ . The system timescale is thus “sampled at rate 1.” We focus on cases of undersampling; that is, when  $u > 1$ . Undersampling implies failure to observe intermediate steps on paths between variables, and so the measurement timescale graph  $\mathcal{G}^u$  can be derived from the causal timescale graph  $\mathcal{G}^1$ . More precisely,  $V_i \rightarrow V_j$  in  $\mathcal{G}^u$  iff there is a path of length  $u$  from  $V_i$  to  $V_j$  in  $\mathcal{G}^1$ . Undersampling can also introduce bidirected edges that represent unobserved common causes of variables at time  $t$ . For example, if  $V_i \leftarrow V_c \rightarrow V_j$  in  $\mathcal{G}^1$ , then for all  $u > 1$ ,  $\mathcal{G}^u$  will contain  $V_i \leftrightarrow V_j$  since the unmeasured  $V_c^{t-1}$  is a parent of both  $V_i^t$  and  $V_j^t$ . If the true system structure  $\mathcal{G}^1$  and the sampling rate  $u$  are known, then there are efficient algorithms for computing the resulting (expected) measurement timescale structure  $\mathcal{G}^u$  [2].

The general problem of inferring  $\mathcal{G}^1$  from data sampled at unknown rate  $u$  is computationally intractable at the current time, and so we principally focus on the special case in which  $u = 2$  (though Section 4 shows how to generalize our algorithm to  $u > 2$ ). That is, what can be learned about  $\mathcal{G}^1$  if the input data is a time series in which every other timestep is unobserved? It is straightforward to see that  $\mathcal{G}^2$  can be quite different from  $\mathcal{G}^1$ ; for example, if  $\mathcal{G}^1$  is a directed cycle over three variables (e.g.,  $X \rightarrow Y \rightarrow Z \rightarrow X$ ), then that cycle will have the reverse direction in  $\mathcal{G}^2$ . At the same time,  $\mathcal{G}^2$  and  $\mathcal{G}^1$  cannot be arbitrarily different; for example, if  $V_i \rightarrow V_i$  in  $\mathcal{G}^1$  (i.e.,  $V_i$  has a self-loop), then  $V_i \rightarrow V_i$  in  $\mathcal{G}^2$ . We now provide a multi-step algorithm for recovering as much information as possible.

### 3 MSL ALGORITHM

There are a number of previously identified structural invariants of  $\mathcal{G}^1$  that hold across sampling rates [2], but many of them provide only a coarse characterization of the struc-

ture of  $\mathcal{G}^1$ . We thus must search in a more direct fashion for the  $\mathcal{G}^1$  that could have produced  $\mathcal{G}^2$ . The Mesochronal Structure Learning (MSL) algorithm has two distinct steps. First, one learns  $\mathcal{G}^2$  from data, expert knowledge, or a combination of the two (Section 3.1). There are many different algorithms for learning causal structure at the measurement timescale (i.e.,  $\mathcal{G}^2$ ), and so we focus on the second step: infer the set of  $\mathcal{G}^1$  that could possibly have produced (given undersampling) the learned  $\mathcal{G}^2$  (Section 3.2). The  $\mathcal{G}^2 \rightarrow \mathcal{G}^1$  mapping is one-to-many, and so the MSL algorithm outputs an equivalence class (possibly a singleton) of possible  $\mathcal{G}^1$ . The MSL algorithm is based on a conceptually simple inferential move, but requires significant algorithmic (Section 3.3) and practical (Section 3.4) optimizations in order to be computationally tractable.

#### 3.1 LEARNING $\mathcal{G}^2$

There are many different algorithms for learning the structure of  $\mathcal{G}^2$  from time series data [6, 7, 11, 14, 15], as the measurement and structure timescales are the same. One can also modify structure learning algorithms designed for i.i.d. data (e.g., the well-known PC or GES algorithms [1, 13]) for the special case of time series data in which the causal direction can be inferred from temporal information. We will mostly treat these algorithms as “black boxes” that simply provide an estimated  $\mathcal{G}^2$  for input to the second stage. We cannot completely abstract away from details of those algorithms, however, since errors learning  $\mathcal{G}^2$  structure can result in errors by the overall MSL algorithm. We return to this issue in Section 4, but focus for now on the algorithmically novel aspect of inferring causal timescale structure from estimated measurement timescale structure.

#### 3.2 FROM $\mathcal{G}^2$ TO $\mathcal{G}^1$

Given a known  $\mathcal{G}^1$  and undersample rate  $u$ , [2] provides an efficient method for computing  $\mathcal{G}^u$ . Thus, for an estimated  $\mathcal{H}^2$ , there is an obvious brute-force approach: for all  $\mathcal{G}^1$ , compute the corresponding  $\mathcal{G}^2$  and check if it equals the estimated  $\mathcal{H}^2$ . The problem with this approach is equally obvious: it must survey every possible  $\mathcal{G}^1$ , of which there are  $2^{n^2}$  many. This brute-force strategy could potentially work for 3-, 4-, or even 5-node graphs, but rapidly becomes computationally completely infeasible. We thus pursue a different strategy.

We focus throughout on the case of a single Strongly Connected Component (SCC): a maximal variable set  $\mathbf{S}$  such that there is a path from every  $X \in \mathbf{S}$  to every  $Y \in \mathbf{S}$ . All systems with feedback are composed of SCCs, and so they are the most scientifically interesting systems when working with time series data. When a very weak additional condition holds,<sup>4</sup> then SCC membership is invariant under

<sup>4</sup>Every SCC  $\mathbf{S}$  can be uniquely expressed as the union of a set

Figure 1: A 3-node SCC at undersampling rates 1 and 2, as well as its virtual nodes and their merging options.

undersampling (Corollary 7 in [2]). Thus, we can use  $\mathcal{G}^2$  structure to reliably identify SCC membership in  $\mathcal{G}^1$ , and then do focused search over each SCC separately.

Theorems 4 and 5 in [2] show that, when  $u$  gets very large, such an SCC becomes a *super-clique*: for every pair of nodes  $A, B$  (possibly  $A = B$ ), we have  $A \rightarrow B$ ,  $A \leftarrow B$ , and  $A \leftrightarrow B$ . (The last two do not apply when  $A = B$ .) That is, a super-clique is a maximally dense graph over the SCC. Moreover, these super-cliques are the worst-case for a “backwards” learning algorithm, as a huge number of SCCs imply a super-clique under (significant) undersampling. Thankfully, super-cliques rarely result for smaller undersample rates; typically, more can be learned at  $u = 2$ .

Given an estimated  $\mathcal{H}^2$  that is an SCC, every directed edge corresponds to a path of length 2 in  $\mathcal{G}^1$ . More generally, if we have estimated  $\mathcal{H}^u$  for a known  $u$ , then each edge must correspond to a path of length  $u$  in  $\mathcal{G}^1$ . Thus, we can add  $u - 1$  “virtual” nodes within each edge in  $\mathcal{H}^u$ , where each virtual node refers to some unknown, but actual, node in  $\mathbf{V}$ . The virtual-to-actual node mapping can clearly be many-to-one, as  $u$  can be significantly larger than the size of  $\mathbf{V}$ . This virtual node representation is shown in Figure 1.

The basic structure of this stage of the MSL algorithm is: (1) “identify” each virtual node with an actual node, thereby yielding a candidate  $\mathcal{G}^1$ ; and then (2) check if that candidate actually implies  $\mathcal{H}^u$ . As noted above, there is a computationally efficient algorithm for step (2); the computational challenge is efficiently considering the relevant possible identifications. We focus in the remainder of this section on the case of  $u = 2$  as that is sufficient to reveal significant complexities. The overall algorithm-schema is importantly not limited to that case, however, and we provide a “proof-of-concept” for  $u = 3$  in Section 4.

For  $e$  edges in  $\mathcal{H}^2$ , there are  $n^e$  possible node identifications,<sup>5</sup> each of which results in a candidate  $\mathcal{G}^1$ . Moving directly to complete identifications can require examining an intractable number of  $\mathcal{G}^1$  (e.g., if  $n > 30$  and  $e > 100$ , as below). We thus instead sequentially identify virtual nodes, coupled with a (local) stopping rule based on the concept

of simple loops  $\mathcal{L}_S$ . Let  $\text{gcd}(\mathcal{L}_S)$  be the greatest common divisor of the lengths of those simple loops. The additional condition is that  $\text{gcd}(\mathcal{L}_S) = 1$ .

<sup>5</sup>In general, there are  $n^{e(u-1)}$  possible identifications.

Figure 2: The search tree for 3-node SCC of Figure 1

of a *conflict*, and a lemma (with corollary):<sup>6</sup>

**conflict**  $\mathcal{G}^u$  contains one or more edges that are not in  $\mathcal{H}^u$ .

**Lemma 3.1. Conflict persistence:** *If a virtual node identification results in a conflict, then no further node identifications will eliminate that conflict.*

**Corollary 3.2.** *If  $\mathcal{G}^1$  conflicts with  $\mathcal{H}^u$ , then every super-graph of  $\mathcal{G}^1$  conflicts with  $\mathcal{H}^u$ .*

Thus, if any partial virtual node identification results in a  $\mathcal{G}^1$  whose  $\mathcal{G}^u$  contains an edge not found in  $\mathcal{H}^u$ , then we need not consider any further identifications that build off of that base. This naturally suggests a backtracking search on a search tree through the possible node identifications, as shown in Figure 2. More precisely, the basic MSL algorithm is:

1. Let  $\mathcal{G}$  be the empty graph, and  $\{E_1, \dots, E_e\}$  be an arbitrary ordering of edges in  $\mathcal{H}^u$  (Table in Figure 1)
2. In a depth-first manner over the edges, consider each possible node identification for the virtual nodes added to  $E_i$  and add the corresponding edges to  $\mathcal{G}$
3. Check whether a conflict is found after adding the edges arising from virtual node identification for  $E_i$
4. If a conflict is found, then prune that search tree branch, backtrack by removing the  $E_i$  identification, and try the next possible node identifications for  $E_i$ .

The process is illustrated in Figure 2 for the graph in Figure 1. In the worst case, this algorithm obviously requires checking as many  $\mathcal{G}^1$  as if we simply surveyed all possible simultaneous node identifications. In practice, however, the proactive pruning of branches in the search tree can lead to considerable speed-ups, especially in cases in which  $e$  is relatively large.

This algorithm is correct but not yet complete, as  $\mathcal{G}^1$  can contain edges that do not have manifest in any way in  $\mathcal{G}^2$ . For example, if  $\mathcal{G}^1$  is  $A \rightarrow B$ , then  $\mathcal{G}^2$  is simply the empty

<sup>6</sup>All proofs are provided in Supplementary Materials.

graph over  $A, B$ . In that case, there are no virtual nodes to identify, so the algorithm would correctly but incompletely return the empty graph as the only  $\mathcal{G}^1$  possibility. More generally, especially for relatively dense  $\mathcal{H}^2$ , the algorithm finds a suitable  $\mathcal{G}^1$  prior to reaching the full depth of the search tree (i.e., without identifying all virtual nodes). One response would be to simply force the algorithm to fully traverse the tree, but this can be quite expensive when the branching factor is high (i.e., for dense  $\mathcal{H}^2$ ). Instead, we pursue a different strategy.

If the algorithm finds a suitable  $\mathcal{G}^1$  before reaching a leaf of the search tree, then we know that every graph below it in the tree will be a supergraph of that  $\mathcal{G}^1$  (since virtual node identifications can only add edges, not remove them). Thus, we only need to find all supergraphs of that  $\mathcal{G}^1$  whose  $\mathcal{G}^2 = \mathcal{H}^2$ . That search is greatly aided by Corollary 3.2.

The supergraph construction step first tries to separately add each of the  $n^2$  possible directed edges that are not yet in  $\mathcal{G}^1$ . Each resulting graph that equals  $\mathcal{H}^2$  is added to the output equivalence class. The step then adds, in a depth-first manner, each edge that did not yield a conflict to the other new graphs, and backtracks whenever an edge addition creates a conflict.<sup>7</sup> This step is extremely fast in practice for graphs of reasonable sparsity despite its worst-case factorial behavior. If no edges create a conflict—for example, when  $\mathcal{H}^2$  is a super-clique—then the running time is indeed  $\Theta(n!)$ . In that particular case, however, the equivalence class has been analytically determined to be any size- $n$  SCC with  $\text{gcd}=1$  (see fn. 4) [2, Theorem 4], and so the present algorithm is actually unnecessary.

The full MSL algorithm (including the supergraph step) has the following desirable property:

**Lemma 3.3.** *The MSL algorithm is correct and complete: given  $\mathcal{H}^2$ , it finds all and only  $\mathcal{G}^1$  such that  $\mathcal{G}^2 = \mathcal{H}^2$ .*

Unfortunately, preliminary experiments demonstrated that the algorithm can be very slow (see Figure 4 for a highlight of the problem) and take days even for smaller ( $n = 10$ ) graphs. The order in which virtual nodes are identified can make a significant difference in runtime speed, but even improving those orders is insufficient to yield an algorithm that is usable on large graphs. Instead, we must exploit additional constraints and optimizations.

### 3.3 USING GRAPHICAL CONSTRAINTS

The key intuition underlying the constraints in this section is that some virtual node identifications can be excluded without ever actually constructing-and-testing the corresponding  $\mathcal{G}^1$ . For example, suppose  $A \rightarrow B \rightarrow C$  in  $\mathcal{H}^2$ . In this case,  $\mathcal{G}^1$  must contain, for some  $X, Y$ :  $A \rightarrow X \rightarrow B \rightarrow Y \rightarrow C$ . There is thus a length-2 path from  $X$  to  $Y$  in  $\mathcal{G}^1$ , and so  $\mathcal{G}^2$  will contain  $X \rightarrow Y$ .

<sup>7</sup>See pseudocode in the Supplementary Material.

Figure 3: Edge-pairs for 3-node SCC of Figure 1 and merging options for their virtual nodes: all possible options (raw) and the one that remain after constructing the pairwise data structure (pruned).

Hence, we only need to consider virtual node identifications for  $A \rightarrow B$  and  $B \rightarrow C$  in which the two identifications correspond to nodes with a directed edge between them in  $\mathcal{H}^2$ . More generally, virtual node identifications can analytically constrain one another in ways that can be exploited in this algorithm.

Recall that the complexity of the MSL algorithm for  $u = 2$  is approximately  $n^e$ , where  $e$  is the number of edges in  $\mathcal{H}^2$ . By identifying pairs of virtual nodes (that analytically constrain one another), we can potentially achieve a large reduction in the exponent in practice, since we will have to consider many fewer branches.

Two different types of structures in  $\mathcal{H}^2$  guide the pairwise identifications. First, consider all *forks* in  $\mathcal{H}^2$ : pairs of edges  $X \leftarrow H \rightarrow Y$ , where possibly  $X = H$  or  $Y = H$  (if there is a self-loop plus another edge). If the two virtual nodes refer to the same actual node, then  $X$  and  $Y$  will have a common cause in the previous (causal) timestep, and so there will be a bidirected edge between them.<sup>8</sup> Thus, if there is no bidirected edge between  $X$  and  $Y$  in  $\mathcal{H}^2$ , then the two virtual nodes cannot identify to the same node. Hence, we only need to consider  $n^2 - n$  possible identifications for that pair of virtual nodes.

The other relevant structure is the two-edge chain described at the start of this section, where the only pairwise virtual node identifications that are considered are those for which there is a corresponding edge in  $\mathcal{H}^2$ .

In practice, the algorithm converts some elements of the edge list  $\{E_1, \dots, E_e\}$  into edge-pairs by first selecting (without replacement) all forks in  $\mathcal{H}^2$ , then selecting all remaining two-edge directed paths. The remaining edges have the usual  $n$  possible virtual node identifications.

Figure 3 shows a search space for the graph from Figure 1, and demonstrates the computational advantage of considering pairwise identifications, as the number of possible identifications is significantly reduced.

<sup>8</sup>Note that the converse does not hold:  $X \leftrightarrow Y$  in  $\mathcal{H}^2$  does not imply that the virtual nodes correspond to the same actual node.

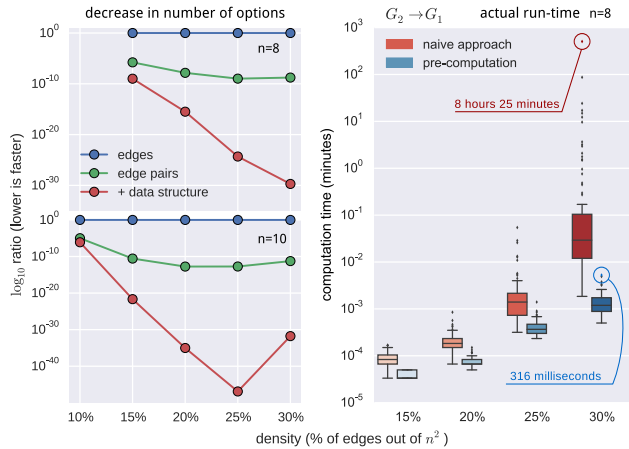

Figure 4: Comparison of the search-space size (left) and computation time (right) between the naive backtracking and our approaches.

In general, let  $\{m_1, \dots, m_l\}$  be the sets of virtual node identifications for each of the edges or edge-pairs derived from the preceding procedure. The computational complexity of using some edge-pairs is simply  $\prod_i \text{len}(m_i)$ , where  $\text{len}$  is the number of possible identifications for that particular edge or edge-pair. Thus, the computational advantage, expressed as a log-ratio, of using (some) edge-pairs is:  $\log r = \sum_i \log \text{len}(m_i) - e \log n$ . This advantage is plotted in Figure 4, which shows (on log-scale) the average log-ratio for 100 random 8- and 10-node SCCs. The practical advantage of edge-pairs is potentially even greater, as Figure 4 does not account for active pruning of the search tree.

### 3.4 PRECOMPUTATION AND OPTIMIZATIONS

The use of edge-pairs provides significant speed-up in the MSL algorithm (as seen in Figure 4), but its worst-case complexity still makes it difficult to use the algorithm for  $n > 10$ . Moreover, around 10% of the graphs took many days to compute, and did not exhibit any noticeable structural difference in  $\mathcal{H}^2$  that could be used to predict computation time.<sup>9</sup> The core problem is that much of the search tree eventually gets pruned, but structural features of  $\mathcal{H}^2$  do not support predictions about *which* parts will be pruned. If we can instead prune conflicting options prior to the traversal of the solution space, then we can potentially further reduce the search time.

The key algorithmic move is to expand the “analytic conflict checking” beyond just particular edge-pairs, to also pre-computing conflicts between multiple edge-pairs. In the extreme, there can be a (seemingly) possible virtual

<sup>9</sup>Even with random restarts to account for order differences in edge-pair selection, the algorithm still behaved similarly to the “only single edge” version.

node identification that conflicts with *every* possible identification for some other edge or edge-pair, in which case the first identification can simply be removed from consideration. Moreover, this precomputation is independent of the evaluation order of the virtual node identifications, since a conflict between identifications  $m_i$  and  $m_j$  does not depend on the particular values  $i$  and  $j$ . This pruning thus also reduces the need for random restarts to be robust against evaluation order effects.

The MSL algorithm was therefore expanded to include significant pre-computation to further prune the initial search tree. Specifically, for each pair of edge-pairs, the algorithm constructs a  $\mathcal{G}^1$  for every possible identification of both edge-pairs. If the resulting  $\mathcal{G}^1$  results in a conflict with  $\mathcal{H}^2$ , then we remove that pair of complex identifications from the search tree. This precomputation can considerably prune the search tree, perhaps even yielding (as in Figure 3) a search “tree” with only one branch. There is a cost because the resulting data structure can be complex: it contains not only the reduced set of (complex) identifications for each edge-pair, but also splits those options into subsets depending on the particular (complex) identification used in the previous level of the search tree. This more complex structure is required because some possible identifications will be incompatible with only a subset of the identifications at the previous level, but we want to avoid checking them during the algorithm flow (since we already checked in the precomputation).

Further algorithmic speed-ups can be achieved by intelligently ordering the virtual node identifications (i.e., the levels of the search tree). In particular, the MSL algorithm will run fastest when search tree levels with significant breadth—that is, virtual nodes or node-pairs for which there are many possible identifications—are pushed further down in the search tree. If this is done, then pruning operations will remove more branches. In addition, each search tree node is also a “conflict check” point, and this ordering of search tree levels minimizes the number of search tree nodes, *even if no branches are ever pruned*. The benefits of intelligent identification ordering can be substantial for deep trees with small numbers of possible identifications for most of the edge-pairs.

These two optimizations—precomputation and intelligent search tree ordering—yield substantial benefits. We again computed the potential reduction in computation for randomly generated graphs (using the equation from Section 3.3). The “+ data structure” line on the left-hand plot in Figure 4 shows that the more optimized approach can achieve over 40 orders of magnitude reduction in the number of conflict checks.

Each conflict check requires the algorithm to add edges to the constructed  $\mathcal{G}^1$ , compute  $\mathcal{G}^2$ , check for conflicts with  $\mathcal{H}^2$ , and then remove the just-added edges in case of a con-

flict. These steps are computationally expensive, and so we can achieve further performance gains if we can analytically determine whether a complex identification creates a conflict before starting these operations. These checks are not precomputed, but rather are performed in an online fashion based on the constraints in the following lemmas (where  $ch_{\mathcal{G}}(A)$  and  $pa_{\mathcal{G}}(A)$  denote the children and parents of  $A$  in  $\mathcal{G}$ , respectively):

**Lemma 3.4.** *A virtual node  $V$  in  $S \xrightarrow{V} E$  cannot be identified with node  $X$  if any of the following holds:*

1.  $\exists W \in ch_{\mathcal{G}^1}(S) \setminus X$  s.t.  $\nexists W \leftrightarrow X \in \mathcal{H}^2$
2.  $\exists W \in ch_{\mathcal{G}^1}(X) \setminus E$  s.t.  $\nexists W \leftrightarrow E \in \mathcal{H}^2$
3.  $\exists W \in ch_{\mathcal{G}^1}(X)$  s.t.  $\nexists S \rightarrow W \in \mathcal{H}^2$
4.  $\exists W \in ch_{\mathcal{G}^1}(E)$  s.t.  $\nexists X \rightarrow W \in \mathcal{H}^2$
5.  $\exists W \in pa_{\mathcal{G}^1}(S)$  s.t.  $\nexists W \rightarrow X \in \mathcal{H}^2$
6.  $\exists W \in pa_{\mathcal{G}^1}(X)$  s.t.  $\nexists W \rightarrow E \in \mathcal{H}^2$

**Lemma 3.5.** *A virtual node pair  $V_1, V_2$  for a fork  $E_1 \xleftarrow{V_1} S \xrightarrow{V_2} E_2$  cannot be identified with nodes  $X_1, X_2$  if any of the following holds:*

1.  $V_1$  in  $E_1 \xleftarrow{V_1} S$  cannot be identified with  $X_1$
2.  $V_2$  in  $S \xrightarrow{V_2} E_2$  cannot be identified with  $X_2$
3.  $V_1 \equiv E_2 \wedge V_2 \notin pa_{\mathcal{H}^2}(E_1)$
4.  $V_2 \equiv E_1 \wedge V_1 \notin pa_{\mathcal{H}^2}(E_2)$
5.  $S \equiv V_2 \wedge V_1 \neq V_2 \wedge V_1 \neq E_2$  and  $\nexists E_2 \leftrightarrow V_1 \in \mathcal{H}^2$
6.  $S \equiv V_1 \wedge (V_1 \equiv V_2 \vee V_2 \equiv E_2)$  and  $\nexists E_1 \leftrightarrow E_2 \in \mathcal{H}^2$
7.  $S \equiv V_1 \wedge (V_1 \equiv V_2 \vee V_2 \equiv E_2)$  and  $\nexists E_1 \leftrightarrow E_2 \in \mathcal{H}^2$
8.  $S \equiv V_2 \wedge (V_1 \equiv V_2 \vee V_1 \equiv E_1)$  and  $\nexists E_1 \leftrightarrow E_2 \in \mathcal{H}^2$
9.  $V_1 \equiv V_2$  and  $\nexists E_1 \leftrightarrow E_2 \in \mathcal{H}^2$

**Lemma 3.6.** *A virtual node pair  $V_1, V_2$  for two-edge sequence  $S \xrightarrow{V_1} M \xrightarrow{V_2} E$  cannot be identified with  $X_1, X_2$  if any of the following holds:*

1.  $V_1$  in  $S \xrightarrow{V_1} M$  cannot be merged to  $X_1$
2.  $V_2$  in  $M \xrightarrow{V_2} E$  cannot be merged to  $X_2$
3.  $V_1 \equiv V_2 \wedge (M \notin pa_{\mathcal{H}^2}(M) \vee V_1 \notin pa_{\mathcal{H}^2}(V_2) \vee S \notin pa_{\mathcal{H}^2}(E))$

As noted above, we apply these constraints in an online manner in order to prune branches of the search tree without having to add edges and check for conflicts. The resulting algorithm exhibits substantial reductions in runtime, enabling us to examine the MSL algorithm’s behavior for  $\mathcal{G}^1$  ranging up to 35 nodes, as shown in the simulation testing described in the next section.

## 4 TESTING AND VALIDATION

As we argued earlier, SCCs represent the scientifically most interesting situations, precisely because they are ones in which feedback loops present a challenging learning task. In addition, although connections between SCCs are

undoubtedly of interest, the formal results of [2] imply that we can reliably treat the SCCs relatively independently. We thus focus on single-SCC graphs in our synthetic data studies. Any SCC can provably be decomposed into a single simple loop with “ears” (i.e., sequences that branch off from, then return to, that simple loop) that build on top of one another. We thus use a simple ear decomposition skeleton to generate SCCs for our simulations.

**SCC generation procedure:** For  $n$  nodes, first generate a single simple loop that passes through all nodes. Without loss of generality, we can assume that this ring graph passes through the nodes in sequential order. There are  $n(n-1)$  possible edges that can be added to this ring graph, including self-loops for each node. We sample uniformly from those possible edges until the required density—i.e., the fraction of the  $n^2$  possible edges that are actual—is achieved.<sup>10</sup> We use overall density rather than average node degree to measure graph complexity because density is normalized by the number of possible edges, so we can (approximately) match graph complexity across different values of  $n$ .

We previously reported the theoretical maximum conflict checks for 8- and 10-node graphs for different versions of the MSL algorithm. We also report (in Figure 4) a comparison of the actual run times. We randomly generated 100 8-node graphs for each density in  $\{15\%, 20\%, 25\%, 30\%\}$  and ran both the naive approach (virtual node identification for each edge separately) and the precomputation approach that takes advantage of edge-pairs and pairwise constraints. The box and whisker plot shows the distribution of the individual run-times expressed in minutes. Not only does the median execution time for 8-node graphs improve by an order of magnitude, but the naive approach also generates considerably more outliers that take much longer to compute. The run-times for the hardest graphs (which provide an empirical estimate on the run-time upper bound) are five orders of magnitude longer for the naive approach.<sup>11</sup>

### 4.1 EQUIVALENCE CLASS SIZES

We earlier noted that, when  $\mathcal{H}^2$  is a super-clique (i.e., every possible edge between each pair of nodes), then there will typically be a large number of  $\mathcal{G}^1$  consistent with that super-clique. That is, the equivalence class will be quite large. One question is about the sizes of the equivalence classes when  $\mathcal{H}^2$  is *not* a super-clique. If the equivalence class is sufficiently small, then expert knowledge or further studies may be a tractable way to reach a unique solution.

To better explore the equivalence class sizes, we generated

<sup>10</sup>Note that the bare ring graph has a density of  $1/n$ .

<sup>11</sup>This may be less relevant in practice, except for the unlucky 10% of researchers who happen to deal with the hardest graphs. Nonetheless, this difference is substantial, and shows the importance of the algorithmic optimizations.

Figure 5: Equivalence class size distribution among 100 randomly generated 6-node SCCs at a given density and examples of 6-node SCCs for each.

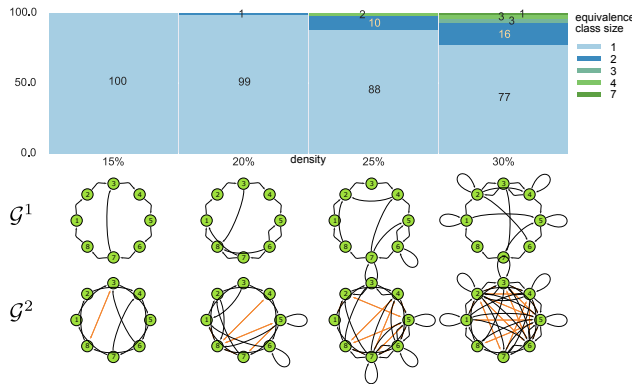

Figure 6: Equivalence class size distribution for 100 randomly generated 8-node SCCs at a given density and examples of 8-node SCCs for each of the densities.

100 random 6-node SCCs (using the above procedure) for each density from 20% to 60% in 5% increments, then analytically computed  $\mathcal{G}^2$  and passed that to the optimized MSL algorithm.  $n = 6$  is sufficiently large that brute-force inference is infeasible, but the graphs are still tractable for the optimized MSL algorithm even at high densities. This is a particular worry since the complexity of the search grows exponentially with the number of edges in  $\mathcal{G}^2$ . Figure 5 shows the sizes of the equivalence classes for the graphs at different densities.

Some of the most notable findings from Figure 5 are *i*) for densities up to 35%, the overwhelming majority of the equivalence classes are singletons; *ii*) for densities above 50%, the equivalence classes often grow to quite large sizes; however, *iii*) those  $\mathcal{G}^2$  graphs are incredibly dense, and so unsurprisingly are difficult to analyze tractably. The MSL algorithm complexity depends exponentially on the number of edges in  $\mathcal{G}^2$ , and so increasing  $n$  for a fixed density rapidly leads to significant computational barriers. Figure 5 suggests that densities above 35% will frequently lead to very large equivalence classes, and so we focus on lower

Figure 7: Distribution of run-time (wall clock) and sizes of equivalence classes across densities of 10-node graphs.

Figure 8: Example 10-node graphs at different densities and their corresponding  $\mathcal{G}^2$ s.

densities for larger  $n$ .

In particular, we performed the same analysis (including run-times) for 8-node (Figure 6) and 10-node graphs (Figure 7). The results for 6-node graphs largely generalize. MSL is a fast and practical algorithm for these graph sizes, as demonstrated by the wall-clock run-time measurements summarized in Figure 7. Note that these are quite challenging graphs, as shown in Figure 8. 10-node graphs with 30% density can have more than 65 edges in  $\mathcal{G}^2$ , and so the naive approach would have to consider  $10^{65}$  virtual node identifications.

The MSL algorithm is also computationally tractable for significantly larger  $n$ . For 15-node graphs, it can readily learn  $\mathcal{G}^1$  structures up to 25% density, though outlier cases can take multiple days to compute. Figure 9 shows results for 100s of random SCCs with density of 10% for node sizes from 15 to 35. This density actually corresponds to quite challenging learning tasks. For example, a 35-node graph with 10% density can have nearly 400 edges in  $\mathcal{G}^2$ . Despite these large numbers of edges, the MSL algorithm rarely takes longer than an hour, even for 35-node graphs.

## 4.2 GENERALITY OF THE MSL ALGORITHM

The MSL algorithm is actually an algorithm-schema that can be generalized to different known  $u$ , though its complexity rapidly increases. We performed a “proof-of-concept” of MSL for  $u = 3$  with 100 random 6-node graphs. In this variant, each  $\mathcal{G}^3$  edge has *two* virtual nodes

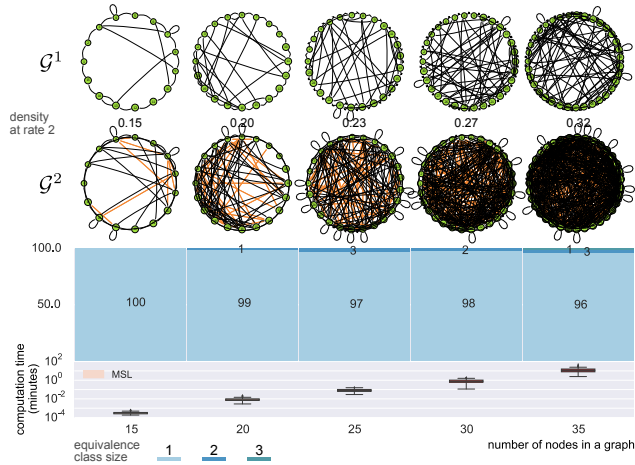

Figure 9: Graphs with 15, 20, 25, 30, and 35 nodes at the density of 10%, their corresponding  $\mathcal{G}^2$  and equivalence class size distribution as well as the running time summarizing the computation of 100 random SCCs per node size.

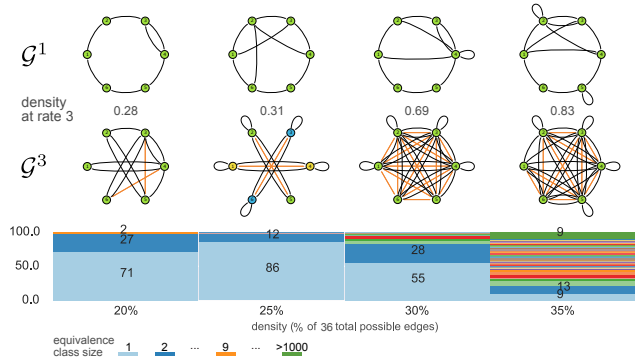

Figure 10: Applying the MSL algorithm to the  $\mathcal{G}^3 \rightarrow \mathcal{G}^1$  problem: results for 100 random 6 node graphs per density. Example  $\mathcal{G}^1$  and their corresponding  $\mathcal{G}^3$  are shown for reference.

that must be identified. Figure 10 shows the equivalence classes for  $u = 3$ . Interestingly, we obtain similar results with singleton equivalence classes dominating at low densities, but a rapid increase in the proportion of larger equivalence classes.

### 4.3 VIOLATIONS OF THE RATE ASSUMPTIONS

If we know that  $u = 2$ , then MSL can successfully recover all graphs in the equivalence class. That assumption could easily be violated, however, as one might (for example) believe  $u = 2$  when actually  $u = 3$ . Figure 11 shows results when MSL assuming  $u = 2$  was applied to the  $\mathcal{G}^3$  for 100 6-node graphs. Importantly, for  $\mathcal{G}^1$  densities up to 30%, the MSL (assuming  $u = 2$ ) algorithm fails to find a solution; that is, there is no  $\mathcal{G}^1$  whose  $\mathcal{G}^2$  matches the given graph (which is actually a  $\mathcal{G}^3$ ). One can thus infer that a key algorithmic assumption has likely been violated. Un-

Figure 11: Equivalence class size distribution for 100 randomly generated 6-node SCCs at a given density after the  $\mathcal{G}^2 \rightarrow \mathcal{G}^1$  MSL search when the input graph to the algorithm was in fact  $\mathcal{G}^3$

fortunately, the testability of the  $u = 2$  assumption does not seem to extend to higher densities, which further suggests focusing our attention on  $\mathcal{G}^1$  with no more than 30% density.

### 4.4 FROM UNDERSAMPLED DATA TO $\mathcal{G}^1$

The above results show that the nonparametric  $\mathcal{G}^2 \rightarrow \mathcal{G}^1$  component of the MSL algorithm is correct and computationally efficient, enabling us to learn equivalence classes for SCCs with densities up to 30%. For finite sample data, we need to incorporate a stable, reliable algorithm to learn the  $\mathcal{H}^2$  structure. As noted earlier, there are multiple learning algorithms for this task (i.e., learning measurement-timescale structure), though they must allow for the possibility of bidirected edges to encode correlation between variables at the same time. We have used both a restricted version of the PC algorithm [11] and direct optimization of log likelihood in a structural vector autoregressive (SVAR) model [10]. In our experiments, we found that SVAR optimization provided more accurate and stable solutions, likely because of errors in conditional independence tests used in the modified PC algorithm. The best choice for learning  $\mathcal{H}^2$  structure is an open research question. In the following, we only show results for the SVAR procedure.

We generated 100 random 8-node SCCs for each density in  $\{15\%, 20\%, 25\%, 30\%\}$ . These graphs are complex and interesting, but also are computationally tractable for the full MSL algorithm. For each random graph, we generated a random transition matrix by sampling weights for the non-zero elements of the adjacency matrix, and controlling system stability (by keeping the maximal eigenvalue at or below 1). This transition matrix was then used for a vector auto-regressive (VAR) model [10] with noise (standard deviation of 1) to generate data. Every other data sample was removed (to undersample at rate 2), and the resulting data was provided to the SVAR optimization to yield a candidate  $\mathcal{H}^2$ . The MSL algorithm was then applied to this  $\mathcal{H}^2$  to obtain an equivalence class of  $\mathcal{G}^1$  that can be compared to ground truth in terms of two error-types: **omission error**: the number of omitted edges normalized to the total number of edges in the ground truth; **omission error**: number of edges not present in the ground truth nor-

Figure 12: The MSL estimation and search errors on synthetic data undersampled at rate 2.

malized to the total possible edges minus the number of those present in the ground truth. Figure 12 shows the results of these simulations. We also plot the estimation errors of the SVAR (on the undersampled data) to understand the dependence of MSL estimation errors on the estimation errors for  $\mathcal{H}^2$ . Interestingly, applying the MSL algorithm does not significantly increase the error rates over those produced by the SVAR estimation.

In some cases, SVAR estimation errors result in an  $\mathcal{H}^2$  for which there are *no* possible  $\mathcal{G}^1$ .<sup>12</sup> For the simulations described in Figure 12, we deal with these cases by *i*) modifying MSL to accept (at the final step) those solutions that produce an undersampled graph that has the same directed edges as the estimated  $\mathcal{H}^2$ ; *ii*) restarting the simulation if a solution is not found. The former improves performance because bidirected edges often contain a weaker signal and are prone to mis-estimation, while the latter is to ensure comparability of results.

We have also modified the MSL algorithm so that, in these cases, it sequentially considers all neighbors of each  $\mathcal{H}^2$  in the Hamming cube constructed on the length  $n^2 + \binom{n}{2}$  binary string that represent directed and bidirected edges. If MSL finds a solution for one of these neighbors of  $\mathcal{H}^2$ , then we return it and compare to the ground truth as before.

We repeated our 8-node experiment successively checking neighborhoods from 1-5 steps away from the learned  $\mathcal{H}^2$ . In the worst case, this can require over  $5.2 \times 10^7$  additional MSL runs (for  $n = 8$ ), so there can be a significant increase in run-time. The results are summarized in Figure 13. The increased complexity did not allow us to proceed to the 30% density. This time, however, we did not have to restart a single computation at densities or 15% and 20% with only few rejected at 25%.

<sup>12</sup>Because the  $\mathcal{G}^1 \rightarrow \mathcal{G}^2$  map is many-to-one, there are multiple such  $\mathcal{H}^2$ . In fact, the set of “reachable”  $\mathcal{H}^2$  is at most  $1/2 \binom{n}{2}$  of the theoretically possible graphs.

Figure 13: The estimation and search errors on synthetic data undersampled at rate 2 when the  $\mathcal{G}^2$  Hamming cube neighborhood search is used.

## 5 CONCLUSIONS

Many scientific contexts depend on learning the structure of a system at some timescale that is faster than the measurement timescale. Standard structure learning algorithms can extract the measurement-level structure, but that structure can be quite different from the structure of the underlying system. The apparent structure given undersampled data is not immediately informative about the actual structure at the causal or system timescale. We have presented the first computationally efficient algorithm for learning the equivalence class of system-timescale structures that could have produced the measurement-timescale data. The algorithm can, in theory, be applied for arbitrary known undersample rates  $u$ , though it is computationally intractable for  $u > 3$ . Nonetheless, we have shown that the MSL algorithm exhibits promising performance for  $u = 2$ , including reliably learning underlying structure over large node-sets. The MSL algorithm also provides a novel tool for investigating the sizes of those equivalence classes. We showed that small amounts of undersampling typically do not destroy much information, as the equivalence class for many  $\mathcal{G}^2$  was a singleton. Undersampling greatly increases the complexity of structure learning, but does not make it impossible or infeasible.

## Abstract

Updating inference in response to new evidence is a fundamental challenge in artificial intelligence. Many real problems require large probabilistic graphical models, containing millions of interdependent variables. For such large models, jointly updating the most likely (i.e., MAP) configuration of the variables each time new evidence is encountered can be infeasible, even if inference is tractable. In this paper, we introduce *budgeted online collective inference*, in which the MAP configuration of a graphical model is updated efficiently by revising the assignments to a subset of the variables while holding others fixed. The goal is to selectively update certain variables without sacrificing quality with respect to full inference. To formalize the consequences of partially updating inference, we introduce the concept of *inference regret*. We derive inference regret bounds for a class of graphical models with strongly-convex free energies. These theoretical insights, combined with a thorough analysis of the optimization solver, motivate new approximate methods for efficiently updating the variable assignments under a budget constraint. In experiments, we demonstrate that our algorithms can reduce inference time by 65% with accuracy comparable to full inference.

## 1 INTRODUCTION

A key challenge of many artificial intelligence problems is that the evidence grows and changes over time, requiring updates to inferences. Every time a user rates a new movie on Netflix, posts a status update on Twitter, or adds a connection on LinkedIn, inferences about preferences, events, or relationships must be updated. When constructing a knowledge base, each newly acquired document prompts the system to update inferences over related facts and re-

solve mentions to their canonical entities. Problems such as these benefit from collective (i.e., joint) reasoning, but incorporating new evidence into a collective model is particularly challenging. New evidence can affect multiple predictions, so updating inference typically involves recomputing all predictions in an expensive global optimization. Even when a full inference update is tractable—which, using the best known methods, can be linear in the number of factors—it may still be impractical. For example, updating a knowledge graph with millions of facts can take hours (Pujara *et al.*, 2013), thereby requiring some compromise, either in the form of a deferment strategy or approximate update. In this work, we consider the task of efficiently updating the *maximum-a-posteriori* (MAP) state of a probabilistic graphical model, conditioned on evolving evidence. We refer to this problem as *online collective inference*.

In online collective inference, a single graphical model, describing the conditional distribution of a set of random variables with fixed dependency structure, is given. Over a series of epochs, the true assignments (i.e., labels) of certain variables are revealed, introducing new evidence with which we can update the assignments to the remaining unknowns. We constrain the problem by adding a budget, such that only a fixed percentage of variables can be updated in each epoch, necessitating some approximation to full inference. This constraint distinguishes our work from the vast body of literature on belief revision (e.g., Gärdenfors, 1992), Bayesian network updates (e.g., Buntine, 1991; Friedman and Goldszmidt, 1997; Li *et al.*, 2006), models for dynamic (Murphy, 2002) or sequential (Fine *et al.*, 1998) data, and adaptive inference (e.g., Acar *et al.*, 2008), which deal with exact updates to inference. We analyze budgeted online collective inference from both the theoretical and algorithmic perspectives, addressing two fundamental questions: How do we choose which variables to update? How “close” is the approximate inference update to the full inference update?

To formalize the latter question, we introduce the concept of *inference regret*. Informally, inference regret measures the amount of change induced by fixing (i.e., condi-

tioning on) certain variables in the inference optimization. We specifically analyze the inference regret of continuous graphical models whose inference objective is strongly convex. One instantiation of this class of models is hinge-loss Markov random fields (Bach *et al.*, 2013), which have been broadly applied and demonstrate state-of-the-art performance in many applications. Using the duality between strong convexity and stability, we upper-bound the inference regret. Our bound is proportional to the distance from the fixed variables to the optimal values of the full inference problem, scaled by a function of several model-specific properties. We use our inference regret bound to quantify the effect of approximate inference updates in response to new evidence (in this case, revealed labels). The bound highlights two terms affecting the regret: the accuracy of the original predictions and the amount that the original predictions change. This latter insight informs our approximate update methods with a simple intuition: fix the predictions that are unlikely to change in a full inference update.

To efficiently determine which variables are least likely to change, we turn to the optimization algorithm used during inference. The alternating direction method of multipliers (ADMM) (Boyd *et al.*, 2011) is a popular convex optimization technique that offers convergence guarantees while remaining highly scalable. We analyze the optimization process and catalog the features that allow us to determine which variables will change the most. Using these features to generate a score for each variable, we establish a ranking capturing the priority of including the variables in subsequent inference. Since the variable scores are produced using the state of the optimization algorithm, our method does not incur computational overhead. By ranking variables, we approximate full inference with an arbitrary budget and support an anytime online inference algorithm.

We evaluate the theoretical guarantees and approximation quality in experiments on a synthetic collective classification task and a real-world collaborative filtering task. These experiments validate our theoretical bounds by measuring the stability and quality of the MAP state as new evidence is revealed. To connect theoretical guarantees with empirical performance, we compare approximate inference to computing the full MAP state at each epoch of graph evolution. We find that our approach to online inference allows a substantial decrease in computation and running time while maintaining the quality of the inferred values. In our experiments, our methods consistently reduce running time by 65% to 70%, show diminishing inference regret, and, in some cases, have lower test error than full inference.

## 1.1 RELATED WORK

Updating inference is a longstanding problem in artificial intelligence. The classic problem of belief revision (Gardenfors, 1992) considers revising and updating a set of

propositional beliefs using a set of axiomatic guarantees to consistency. Diverse research has considered updating the parameters or structure of Bayesian networks in response to evolving evidence (Buntine, 1991; Friedman and Goldszmidt, 1997; Li *et al.*, 2006, e.g.). Finally, many models address dynamic or sequential data, such as Dynamic Bayesian Networks (Murphy, 2002) and hierarchical hidden Markov models (Fine *et al.*, 1998). Our work addresses the specific problem of approximating full MAP inference in the online setting when a model is given and provides formal guarantees for the approximation quality.

Making efficient updates to the full inference result is the goal of a related area of research, *adaptive inference*. Adaptive marginal inference (Acar *et al.*, 2008; Sümer *et al.*, 2011) can update the marginal probability of a query in  $O(2^{\text{tw}(G)} \log n)$ -time, where  $\text{tw}(G)$  is the tree-width of the graph and  $n$  is the number of variables. Adaptive MAP inference (Acar *et al.*, 2009) can update the MAP state in  $O(m + m \log(n/m))$ -time, where  $m$  is the number of variables that change their state. Though the algorithm does not need to know  $m$  beforehand, a model change could result in changes to all  $n$  variables’ states, with cost equivalent to exact inference. These adaptive inference techniques do not currently support partial updates to the MAP state or accommodate budgeted updates.

Approximate adaptive inference was considered by Nath and Domingos (2010), who proposed *expanding frontier belief propagation* (EFBP), a belief propagation algorithm that only updates messages in the vicinity of the updated potentials. They showed that the beliefs generated by EFBP lower- and upper-bound the beliefs of full BP, thereby providing guarantees on the quality of the approximation. This result differs from ours in that it bounds the individual marginal probabilities, whereas we bound the  $L^1$  distance between MAP states. Unlike our approximation algorithm, EFBP does not explicitly limit computation and, in the worst case, may need to update all variables to achieve convergence conditions.

The quantity we call inference regret is conceptually similar to *collective stability* (London *et al.*, 2013a). Collective stability measures the amount of change in the output of a structured predictor induced by local perturbations of the evidence. London *et al.* (2013a, 2014) analyzed the collective stability of marginal inference in discrete graphical models, concluding that (approximate) inference with a strongly convex entropy function enhances stability. Our technical approach is similar, in that we also leverage strong convexity. However, the types of perturbations we consider—fixing target variables—are not covered by their analysis. Stability analysis is closely related to *sensitivity analysis*. Since the terms are used interchangeably in the literature, we distinguish them as follows: sensitivity analysis examines *if* and *when* the solution changes; stability analysis examines *how much* it changes by. Laskey

analyzed the sensitivity of queries (which can be used for marginal inference) in Bayesian networks. Chan and Darwiche studied the sensitivity of queries (2005) and MAP inference (2006) in Markov networks. Their 2005 paper also analyzes the stability of queries.

## 2 PRELIMINARIES

The theory and methods introduced in this paper apply to any continuous-valued MRF with a strongly convex MAP inference objective function. One case of particular interest is a class of graphical models known as *hinge-loss Markov random fields* (HL-MRFs) (Bach et al., 2013). An HL-MRF is a continuous-valued Markov network in which the potentials are hinge functions of the variables. Our choice of HL-MRFs comes from technical considerations: we reason about the strength of convexity of the inference objective, and *maximum a posteriori* (MAP) inference in HL-MRFs can be strongly convex. However, from a practical standpoint, HL-MRFs have many benefits. MAP inference in HL-MRFs is provably and empirically efficient, in theory growing  $O(N^3)$  with the number of potentials,  $N$ , but in practice often converging in  $O(N)$  time. Models built using HL-MRFs achieve state-of-the-art performance for a variety of applications (Bach et al., 2013; Beltagy et al., 2014; Chen et al., 2014; Fakhraei et al., 2014; London et al., 2013b; Ramesh et al., 2014). Finally, HL-MRFs are easily specified through *probabilistic soft logic* (PSL) (Bach et al., 2015), a probabilistic programming language with a first-order logical syntax.

To better understand HL-MRFs and PSL, consider a model for collective classification of network data, in which the goal is to assign labels to nodes, conditioned on some local evidence and network structure. Let  $G \triangleq (\mathcal{V}, \mathcal{E})$  denote an undirected graph on  $n \triangleq |\mathcal{V}|$  nodes. Each node  $i \in \mathcal{V}$  is associated with a set of local observations,  $X_i$ , and an unknown label,  $L_i$ . (In some settings, a subset of the labels are revealed.) In general, the observations and labels can be real-valued; but for simplicity of exposition, let us assume that each observation is binary-valued, and each label is categorical. The following logical rules define a PSL program for a typical collective classification model:

$$w_{x,\ell} : \text{FEATURE}(N, x) \Rightarrow \text{LABEL}(N, \ell)$$

$$w_{e,\ell} : \text{EDGE}(N_1, N_2) \wedge \text{LABEL}(N_1, \ell) \Rightarrow \text{LABEL}(N_2, \ell)$$

Variables  $N$ ,  $N_1$  and  $N_2$  denote nodes;  $x$  indexes a local feature; and  $\ell$  denotes a label. The rules are weighted by  $w_{x,\ell}$  and  $w_{e,\ell}$  respectively. Given  $G$  and  $\mathbf{X} \triangleq (X_1, \dots, X_n)$  (and possibly some subset of the labels), the rules are *grounded out* for all possible instantiations of the predicates. The groundings involving unknown variables—in this case, groundings of the LABEL predicate—are represented by  $[0, 1]$ -valued variables,  $\mathbf{Y} \triangleq (Y_{i,\ell})_{i,\ell}$ . Using a relaxation of the MAX-SAT problem to continuous do-

main (Globerson and Jaakkola, 2007), each grounding is converted to a convex hinge function of the form

$$f(\mathbf{X}, \mathbf{Y}) = (\max\{0, \varphi(\mathbf{X}, \mathbf{Y})\})^q,$$

where  $\varphi$  is a linear function of  $(\mathbf{X}, \mathbf{Y})$ , and  $q \in \{1, 2\}$  is an exponent that is set *a priori* for the given rule. Each hinge function becomes a potential in an HL-MRF.

The resulting HL-MRF enables probabilistic inference over the set of PSL rules. Fix a set of  $r$  PSL rules, with corresponding weights  $\mathbf{w} \triangleq (w_1, \dots, w_r)$ . For the  $i^{\text{th}}$  rule, let  $\mathcal{G}(i)$  denote its set of groundings in  $G$ , and let  $f_j^i$  denote the  $j^{\text{th}}$  grounding of its associated hinge function. To compactly express the weighted sum of grounded rules, we let

$$\mathbf{f}(\mathbf{X}, \mathbf{Y}) \triangleq \left[ \sum_{j=1}^{|\mathcal{G}(1)|} f_j^1(\mathbf{X}, \mathbf{Y}), \dots, \sum_{j=1}^{|\mathcal{G}(r)|} f_j^r(\mathbf{X}, \mathbf{Y}) \right]^\top$$

denote the aggregate of the grounded hinge functions. We can thus write the weighted sum of groundings as  $\mathbf{w} \cdot \mathbf{f}(\mathbf{X}, \mathbf{Y})$ . This inner product defines a distribution over  $(\mathbf{Y} | \mathbf{X})$  with probability density function  $p(\mathbf{Y} = \mathbf{y} | \mathbf{X} = \mathbf{x}; \mathbf{w}) \propto \exp(-\mathbf{w} \cdot \mathbf{f}(\mathbf{X}, \mathbf{Y}))$ . The maximizer of the density function (alternately, the minimizer of  $-\mathbf{w} \cdot \mathbf{f}(\mathbf{X}, \mathbf{Y})$ ) is the MAP state. The values of  $\mathbf{Y}$  in the MAP state can be interpreted as confidences. Additionally, we can define a prior distribution over each  $\mathbf{Y}$ . In this case, we will use an  $L^2$ , or Gaussian, prior. This can be accomplished using the rule  $w_{p,\ell} : \neg \text{LABEL}(N, \ell)$ , with a squared hinge (i.e.,  $q = 2$ ). Let us assume, without loss of generality, that each prior rule has weight  $w_{p,\ell} = w_p/2$ , for some  $w_p > 0$ . Thus, the corresponding hinge function for grounding LABEL( $i, \ell$ ) is simply  $(Y_{i,\ell})^2$ ; the aggregate features for the prior are  $\|\mathbf{Y}\|_2^2$ . So as to simplify notation, let  $\dot{\mathbf{w}} \triangleq (\mathbf{w}, w_p)$  and define an *energy* function,

$$E(\mathbf{y} | \mathbf{x}; \dot{\mathbf{w}}) \triangleq \mathbf{w} \cdot \mathbf{f}(\mathbf{x}, \mathbf{y}) + \frac{w_p}{2} \|\mathbf{y}\|_2^2. \quad (1)$$

The resulting probability density function is

$$p(\mathbf{Y} = \mathbf{y} | \mathbf{X} = \mathbf{x}; \dot{\mathbf{w}}) \propto \exp(-E(\mathbf{y} | \mathbf{x}; \dot{\mathbf{w}})).$$

MAP inference, henceforth denoted  $h(\mathbf{x}; \dot{\mathbf{w}})$ , is given by

$$h(\mathbf{x}; \dot{\mathbf{w}}) = \arg \min_{\mathbf{y}} E(\mathbf{y} | \mathbf{x}; \dot{\mathbf{w}}).$$

## 3 INFERENCE REGRET

The notion of *regret* has often been used to measure the loss incurred by an online learning algorithm relative to the optimal hypothesis. We extend this concept to online inference. Fix a model. Suppose we are given evidence,  $\mathbf{X} = \mathbf{x}$ , from which we make a prediction,  $\mathbf{Y} = \mathbf{y}$ , using MAP inference. Then, some subset of the unknowns are

revealed. Conditioning on the new evidence, we have two choices: we can recompute the MAP state of the remaining variables, using full inference; or, we can fix some of the previous predictions, and only update a certain subset of the variables. To understand the consequences of fixing our previous predictions we must answer a basic question: how much have the old predictions changed?

We formalize the above question in the following concept.

**Definition 1.** Fix a budget  $m \geq 1$ . For some subset  $\mathcal{S} \subseteq \{1, \dots, n\}$ , such that its complement  $\bar{\mathcal{S}} \triangleq \{1, \dots, n\} \setminus \mathcal{S}$ , has size  $|\bar{\mathcal{S}}| = m$ , let  $\mathbf{Y}_{\mathcal{S}}$  denote the corresponding subset of the variables, and let  $\mathbf{Y}_{\bar{\mathcal{S}}}$  denote its complement. Assume there is an operator  $\Gamma$  that concatenates  $\mathbf{Y}_{\mathcal{S}}$  and  $\mathbf{Y}_{\bar{\mathcal{S}}}$  in the correct order. Fix a model,  $\hat{\mathbf{w}}$ , and an observation,  $\mathbf{X} = \mathbf{x}$ . Further, fix an assignment,  $\mathbf{Y}_{\mathcal{S}} = \mathbf{y}_{\mathcal{S}}$ , and let

$$h(\mathbf{x}, \mathbf{y}_{\mathcal{S}}; \hat{\mathbf{w}}) \triangleq \Gamma \left( \mathbf{y}_{\mathcal{S}}, \arg \min_{\mathbf{y}_{\bar{\mathcal{S}}}} E(\Gamma(\mathbf{y}_{\mathcal{S}}, \mathbf{y}_{\bar{\mathcal{S}}}) | \mathbf{x}; \hat{\mathbf{w}}) \right)$$

denote the new MAP configuration for  $\mathbf{Y}_{\bar{\mathcal{S}}}$  after fixing  $\mathbf{Y}_{\mathcal{S}}$  to  $\mathbf{y}_{\mathcal{S}}$ . We define the *inference regret* for  $(\mathbf{x}, \mathbf{y}_{\mathcal{S}}; \hat{\mathbf{w}})$  as

$$\mathfrak{R}_n(\mathbf{x}, \mathbf{y}_{\mathcal{S}}; \hat{\mathbf{w}}) \triangleq \frac{1}{n} \|h(\mathbf{x}; \hat{\mathbf{w}}) - h(\mathbf{x}, \mathbf{y}_{\mathcal{S}}; \hat{\mathbf{w}})\|_1. \quad (2)$$

In general, the inference regret can be as high as 1 for variables in  $[0, 1]$ . For example, consider network classification model in which probability mass is only assigned to configurations where all nodes have the same label. Fixing a variable corresponding to a single node label in this setting is tantamount to fixing the label for all nodes. In the presence of strong evidence for a different label, incorrectly fixing a single variable results in incorrectly inferring all variables.

In online inference, regret can come from two sources. First, there is the regret of not updating the MAP state given new evidence (in this case, revealed labels). If this regret is low, it may not be worthwhile to update inference, which can be useful in situations where updating inference is expensive (such as updating predicted attributes for all users in a social network). The second type of regret is from using an approximate inference update in which only certain variables are updated, while the rest are kept fixed to their previous values. We describe several such approximations in Section 4. In practice, one may have both types of regret, caused by approximate updates in response to new evidence. Note that the inference regret obeys the triangle inequality, so one can upper-bound the compound regret of multiple updates using the regret of each update.

### 3.1 REGRET BOUNDS FOR STRONGLY CONVEX INFERENCE

A convenient property of the  $L^2$  prior is that it is *strongly convex*, by which we mean the following.

**Definition 2.** Let  $\Omega \subseteq \mathbb{R}^n$  denote a convex set. A differentiable function,  $f : \Omega \rightarrow \mathbb{R}$ , is  $\kappa$ -strongly convex (w.r.t. the 2-norm) if, for all  $\boldsymbol{\omega}, \boldsymbol{\omega}' \in \Omega$ ,

$$\frac{\kappa}{2} \|\boldsymbol{\omega} - \boldsymbol{\omega}'\|_2^2 + \langle \nabla f(\boldsymbol{\omega}), \boldsymbol{\omega}' - \boldsymbol{\omega} \rangle \leq f(\boldsymbol{\omega}') - f(\boldsymbol{\omega}). \quad (3)$$

Strong convexity has a well-known duality with stability, which we will use in our theoretical analysis.

The function  $f(\boldsymbol{\omega}) \triangleq \frac{1}{2} \|\boldsymbol{\omega}\|_2^2$  is 1-strongly convex. Therefore, the prior,  $\frac{w_p}{2} \|\mathbf{y}\|_2^2$ , is at least  $w_p$ -strongly convex. We also have that the aggregated hinge functions,  $\mathbf{f}(\mathbf{x}, \mathbf{y})$ , are convex functions of  $\mathbf{Y}$ . Thus, it is easily verified that the energy,  $E(\mathbf{y} | \mathbf{x}; \hat{\mathbf{w}})$ , is at least a  $w_p$ -strongly convex function of  $\mathbf{y}$ . This yields the following upper bound on the inference regret.

**Proposition 1.** Fix a model with weights  $\hat{\mathbf{w}}$ . Assume there exists a constant  $B \in [0, \infty)$  such that, for any  $\mathbf{x}$ , and any  $\mathbf{y}, \mathbf{y}'$  that differ at coordinate  $i$ ,

$$\|\mathbf{f}(\mathbf{x}, \mathbf{y}) - \mathbf{f}(\mathbf{x}, \mathbf{y}')\|_2 \leq B |y_i - y'_i|. \quad (4)$$

Then, for any observations  $\mathbf{x}$ , any budget  $m \geq 1$ , any subset  $\mathcal{S} \subseteq \{1, \dots, n\} : |\bar{\mathcal{S}}| = m$ , and any assignments  $\mathbf{y}_{\mathcal{S}}$ , with  $\hat{\mathbf{y}} \triangleq h(\mathbf{x}; \hat{\mathbf{w}})$ , we have that

$$\mathfrak{R}_n(\mathbf{x}, \mathbf{y}_{\mathcal{S}}; \hat{\mathbf{w}}) \leq \sqrt{\frac{1}{n} \left( \frac{3}{2} + \frac{B \|\mathbf{w}\|_2}{w_p} \right) \|\mathbf{y}_{\mathcal{S}} - \hat{\mathbf{y}}_{\mathcal{S}}\|_1}.$$

**Proof** Due to space restrictions, the proof is somewhat abbreviated. Let  $\hat{\mathbf{y}} \triangleq h(\mathbf{x}; \hat{\mathbf{w}})$  denote the original MAP configuration, i.e., the minimizer of  $E(\cdot | \mathbf{x}; \hat{\mathbf{w}})$ . Let  $\hat{\mathbf{y}}' \triangleq h(\mathbf{x}, \mathbf{y}_{\mathcal{S}}; \hat{\mathbf{w}})$  denote the updated MAP state after conditioning, and note that  $\hat{\mathbf{y}}'_{\bar{\mathcal{S}}}$  is the minimizer of  $E(\Gamma(\mathbf{y}_{\mathcal{S}}, \cdot) | \mathbf{x}; \hat{\mathbf{w}})$ . Since  $\hat{\mathbf{y}}_{\mathcal{S}}$  may be different from  $\mathbf{y}_{\mathcal{S}}$ , we have that  $\hat{\mathbf{y}}$  may not be in the domain of  $E(\Gamma(\mathbf{y}_{\mathcal{S}}, \cdot) | \mathbf{x}; \hat{\mathbf{w}})$ . We therefore define a vector  $\tilde{\mathbf{y}} \in [0, 1]^n$  that is in the domain, and has minimal Hamming distance to  $\hat{\mathbf{y}}$ . Let  $\tilde{y}_i \triangleq y_i$  for all  $i \in \mathcal{S}$ , and  $\tilde{y}_j \triangleq \hat{y}_j$  for all  $j \notin \mathcal{S}$ . It can be shown that

$$\|\hat{\mathbf{y}}' - \hat{\mathbf{y}}\|_2^2 = \|\hat{\mathbf{y}}' - \tilde{\mathbf{y}}\|_2^2 + \|\tilde{\mathbf{y}} - \hat{\mathbf{y}}\|_2^2. \quad (5)$$

Further, since the domain of each  $Y_i$  is  $[0, 1]$ ,

$$\|\tilde{\mathbf{y}} - \hat{\mathbf{y}}\|_2^2 = \|\mathbf{y}_{\mathcal{S}} - \hat{\mathbf{y}}_{\mathcal{S}}\|_2^2 \leq \|\mathbf{y}_{\mathcal{S}} - \hat{\mathbf{y}}_{\mathcal{S}}\|_1. \quad (6)$$

Therefore, combining Equations 5 and 6,

$$\begin{aligned} \|\hat{\mathbf{y}} - \hat{\mathbf{y}}'\|_2^2 &= \frac{1}{2} \left( \|\hat{\mathbf{y}} - \hat{\mathbf{y}}'\|_2^2 + \|\hat{\mathbf{y}}' - \hat{\mathbf{y}}\|_2^2 \right) \\ &\leq \frac{1}{2} \left( \|\hat{\mathbf{y}} - \hat{\mathbf{y}}'\|_2^2 + \|\hat{\mathbf{y}}' - \tilde{\mathbf{y}}\|_2^2 + \|\mathbf{y}_{\mathcal{S}} - \hat{\mathbf{y}}_{\mathcal{S}}\|_1 \right). \end{aligned} \quad (7)$$

For any  $\kappa$ -strongly convex function,  $\varphi : \Omega \rightarrow \mathbb{R}$ , where  $\hat{\boldsymbol{\omega}} = \arg \min_{\boldsymbol{\omega} \in \Omega} \varphi(\boldsymbol{\omega})$  is the minimizer, then  $\forall \boldsymbol{\omega}' \in \Omega$ ,

$$\frac{1}{2} \|\hat{\boldsymbol{\omega}} - \boldsymbol{\omega}'\|_2^2 \leq \frac{1}{\kappa} (\varphi(\boldsymbol{\omega}') - \varphi(\hat{\boldsymbol{\omega}})). \quad (8)$$

Applying this identity to the first two terms in Equation 7, since  $E(\cdot | \mathbf{x}; \hat{\mathbf{w}})$  is  $w_p$ -strongly convex, we have that

$$\begin{aligned} & \frac{1}{2} \|\hat{\mathbf{y}} - \hat{\mathbf{y}}'\|_2^2 + \frac{1}{2} \|\hat{\mathbf{y}}' - \tilde{\mathbf{y}}\|_2^2 \\ & \leq \frac{1}{w_p} (E(\tilde{\mathbf{y}} | \mathbf{x}; \hat{\mathbf{w}}) - E(\hat{\mathbf{y}} | \mathbf{x}; \hat{\mathbf{w}})). \end{aligned} \quad (9)$$

The  $E(\hat{\mathbf{y}}' | \mathbf{x}; \hat{\mathbf{w}})$  terms cancel out. Expanding  $E(\cdot | \mathbf{x}; \hat{\mathbf{w}})$ ,

$$\begin{aligned} & E(\tilde{\mathbf{y}} | \mathbf{x}; \hat{\mathbf{w}}) - E(\hat{\mathbf{y}} | \mathbf{x}; \hat{\mathbf{w}}) \\ & = \mathbf{w} \cdot (\mathbf{f}(\mathbf{x}, \tilde{\mathbf{y}}) - \mathbf{f}(\mathbf{x}, \hat{\mathbf{y}})) + \frac{w_p}{2} (\|\tilde{\mathbf{y}}\|_2^2 - \|\hat{\mathbf{y}}\|_2^2) \\ & \leq \|\mathbf{w}\|_2 \|\mathbf{f}(\mathbf{x}, \tilde{\mathbf{y}}) - \mathbf{f}(\mathbf{x}, \hat{\mathbf{y}})\|_2 + w_p \|\mathbf{y}_S - \hat{\mathbf{y}}_S\|_1. \end{aligned} \quad (10)$$

The last inequality uses Cauchy-Schwarz and

$$\|\tilde{\mathbf{y}}\|_2^2 - \|\hat{\mathbf{y}}\|_2^2 \leq 2 \|\mathbf{y}_S - \hat{\mathbf{y}}_S\|_1.$$

Finally, we construct a series of vectors, indexed by each  $i \in \mathcal{S}$ , that transform  $\hat{\mathbf{y}}$  into  $\tilde{\mathbf{y}}$ , one coordinate at a time. For the following, let  $\mathcal{S}(j)$  denote the  $j^{\text{th}}$  element in  $\mathcal{S}$ . First, let  $\tilde{\mathbf{y}}^{(0)} \triangleq \hat{\mathbf{y}}$ ; then, for  $j = 1, \dots, m$ , let  $\tilde{\mathbf{y}}^{(j)}$  be equal to  $\tilde{\mathbf{y}}^{(j-1)}$  with index  $\mathcal{S}(j)$  replaced with value  $\tilde{y}_{\mathcal{S}(j)}$ . Note that  $\tilde{\mathbf{y}}^{(m)} = \tilde{\mathbf{y}}$ . Using the triangle inequality, one can show that

$$\begin{aligned} \|\mathbf{f}(\mathbf{x}, \tilde{\mathbf{y}}) - \mathbf{f}(\mathbf{x}, \hat{\mathbf{y}})\|_2 & \leq \sum_{j=1}^m \left\| \mathbf{f}(\mathbf{x}, \tilde{\mathbf{y}}^{(j)}) - \mathbf{f}(\mathbf{x}, \tilde{\mathbf{y}}^{(j-1)}) \right\|_2 \\ & \leq B \|\mathbf{y}_S - \hat{\mathbf{y}}_S\|_1. \end{aligned} \quad (11)$$

The last inequality uses Equation 4, since  $\tilde{\mathbf{y}}^{(j)}$  and  $\tilde{\mathbf{y}}^{(j-1)}$  differ at a single coordinate,  $\mathcal{S}(j)$ . Combining Equations 7 and 9 to 11, we have that

$$\|\hat{\mathbf{y}} - \hat{\mathbf{y}}'\|_2^2 \leq \left( \frac{3}{2} + \frac{B \|\mathbf{w}\|_2}{w_p} \right) \|\mathbf{y}_S - \hat{\mathbf{y}}_S\|_1.$$

We then multiply both sides of the inequality by  $1/n$  and take the square root. Using  $\frac{1}{n} \|\hat{\mathbf{y}} - \hat{\mathbf{y}}'\|_1 \leq \frac{1}{\sqrt{n}} \|\hat{\mathbf{y}} - \hat{\mathbf{y}}'\|_2$  finishes the proof. ■

Proposition 1 states that the inference regret is proportional to the  $L^1$  distance from  $\mathbf{y}_S$  to  $\hat{\mathbf{y}}_S$ , multiplied by a model-dependent quantity,  $O\left(\frac{B \|\mathbf{w}\|_2}{n w_p}\right)$ . Later in this section, we discuss how to bound the features' Lipschitz constant,  $B$ , demonstrating that it is typically a small constant (e.g., 1). Thus, assuming  $\|\mathbf{w}\|_2$  is bounded from above, and the weight on the prior,  $w_p$ , is bounded from below, the model-dependent term should decrease with the number of variables,  $n$ . For variables bounded in  $[0, 1]$ , the Hamming distance upper-bounds the  $L^1$  distance. Using this identity, a pessimistic upper bound for the distance term is  $\|\mathbf{y}_S - \hat{\mathbf{y}}_S\|_1 \leq |\mathcal{S}|$ . In this case, the regret is proportional to  $O(\sqrt{|\mathcal{S}|/n})$ ; i.e., the square root of the fraction of the

variables that are fixed. While this yields a uniform, analytic upper bound, we gain more insight by considering the specific contexts.

For instance, suppose  $\mathbf{y}_S$  is a set of labels that has been revealed. Then  $\mathfrak{R}_n(\mathbf{x}, \mathbf{y}_S; \hat{\mathbf{w}})$  is the regret of not updating inference conditioned on new evidence, and  $\|\mathbf{y}_S - \hat{\mathbf{y}}_S\|_1$  is the  $L^1$  error of the original predictions w.r.t. the true labels. Now, suppose  $\mathbf{y}_S$  is a set of labels that are fixed from a previous round of inference. Then  $\mathfrak{R}_n(\mathbf{x}, \mathbf{y}_S; \hat{\mathbf{w}})$  is the regret of an approximate inference update, and  $\|\mathbf{y}_S - \hat{\mathbf{y}}_S\|_1$  is the  $L^1$  distance between the old predictions and the new predictions in the full inference update. Thus, to minimize this regret, we must fix values that are already close to what we think they will be in the updated MAP state. This criteria motivates our approximate update methods in Section 4.

### 3.1.1 The Lipschitz Constant of the Features

In this section, we give some intuition on how to bound the Lipschitz constant of the features,  $B$ , by considering a specific example. Suppose the model has a single rule:  $X \Rightarrow Y$ . The corresponding hinge is  $f(X, Y) \triangleq \max\{0, X - Y\}$ . Using the fact that  $|\max\{0, a\} - \max\{0, b\}| \leq |a - b|$ , one can show that  $\|\mathbf{f}(\mathbf{x}, \mathbf{y}) - \mathbf{f}(\mathbf{x}, \mathbf{y}')\|_2 \leq |y_i - y'_i| \leq 1$ , so  $B = 1$ .

PSL models typically use rules of this nature, with varying arity (i.e., diadic, triadic, etc.). In general,  $B$  should grow linearly with the number of groundings involving any single variable (i.e., the maximum degree of the factor graph). The number of groundings generated by each rule depends on its arity and the data. For instance, the relational rule in Section 2 will ground out once for each edge and each label; if there are 2 labels, and the maximum degree is bounded by a constant,  $\Delta$ , then the number of groundings generated by this rule for any single variable is at most  $2\Delta$ . Thus, in many practical models,  $B$  will be a small constant.

## 4 BUDGETED ONLINE INFERENCE

The bounds presented in Section 3.1 suggest that online collective inference under budget constraints is close to the full inference update when one is able to successfully choose and fix variables whose inferred values will have little or no change. We refer to the complementary process of selecting which variables to infer as *activation*. In practice, designing an activation algorithm is difficult. The optimization problem required to choose a set of variables, each with heterogeneous regret and optimization cost, that do not exceed an optimization budget is an instance of the NP-hard knapsack problem. Given the intrinsic intractability of selecting an optimal set of variables, we present two algorithms that employ theoretical insights from the previous section and show promise in empirical experiments.

## 4.1 BACKGROUND: ADMM OPTIMIZATION

To develop activation algorithms, we turn to the optimization technique used to determine the MAP state in HL-MRFs. [Bach et al. \(2012\)](#) have shown that applying consensus optimization using the Alternating Direction Method of Multipliers (ADMM) ([Boyd et al., 2011](#)) provides scalable inference for HL-MRFs. For clearer exposition, we express the inference in terms of the set of ground rules,  $\mathcal{G}$  and rewrite the energy function in Section 2 as:

$$E(\mathbf{y} | \mathbf{x}; \dot{\mathbf{w}}) \triangleq \sum_{g \in \mathcal{G}} w_g f_g(\mathbf{x}, \mathbf{y}) + \frac{w_p}{2} \|\mathbf{y}\|_2^2$$

Here,  $w_g f_g(\mathbf{x}, \mathbf{y})$  is a weighted potential corresponding to a single ground rule. ADMM substitutes the global optimization problem with local optimizations for each potential using independent copies of the variables. For each grounding  $g \in \mathcal{G}$ , let  $\mathbf{y}_g$  denote the variables involved in  $g$  and  $\tilde{\mathbf{y}}_g$  indicate the local copy of those variables. To reconcile the local optimizations, ADMM introduces a constraint that local variable copies agree with the global “consensus” for each variable  $i$  involved in the grounding; that is,  $\mathbf{y}_g[i] = \tilde{\mathbf{y}}_g[i]$ . This constraint is transformed into an augmented Lagrangian with penalty parameter  $\rho > 0$  and Lagrange multipliers  $\alpha_g$ :

$$\min_{\tilde{\mathbf{y}}_g} w_g f_g(\mathbf{x}, \tilde{\mathbf{y}}_g) + \frac{\rho}{2} \left\| \tilde{\mathbf{y}}_g - \mathbf{y}_g + \frac{1}{\rho} \alpha_g \right\|^2 \quad (12)$$

ADMM iteratively alternates optimizing the local potentials, then updating the consensus estimates and associated Lagrange multipliers for each variable, as such:

$$\begin{aligned} \tilde{\mathbf{y}}_g &\leftarrow \operatorname{argmin}_{\tilde{\mathbf{y}}_g} w_g f_g(\mathbf{x}, \tilde{\mathbf{y}}_g) + \frac{\rho}{2} \left\| \tilde{\mathbf{y}}_g - \mathbf{y}_g + \frac{1}{\rho} \alpha_g \right\|^2; \\ \mathbf{y}[i] &\leftarrow \operatorname{mean}_g(\tilde{\mathbf{y}}_g[i]); \quad \alpha_g[i] \leftarrow \alpha_g[i] + \rho(\tilde{\mathbf{y}}_g[i] - \mathbf{y}_g[i]). \end{aligned}$$

A key element of this optimization is the interplay of two components: the weighted potential corresponding to a grounding and the Lagrangian penalty for deviating from the consensus estimate. As optimization proceeds, the Lagrange multipliers are updated to increase the penalty for deviating from the global consensus. At convergence, a balance exists between the two components, reconciling the local minimizer and the aggregate of global potentials.

## 4.2 ADMM FEATURES

The goal of activation is to determine which variables are most likely to change in a future inference. From the analysis in the previous section, we can identify several basic elements for each variable in the model that serve as features for an activation algorithm. For each variable, we have its value at convergence ( $\mathbf{y}[i]$ ), and for each grounding  $g$ , the weight ( $w_g$ ), the value of the potential ( $f_g(\mathbf{x}, \tilde{\mathbf{y}}_g)$ ), and the

Lagrange multipliers ( $\alpha_g[i]$ ) measuring the aggregate deviation from consensus. We discuss each of these features to motivate their importance in an activation algorithm.

The value of a variable at convergence can provide a useful signal in certain situations, where a model has clear semantics. For example, the formulation of HL-MRFs often lends itself to a logical interpretation with binary outcomes, as in the cases of collective classification of attributes that are either present or absent. In this setting, assignments in the vicinity of 0.5 represent uncertainty, and therefore provide good candidates for activation. Unfortunately, this feature is not universal. Many successful HL-MRF models adopt semantics that use continuous values to model continuous variables, such as pixel intensity in image completion tasks or Likert-scale ratings in recommender systems. In this case, the semantics of the variable’s consensus value may provide an ambiguous signal for activation.

The weighted potentials of each variable contribute directly to the probability of the MAP configuration. Since the log-probability is proportional to the *negated* energy,  $-E$ , high weights and high potential values decrease the probability of the assignment. Intuitively, activating those variables that contribute high weighted potentials provides the best mechanism for approaching the full inference MAP state. A complication to this approach is that each weighted potential can depend on many variables. However, the potential value is a scalar quantity and there is no general mechanism to apportion the loss to the contributing variables.

In contrast, the Lagrange multipliers provide a granular perspective on each variable’s effect on Equation 12. For each variable copy ( $\tilde{\mathbf{y}}_g$ ), the Lagrange multiplier aggregates the difference between the copy and the global consensus across iterations. High Lagrange multipliers signal discord between the local minimizer and the global minimizer, indicating volatility. Activating variables with high Lagrange multipliers can resolve this discord in future inference using updated evidence. However, updated evidence may also resolve the disagreement between the local and global minimum, obviating an update to the variable.

## 4.3 ACTIVATION ALGORITHMS

Building on our analysis of ADMM optimization, we introduce two activation algorithms for online collective inference, “agnostic activation” and “relational activation”. Both algorithms produce a ranking that prioritizes each variable for inclusion in inference. The key difference between these algorithms is whether new or updated evidence is an input to the algorithm. Agnostic activation scores variables concurrently with inference, based on their susceptibility to change in future inferences. In contrast, relational activation runs prior to inference, with scores based primarily on relationships between variables and updated evidence in the factor graph.

Each approach has different advantages. Agnostic activation scores variables during inference, providing a performance advantage since the scoring algorithm does not delay a future run of inference. However, this technique has a slower response to new evidence since scoring occurs before such evidence is available. Relational activation can respond to newly-arrived evidence and choose variables related to new evidence, but this requires delaying scoring which can add a computational overhead to inference.

Both activation algorithms output a ranking of the variables, which requires a scoring function. We introduce two scoring functions that use the ADMM features described Section 4.2. Our first scoring function, VALUE, captures the intuition that uncertain variables are valuable activation candidates using the function  $1 - |0.5 - \mathbf{y}[i]|$ , where  $\mathbf{y}[i]$  is the consensus value for variable  $i$ . The second scoring function, WLM, uses both the weight and Lagrange multipliers of each potential. For each variable, we define a set of weighted Lagrange multiplier magnitudes,  $\mathcal{A}_w[i] \triangleq \{|w_g \alpha_g[i]|\}$ . To obtain a single scalar score, we take the maximum value of  $\mathcal{A}_w[i]$ .

The agnostic activation algorithm simply ranks each variable by their score from a scoring function, irrespective of the new evidence. The RELATIONAL algorithm combines the score with information about the new evidence. Using the existing ground model, RELATIONAL first identifies all ground potentials dependent on the new evidence. Then, using these ground potentials as a seed set, the algorithm performs a breadth-first search of the factor graph adding the variables involved in each factor it encounters to the frontier. Traversing the factor graph can quickly identify many candidate variables, so we prioritize variables in the frontier by  $\frac{S}{2^d}$  where  $S$  is the score assigned by a scoring function and  $d$  is the minimum distance between the variable and an element of the seed set in the factor graph.

The ranking output by either agnostic or relational activation lets us prioritize which variables to activate. Given a budget for the number or percentage of variables to infer, we activate a corresponding number of variables from the ranking. The remaining variables are constrained to their previously inferred values. We selectively ground the model, including only those rules that involve an activated variable. Following inference on the ground model, we use the updated optimization state to produce new scores.

When an inactive variable is treated as a constant, it does not have any associated Lagrange multipliers, and lacks features for the WLM scoring function. Therefore, instead of treating fixed variables as constants, we introduce them as constrained variables in the optimization. This allows us to generate features by capturing the discrepancy between a variable’s constrained value and the value of its local copies in groundings involving activated variables.

Our implementation of the agnostic activation algorithm is

extremely efficient; all necessary features are byproducts of the inference optimization. Once scores are computed and the activated atoms are selected, the optimization state can be discarded to avoid additional resource commitments. In relational activation, scoring is similarly efficient, but there is an additional overhead of preserving the ground model to allow fast traversal of the factor graph. By selectively grounding the model, we replace queries that scan the entire database, potentially many times, with precise queries that exploit indices for faster performance. Finally, selectively activating atoms produces an optimization objective with fewer terms, allowing quicker optimization.

## 5 EVALUATION

To better understand the regret bounds and approximation algorithms for online inference, we perform an empirical evaluation on two online collective inference settings. The first setting is a synthetic online collective classification task where the data generator allows us to modulate the importance of collective dependencies and control the amount of noise. The second evaluation setting is a real-world collaborative filtering task, where user preferences are incrementally revealed and the outputs of a recommender system are correspondingly updated.

In both evaluation settings, we measure regret relative to full inference and inference error relative to ground truth. The results demonstrate that empirical regret follows the form of our regret bounds. We also evaluate the approximation algorithms presented in Section 4.3, to investigate whether features from the optimization algorithm can reliably determine which variables to activate. The results show that our approximation algorithms are able to reduce running time by upwards of 65%, with inference regret relative to full inference.

All experiments are implemented using the open-source PSL framework and our code is available on GitHub<sup>1</sup>.

### 5.1 ONLINE COLLECTIVE CLASSIFICATION

Our evaluation data simulates a collective classification problem of inferring labels for users in a social network as new evidence is incrementally revealed. Each user is assigned one of two mutually exclusive labels. Some portion of the users have observed labels, while the labels of the remaining users are inferred. At each epoch, the label of one more user is revealed, so the model must update the inferred labels for the remaining users with unknown labels.

For each user, we generate local and collective features correlated with the user’s label. Local features are generated for each user and label by drawing from a Gaussian distribution conditioned on the label, such that the mean is  $t$  for

<sup>1</sup><https://github.com/puuju/uai15-boci-code>

Figure 1: Inference regret, w.r.t. full inference, of fixing the original MAP state (i.e., no updates) in the HIGHLOCAL, HIGHCOLLECTIVE and BALANCED data models.

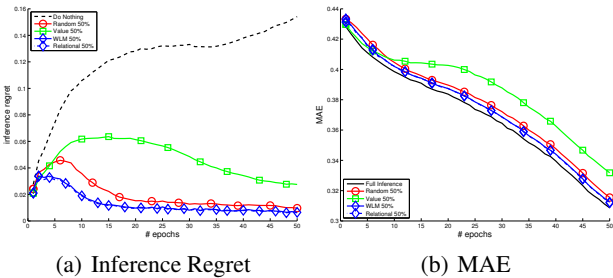

Figure 2: Inference regret (w.r.t. full inference) and MAE (w.r.t. ground truth) using various approximation algorithms, with 50% activation, in the COMPLEX data model.

the true label and  $1 - t$  for the incorrect label. The collective features are links between users, generated randomly using the following process: for each pair of users with the same label, a link is generated with probability  $p$ ; for each pair of users with different labels, a link is created with probability  $1 - p$ . We refer to  $p$  as the affinity of the network.

We model the data using the PSL rules described in Section 2 and learn weights for the model. Varying the parameters of the data generator impacts inference in the learned model, since the learned weights are proportional to the discriminative power of their associated rules. For example, varying the distance between the conditional means of the local features controls the importance of the local evidence rule: when the means are far apart, local evidence has high discriminative power; however, when the means are close, local evidence does not provide much signal.

We introduce three data models: HIGHLOCAL ( $t = .8, p = .75$ ), HIGHCOLLECTIVE ( $t = .55, p = .9$ ), and BALANCED ( $t = .7, p = .75$ ). We combine these three conditions in a fourth data model, COMPLEX, which samples uniformly from the three settings on a per-user basis resulting in heterogeneous evidence. For each condition, we generate 10 trials, each with a training social network used to learn the model parameters and a separate test social network to evaluate inference quality. Both the training and test graph have 100 users, with 60 observed user la-

els in the training graph and 10 observed user labels in the test graph. To infer user attributes, we use the simple collective classification model introduced in Section 2. We simulate the process of online inference by creating a sequence of observations consisting of 50 epochs. In each epoch, the true label of a previously unknown user is revealed, resulting in 60 observed user labels at the end of the sequence. For each trial, we generate 10 such sequences from a breadth-first traversal of the network from a randomly chosen user, resulting in a total of 5000 inferences.

In the first experiment, shown in Figure 1 we measure the inference regret of fixing variables to the initial MAP state (i.e., not updating inference) over 50 epochs, comparing the HIGHLOCAL, HIGHCOLLECTIVE and BALANCED conditions. Our theoretical analysis predicts that the worst-case regret grows at rate  $O(1/\sqrt{\text{epoch}})$ . The experimental results exhibit the same growth rate, which is very pronounced for the HIGHCOLLECTIVE data model, where variables are strongly interdependent, and less so for HIGHLOCAL, where variables are largely independent. The key insight is that the collective nature of the inference task determines the regret of online updates.

In the second experiment (Figure 2), we compare the approximate scoring algorithms with a budget of 50% of unknowns to running full inference on the COMPLEX network. We measure significance across 100 total sequences using a paired  $t$ -test with rejection threshold .05. For inference regret, we compare against the static algorithm, DONOTHING, which does not update the MAP state, and a random baseline, RANDOM, that fixes an arbitrary subset of 50% of the variables. We compare these to three approximation algorithms described in Section 4.1: VALUE, which uses the value assigned to the variable; WLM, which uses the maximum of the weighted Lagrange multipliers; and RELATIONAL, which uses WLM to prioritize exploration.

All methods exhibit low regret relative to full inference, contrasting the high regret of the static algorithm, although VALUE exhibits somewhat higher regret. The WLM and RELATIONAL methods have significantly lower regret relative to RANDOM, in 98% and 100% of epochs, respectively. We also compare the mean average error (MAE), with respect to ground truth, of using full inference vs. the approximations. This illustrates that the approximation algorithms remain competitive with full inference, although VALUE again lags in accuracy. Here, the WLM and RELATIONAL methods have significantly lower error than RANDOM in 80% and 100% of epochs, respectively. Comparing the running times highlights the computational benefit of using the approximation algorithms. The average running time for a single trial (which includes training and 10 random sequences of revealed variables) using full inference is 3076 seconds, while approximate inference requires only 955 seconds, a reduction of 69%, with inference time varying less than 3% across methods.

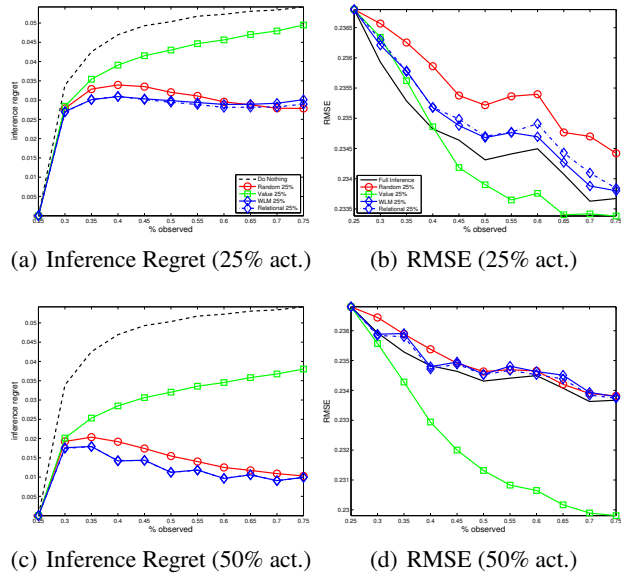

Figure 3: Inference regret (w.r.t. full inference) and RMSE (w.r.t. ground truth) for the Jester dataset.

## 5.2 COLLABORATIVE FILTERING

Our second evaluation task is a collaborative filtering task that employs a collective model to infer the preferences of users. We use the Jester dataset (Goldberg *et al.*, 2001) which includes ratings from 24,983 users on a set of 100 jokes. The task in this setting is to infer the user’s rating of each joke. We use the model from Bach *et al.* (2013) which assigns ratings to jokes based on the joke’s similarity to other jokes rated highly by the user. Joke similarity is measured using the mean-adjusted cosine similarity of the observed ratings of two jokes. (Refer to Bach *et al.* (2013) for further model details.) We sample 200 users who have rated all 100 jokes and split them into 100 training users and 100 testing users. We generate 10 sequences, each of which consists of a training and testing phase. Model weights are learned using 75% of the training users’ ratings observed. During testing, we incrementally reveal [25%, 30%, 40%, . . . , 75%] of the testing users’ ratings, performing online collective inference at each epoch.

We compare inference regret, relative to full inference, for the RANDOM, VALUE, WLM and RELATIONAL approximate methods. We also plot the RMSE, relative to ground truth, for full inference and all approximate methods. Figure 3a-b show results for 25% activation, and Figure 3c-d show 50% activation. Inference regret follows a similar pattern for both budgets, with VALUE showing increasing regret over epochs, and the remaining methods exhibiting level or diminishing regret after the first few epochs. The high regret for VALUE can be explained by considering the RMSE—VALUE actually *improves* the results of full inference, incurring high regret but low RMSE. Our intuition for

this improvement is that VALUE fixes polarized user ratings and allows these ratings to have greater influence on other unknown ratings, while full inference produces more moderate ratings for the entire set. The other approximation algorithms remain close to the full inference RMSE (at 50% activation) or perform slightly worse (at 25% activation). Comparing the running times, we find a similar improvement in speed. The average time for a sequence using full inference is 137 seconds, while the approximate methods require only 46 seconds, yielding a speedup of 66%. Approximation methods had consistent timing, varying less than 6%.

## 6 CONCLUSION

In this paper, we introduce a new problem, *budgeted online collective classification*, which addresses a common problem setting where online inference is necessary but full inference is infeasible, thereby requiring approximate inference updates. Our contributions are: (1) a formal analysis of online collective inference, introducing the concept of inference regret to measure the quality of the approximation; (2) analytic upper bounds on the inference regret incurred by strongly convex inference; and (3) several algorithms to address the practical problem of activation (i.e., choosing which variables to infer at each epoch), through a close analysis of the MAP inference optimization. Our empirical results demonstrate that our activation algorithms exhibit low inference regret and error that is competitive with full inference, while reducing the time required for inference by 65% or more.

This work inspires many exciting areas of future research. One open question is whether one can derive a tighter regret bound using the mechanics of the activation strategy, thus characterizing how performance degrades as a function of the budget. We are also interested in training an “optimal” activation policy that is trained using the variables whose values change the most during full inference. Finally, a crucial assumption in our analysis is that the model structure is fixed, but it is useful to consider the setting in which the set of variables change over time, allowing us to address situations such as new users joining a social network.

## Abstract

A piecewise-constant conditional intensity model (PCIM) is a non-Markovian model of temporal stochastic dependencies in continuous-time event streams. It allows efficient learning and forecasting given complete trajectories. However, no general inference algorithm has been developed for PCIMs. We propose an effective and efficient auxiliary Gibbs sampler for inference in PCIM, based on the idea of thinning for inhomogeneous Poisson processes. The sampler alternates between sampling a finite set of auxiliary virtual events with adaptive rates, and performing an efficient forward-backward pass at discrete times to generate samples. We show that our sampler can successfully perform inference tasks in both Markovian and non-Markovian models, and can be employed in Expectation-Maximization PCIM parameter estimation and structural learning with partially observed data.

## 1 INTRODUCTION

Modeling temporal dependencies in event streams has wide applications. For example, users' behaviors in online shopping and web searches, social network activities, and machines' responses in datacenter management can each be viewed as a stream of events over time. Models that can successfully learn the complex dependencies among events (both label and timing) allow targeted online advertising, automatic policy selection in datacenter management, user behavior modeling, or event prediction and dependency understanding in general.

[Gunawardana et al., 2011] proposed the piecewise-constant conditional intensity model (PCIM) which captures the dependencies among the types of events through a set of piecewise-constant conditional intensity

functions. A PCIM is represented as a set of decision trees, which allow for efficient model selection. Forecasting via forward sampling is also simple by iteratively sampling next events based on the current history.

However, currently model selection and forecasting for PCIMs is only effective given complete data. When there are missing data, an inference method is needed to answer general queries or be employed in expectation-maximization (EM) algorithms for model selection and parameter learning. Currently, no inference algorithm has been proposed for PCIM that can condition on general evidence.

In this work, we propose the first general inference algorithm for PCIMs, based on the idea of *thinning* for inhomogeneous Poisson process [Lewis and Shedler, 1979]. This results in an auxiliary Gibbs sampler that alternates between sampling a finite set of virtual event times given the current trajectory, and then sampling a new trajectory given the set of evidences and event times (virtual and actual). Our method is convergent, does not involve approximations like fixed time-discretization, and the samples generated can answer any type of query. We propose an efficient state-vector representation to maintain only necessary information for diverging trajectories, reducing the exponentially increasing sampling complexity to linear in most cases. We show empirically our inference algorithm converges to the true distribution, permits effective query answering, and aids model selection with incomplete data for PCIM models with both Markovian and complex non-Markovian dynamics. We also show the connection between PCIMs and continuous-time Bayesian networks (CTBNs), and compare our method with an existing method on such models.

## 2 PREVIOUS WORK

A dynamic Bayesian network (DBN) [Dean and Kanazawa, 1988] models temporal dependencies between variables in discrete time. For systems that evolve asynchronously without a global clock, it is

often not clear how timestamps should be discretized. Health records, computer server logs, and social networks are examples of asynchronous event data streams. For such systems, too slow a sampling rate would poorly represent the data, while too fast a sampling rate makes learning and inference more costly.

Continuous-time models have drawn attention recently in applications ranging from social networks [Du et al., 2013, Saito et al., 2009, Linderman and Adams, 2014] to genetics [Cohn et al., 2009] to biochemical networks [Golightly and Wilkinson, 2011]. Continuous Time Bayesian Networks (CTBN) [Nodelman et al., 2002] are homogeneous Markovian models of the joint trajectories of discrete finite variables, analogous to DBNs. Non-Markovian continuous models allow the rate of an event to be a function of the process’s history. Poisson Networks [Rajaram et al., 2005] constrain this function to depend only on the counts of the number of events during a finite time window. Poisson cascades [Simma and Jordan, 2010] define the rate function to be the sum of a kernel applied to each historic event, and requires the modeler to choose a parametric form for temporal dependencies.

A PCIM defines the intensity function as decision trees, with internal nodes’ tests mapping time and history to leaves. Each leaf is associated with a constant rate. A PCIM is able to model non-Markovian temporal dependencies, and is an order of magnitude faster to learn than Poisson networks. Applications include modeling super-computer event logs and forecasting future interests of web search users. While PCIMs have been extended in a number of ways [Parikh et al., 2012, Weiss and Page, 2013], there is no general inference algorithms.

Inference algorithms developed for continuous systems are mainly for Markovian models or specifically designed for a particular application. For CTBNs, there are variational approaches such as expectation propagation [El-Hay et al., 2010] and mean field [Cohn et al., 2009], which do not converge to the true value as computation time increases. Sampling based approaches include importance sampling [Fan et al., 2010] and Gibbs sampling [Rao and Teh, 2011, Rao and Teh, 2013] that converge to the true value. The latter is the current state-of-the-art method designed for general Markov Jump Processes (MJPs) and its extensions (including CTBNs). It uses the idea of uniformization [Grassmann, 1977] for Markov models, similar to thinning [Lewis and Shedler, 1979] for inhomogeneous Poisson processes. We note that our inference method generalizes theirs to non-Markovian models.

### 3 PCIM BACKGROUND

Assume events are drawn from a finite label set  $L$ . An event then can be represented by a time-stamp  $t$  and a label  $l$ . An event sequence  $x = \{(t_i, l_i)\}_{i=1}^n$ , where  $0 < t_1 <$

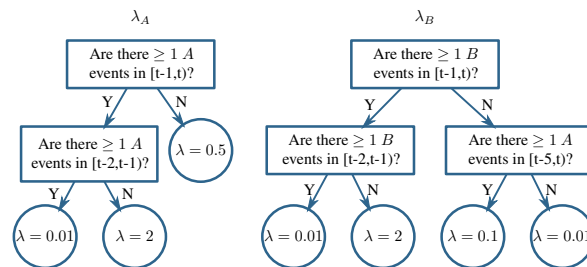

Figure 1: Decision tree representing  $S$  and  $\theta$  for events of labels  $A$  and  $B$ . Note the dependency among event labels (the rate of  $B$  depends on  $A$ ). [Gunawardana et al., 2011]

$\dots < t_n$ . We use  $h_i = \{(t_j, l_j) \mid (t_j, l_j) \in x, t_j < t_i\}$  for the history of event  $i$ , when it is clear from context which  $x$  is meant. We define the ending time  $t(y)$  of an event sequence  $y$  as the time of the last event in  $y$ , so that  $t(h_i) = t_{i-1}$ . A conditional intensity model (CIM) is a set of non-negative conditional intensity functions indexed by label  $\{\lambda_l(t|x; \theta)\}_{l=1}^{|L|}$ . The data likelihood is

$$p(x|\theta) = \prod_{l \in L} \prod_{i=1}^n \lambda_l(t_i|h_i; \theta)^{\mathbf{1}_{l(i)}} e^{-\Lambda_l(t_i|h_i; \theta)} \quad (1)$$

where  $\Lambda_l(t|h; \theta) = \int_{t(h)}^t \lambda_l(\tau|h; \theta) d\tau$ . The indicator function  $\mathbf{1}_{l'}$  is one if  $l' = l$  and zero otherwise.  $\lambda_l(t|h; \theta)$  is the expected rate of event  $l$  at time  $t$  given history  $h$  and model parameters  $\theta$ . Conditioning on the entire history causes the process to be non-Markovian. The modeling assumptions for a CIM are quite weak, as any distribution for  $x$  in which the timestamps are continuous random variables can be written in this form. Despite the weak assumptions, the per-label conditional factorization allows the modeling of label-specific dependence on past events.

A PCIM is a particular class of CIM that restricts  $\lambda(h)$  to be piecewise constant (as a function of time) for any history, so the integral for  $\Lambda$  breaks down into a finite number of components and forward sampling becomes feasible. A PCIM represents the conditional intensity functions with decision trees. Each internal node in a tree is a binary test of the history, and each leaf contains an intensity. If the tests are piecewise-constant functions of time for any event history, the resulting function  $\lambda(t|h)$  is piecewise-constant. Examples of admissible tests include

- Was the most recent event of label  $l$ ?
- Is the time of the day between 6am and 9am?
- Did an event with label  $l$  happen at least  $n$  times between 5 seconds ago and 2 seconds ago?
- Were the last two events of the same label?

Note some tests are non-Markovian in that they require knowledge of more than just which event was most recent. See Fig. 1 for an example of a PCIM model.

The decision tree for label  $l$  maps the time and history to a

leaf  $s \in \Sigma_l$ , where  $\Sigma_l$  is the set of leaves for  $l$ . The resulting data likelihood can be simplified:

$$p(x|S, \theta) = \prod_{l \in L} \prod_{s \in \Sigma_l} \lambda_{l_s}^{c_{l_s}(x)} e^{-\lambda_{l_s} d_{l_s}(x)}. \quad (2)$$

$S$  is the PCIM structure represented by the decision trees; the model parameters  $\theta$  are rates at the leaves.  $c_{l_s}(x)$  is the number of times label  $l$  occurs in  $x$  and is mapped to leaf  $s$ .  $d_{l_s}(x)$  is the total duration when the event trajectory for  $l$  is mapped to  $s$ .  $c$  and  $d$  are the sufficient statistics for calculating data likelihood.

[Gunawardana et al., 2011] showed that given the structure  $S$ , by using a product of Gamma distributions as a conjugate prior for  $\theta$ , the marginal likelihood of the data can be given in closed form, and thus parameter estimation can be done in closed form. Furthermore, imposing a structural prior allows a closed form Bayesian score to be used for greedy tree learning.

## 4 AUXILIARY GIBBS SAMPLING FOR PCIM

In this section we introduce our new inference algorithm for PCIM, called ThinnedGibbs, based on the idea of *thinning* for inhomogeneous Poisson processes. We handle incomplete data in which there are intervals of time during which events for particular label(s) are not observed.

### 4.1 Why Inference in PCIM is Difficult

Filling in partially observed trajectories for PCIM is hard due to the complex dependencies between unobserved events and both past and future events. See Fig. 2 for an example. While the history (the event at  $t$ ) says it is likely that there should be events in the unobserved area (with an expected rate of 2), future evidence (no events in  $R$ ) is contradictory: If there were indeed events in the unobserved area, those events should stimulate events happening in  $R$ .

Such a phenomenon might suggest existing algorithms such as the forward-filtering-backward-sampling (FFBS) algorithm for discrete-time Markov chains. However, there are two subtleties here: First, we are dealing with non-Markovian models. Second, we are dealing with continuous-time systems, so the number of time steps over which to propagate is infinite.

### 4.2 Thinning

Thinning [Lewis and Shedler, 1979] can be used to turn a continuous-time process into a discrete-time one, without using a fixed time-slice granularity. We select a rate  $\lambda^*$  greater than any in the inhomogeneous Poisson process and sample from a *homogeneous* process with this rate. To get a

Figure 2: A simple PCIM with a partially observed trajectory. The vertical solid arrow indicates an evidence event. Areas between parentheses are unobserved. History alone indicates there should be events filled in, while the future (no events in  $R$ ) provides contradictory evidence.

sample from the original inhomogeneous process, an event at time  $t$  is thinned (dropped) with probability  $1 - \frac{\lambda(t)}{\lambda^*}$ .

This process can also be reversed. If given the set of thinned event times (samples from the inhomogeneous process), extra events can be added to a sample from the original constant-rate process by sampling from a Poisson process with rate  $\lambda^* - \lambda(t)$ . The cycle can then repeat by thinning the new total set of times (ignoring how they were generated). At each cycle, the times (after thinning) are drawn from the original inhomogeneous process. It is this type of cycle we will employ in our sampler.

The difficulty is a PCIM is not an inhomogeneous Poisson process. Its intensity depends on the entire history of events, not just the current time. For thinning, this means that we cannot independently sample whether each event is to be thinned. Furthermore, we wish to sample from the posterior process, conditioned on evidence. All evidence (both past and future) affect the probability of a specific thinning configuration.

### 4.3 Overview of Our Method

To overcome both of these problems, we extend thinning to an auxiliary Gibbs sampler in the same way that [Rao and Teh, 2011, Rao and Teh, 2013] extended Markovian-model uniformization [Grassmann, 1977] (a specific example of thinning in a Markov process) to a Gibbs sampler. To do this we introduce auxiliary variables representing the events that were dropped. We call these events *virtual* events.

As a standard Gibbs sampler, our method cycles through each variable in turn. In our case, a variable corresponds to an event label. For event label  $l$ , let  $x_l$  be the sampled event sequence for this label. Let  $Y_l$  be all evidence (for  $l$  and other labels) and all (currently fixed) samples for other labels. Our goal is to sample from  $p(x_l | Y_l)$ .

Let  $v_l$  be the virtual events (the auxiliary variable) associated with  $l$  and  $z_l = x_l \cup v_l$  (all event times, virtual and non-virtual). Our method first samples from  $p(v_l | x_l, Y_l)$  and then samples from  $p(x_l | z_l, Y_l)$ . The first step adds vir-

tual events given the non-virtual events are “correct.” The second step treats all events as potential events and drops or keeps events. The dropped events are removed completely. The kept events,  $x_l$ , remain as the new sampled trajectory.

The proof of correctness follows analogously to that of [Rao and Teh, 2013] for Markovian systems. However, the details for sampling from  $p(v_l | x_l, Y_l)$  and  $p(x_l | z_l, Y_l)$  differ. We describe them next.

#### 4.4 Sampling Auxiliary Virtual Events with Adaptive Rates

Sampling from  $p(v_l | x_l, Y_l)$  amounts to adding just the virtual (dropped) events. As the full trajectory ( $x_l$  for all  $l$ ) is known, the rate at any time step for a virtual event is independent of any other virtual events. Therefore, the process is an inhomogeneous Poisson process for which the rate at  $t$  is equal to  $\lambda^* - \lambda_l(t|h)$  where  $h$  is fully determined by  $x_l$  and  $Y_l$ . Recall that  $\lambda_l(t|h)$  is piecewise-constant in time, so sampling from such an inhomogeneous Poisson process is simple.

The auxiliary rate,  $\lambda^*$ , must be strictly greater than the maximum rate possible for irreducibility. We use an auxiliary rate of  $\lambda^* = 2 \max(\lambda(t|h))$  to sample virtual events in the unobserved intervals. This choice balances mixing time (better with higher  $\lambda^*$ ) and computational complexity (better with lower  $\lambda^*$ ).

A naïve way to pick  $\lambda^*$  is to find  $\lambda_{max}$ : the maximum rate in the leaves of PCIM, and use  $2\lambda_{max}$ . However, there could be unobserved time intervals with a possible maximum rate much smaller than  $\lambda_{max}$ . Using  $\lambda_{max}$  in those regions would generate too many virtual events, most of which will be dropped in the next step leading to computational inefficiency. We therefore use an adaptive strategy.

Our adaptive  $\lambda^*(t|h)$  cannot depend on  $x_l$  (this would break the simplicity of sampling mentioned above). Therefore, we determine  $\lambda^*(t|h)$  by passing  $(t, h)$  down the PCIM tree for  $\lambda_l$ . At each internal node, if the branch does not depend on  $x_l$ , we can directly take one branch. Otherwise, the test is related to the sampled events, and we take the maximum rate of taking both branches. This method results in  $\lambda^*(t|h)$  as a piecewise-constant function of time (for the same reasons that  $\lambda_l(t|h)$  is piecewise-constant).

Consider Fig. 3 as an example. When sampling event  $l = A$  on the interval  $[1, 5)$ , we would not take the left branch at the root (no matter what events for  $A$  have been sampled), but must maximize over the other two leaves (as different  $x_l$  values would result in different leaves). This results in a  $\lambda^* = 4$  over this interval, which is smaller than 6.

Figure 3: Adaptive auxiliary rate example. When sampling  $A$ , the branch to take at the root does not depend on unobserved events for  $A$ . If the test is related to the sampled event, we take the maximum rate from both branches. The red arrows indicate the branches to take between time  $[1, 5]$ , and  $\lambda^* = 2 \times 2$  in that interval, instead of 6.

#### 4.5 The Naïve FFBS Algorithm

Once these virtual events are added back in, we take  $z_l$  (the union of virtual events and “real” sampled events) as a sample from the Poisson process with rate  $\lambda^*$  and ignore which were originally virtual and which were originally “real.” We then thin this set to get a sample from the conditional marginal over  $l$ .

The restriction to consider events only at times in  $z_l$  transforms the continuous-time problem into a discrete one. Given  $z_l$  with  $m$  possible event times  $(z_{l,1}, z_{l,2}, \dots, z_{l,m})$ , let  $b = \{b_i\}_{i=1}^m$  be a set of binary variables, one per event, where  $b_i = 1$  if event  $i$  is included in  $x_l$  (otherwise  $b_i = 0$  and the event is not included in  $x_l$ ). Thus sampling  $b$  is equivalent to sampling  $x_l$  ( $z_l$  is known) as it specifies which events in  $z_l$  are in  $x_l$ . Let  $Y_l^{i:j}$  be the portion of  $Y$  between times  $z_{l,i}$  and  $z_{l,j}$ , and  $b^{i:j} = \{b_k | i \leq k \leq j\}$ . We wish to sample  $b$  (and thereby  $x_l$ ) from  $p(b | Y) \propto$

$$\left( \prod_i p(Y_l^{i-1:i}, b_i | b^{1:i-1}, Y_l^{1:i-1}) \right) p(Y_l^{m:\infty} | b) \quad (3)$$

where the final  $Y_l^{m:\infty}$  signifies all of the evidence after the last virtual event time  $z_{l,m}$  and can be handled similarly to the other terms.

The most straight-forward method for such sampling considers each possible assignment to  $b$  (of which there are  $2^m$ ). For each interval, we multiply terms from Eq. 3 of the form  $p(Y_l^{i-1:i}, b_i | b^{1:i-1}, Y_l^{1:i-1}) =$

$$p(Y_l^{i-1:i} | b^{1:i-1}, Y_l^{1:i-1}) p(b_i | b^{1:i-1}, Y_l^{1:i-1}) \quad (4)$$

where the first term is the likelihood of the trajectory interval from  $z_{l,i-1}$  to  $z_{l,i}$  and the second term is the probability of the event being thinned, given the past history. The first can be computed by tallying the sufficient statistics (counts and durations) and applying Eq. 2. Note that these sufficient statistics take into account  $b^{1:i-1}$  which specifies

events for  $l$  during the unobserved region(s), and the likelihood must also be calculated for labels  $l' \neq l$  for which  $\lambda_{l'}(t|h)$  depends on events from  $l$ . The second term is equal to  $\frac{\lambda_l(t|h)}{\lambda^*(t)}$  if  $b_i = 1$  (and  $1 - \frac{\lambda_l(t|h)}{\lambda^*(t)}$  if  $b_i = 0$ ). The numerator's dependence on the full history similarly dictates a dependence on  $b^{1:i-1}$ .

This might be formulated as a naïve FFBS algorithm: To generate one sample, we propagate possible trajectories forward in time, multiplying in Eq. 4 at each inter-event interval to account for the evidence. Every time we see a virtual event, each possible trajectory diverges into two (depending on whether the virtual event is to be thinned or not). By the end, we have all  $2^m$  possible trajectories, each with its probability (Eq. 3). We sample one trajectory as the output, in proportion of the calculated likelihoods. As we explicitly keep all possible trajectories, the sampled trajectory immediately tells us which virtual events are kept, so no actual backward pass is needed.

#### 4.6 An Efficient State-Vector Representation

The naïve FFBS algorithm is clearly not practical, as the number of possible trajectories grows exponentially with the number of auxiliary virtual events ( $m$ ). We propose a more efficient state-vector representation to only keep the necessary information for each possible trajectory. The idea takes advantage of the structure of the PCIM and leads to state merges, similar to what happens in FFBS for hidden Markov models (HMMs).

The terms in Eq. 4 depend on  $b^{1:i-1}$  only through the tests in the internal nodes of the PCIM trees. Therefore, we do not have to keep track of all of  $b^{1:i-1}$  to calculate these likelihoods, but only the current state of such tests that depend on events with label  $l$ . For example, a test that asks “Is the last event of label  $l$ ?” only needs to maintain a bit as the indicator. The test “Are there more than 3 events of label  $q$  in the last 5 seconds?” for  $q \neq l$  has no state, as  $b^{1:i-1}$  does not affect its choice. By contrast, a test such as “Is the last event of label  $q$ ?” does depend on  $b$ , even if  $q \neq l$ .

As we propagate forward, we merge  $b^{1:i}$  sequences that result in the same set of states for all internal tests inside the PCIM. See Fig. 4 as a simple example. Though there are 8 possible trajectories, they merge to only 2 states that we can sample from. Similar to FFBS for HMM, we need to maintain the transition probabilities in the forward pass and use them in a backward sampling pass to recover the full trajectory, but such information is also linear.

Note that this conversion to a Markov system for sampling is *not* possible in the original continuous-time system. Thinning allows it by randomly selecting a few discrete time points, thereby restricting the possible state space to be finite.

The state space depends on the actual tests in the PCIM

Figure 4: Dotted events are the virtual events that we sample as binary variables ( $b_i$  is 1 if event  $i$  is kept). The state diagram below the trajectory indicates the state of the test as we diverge (keep or drop a virtual event). Though there are  $2^3$  possible configurations, state merges can reduce the exponentially increasing complexity to linear in this case.

model. See Tbl. 1 for the tests we currently support and their state representations. The LastStateTest and StateTest are used to support discrete finite variable systems such as CTBN, as we will use in Sec. 5 and in experiments. Note the EventCountTest was the only supported test in the original PCIM paper. We can see that for tests that only depend on the *current* time (i.e. TimeTest), the diverging history does not affect them, so no state is needed. For Markovian tests (LastEventTest and LastStateTest), we only need a Boolean variable. For the non-Markovian test (EventCountTest), the number of possible states does grow exponentially with the number of virtual events maintained in the queue. This is the best we can do and still be exact. It is much better than growing with the number of all virtual events. However, note that commonly  $lag2 = 0$  and  $n$  is a small number. In this case, the state space size at any point is bounded as  $\binom{m'}{n}$ , where  $m'$  is the maximum number of sampled events in any time interval of duration  $lag1$  (which is upper bounded by  $m$ ). If  $n$  is 1, this is linear in the number of samples generated in during  $lag1$  time units.

As noted above, if the test is not related to the sampled event (for example, in sampling event  $l = A$  with test “are there  $\geq 3$  B events in the last 5 seconds”), the state of the test is null. This is because the evidence and sampled values for  $B$  (not the current variable for Gibbs sampling) can answer this test without reference to samples of  $l$ .

See Alg. 1 for the algorithm description for resampling event  $l$ . The complete algorithm iterates this procedure for each event label to get a new sample. The helper function UpdateState(s,b,t) returns the new state given the old state (s), the new time (t), and whether an event occurs at t (b). SampProbMap(M) takes a mapping from objects to positive values (M) and randomly returns one of the objects with probability proportional to the associate value. AddtoProbMap(M,o,p) checks to see if o is in M. If so, it adds p to the associated probability. Otherwise, it adds the

Table 1: Tests and their corresponding state representations.

| Test           | Example  | State Representation   | Property           |
|----------------|--|--|--------------------|
| TimeTest       | Is the time between 6am and 9am?                       | Null   | independent of $b$ |
| LastEventTest  | Is the last event A?                                   | Boolean  | Markovian          |
| EventCountTest | Are there $\geq n$ A event in $[t - lag1, t - lag2]$ ? | A queue maintaining all the times of A between $[t - lag2, t]$ , and the most recent $n$ events between $[t - lag1, t - lag2]$ . | Non-Markovian      |
| LastStateTest  | Is the last sublabel of var $A=0$ ?                    | Boolean  | Markovian          |
| StateTest      | Is the current sublabel of var $A=0$ ?                 | Null   | independent of $b$ |

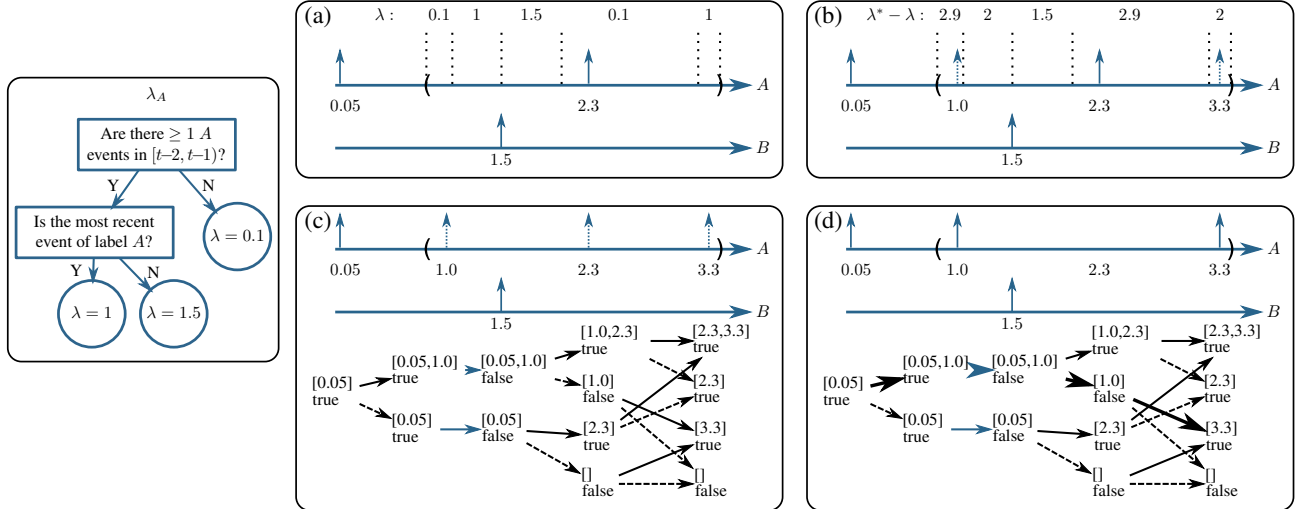

Figure 5: Extended Example, see Section 4.7

mapping  $o \rightarrow p$  to  $M$ .

#### 4.7 Extended Example

Fig. 5 shows an example of resampling the events for label  $A$  on the unobserved interval  $[0.8, 3.5)$ . On the far left is the PCIM rate tree for event  $A$ . Box (a) shows the sample from previous iteration (single event at 2.3). Dashed lines and  $\lambda$  show the piecewise-constant intensity function given the sample. Box (b) shows the sampling of virtual events. For this case  $\lambda^* = 3$  for all time.  $\lambda^* - \lambda$  is the rate for virtual events. The algorithm samples from this process, resulting in two virtual events (dashed). In box (c) all events become potential events. The state of the root test is a queue of recent events. The state of the other test is Boolean (whether  $A$  is more recent). On the bottom is the lattice of joint states over time. Solid arrows indicate  $b_i = 1$  (the event is kept). Dash arrows indicate  $b_i = 0$  (the event is dropped). Each arrow's weight is as per Eq. 4. The probability of a node is the sum over all paths to the node of the product of the weights on the path (calculated by dynamic programming). In box (d) a single path is sampled with backward sampling, shown in bold. This path corresponds to keeping the first and last virtual events and dropping the middle one.

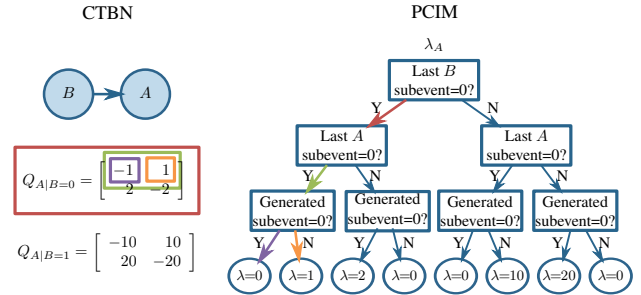

Figure 6: Explicit conversion from a CTBN to a PCIM by using specific tests. Only rates for variable  $A$  shown. The colored arrows and boxes show one-to-one correspondence of a path in the tree and an entry in the rate matrix of CTBN. Diagonal elements in the CTBN are redundant and do not need to be represented in the PCIM.

## 5 REPRESENTING CTBNS AS PCIMS

A non-Markovian PCIM is more general than the Markovian CTBN model. We can, therefore represent a CTBN using a PCIM. In this way, we can extend PCIMs and we can compare our PCIM method with existing methods for CTBNS.

- 

We associate a PCIM label with each CTBN variable. We also augment the notion of a PCIM label to include a sub-label. For each CTBN variable, its PCIM label has one sublabel for each state of the CTBN variable. Therefore, a PCIM event with label  $X$  and sublabel  $x$  corresponds to a transition of the CTBN variable  $X$  from its previous value to the value  $x$ . The PCIM trees' tests can also check the sublabel associated with the possible event.

We augment the auxiliary Gibbs sampler to not only sample which virtual events are kept, but also which sublabel is associated with each. This involves modifying the  $b_i$  variables from the previous section to be multi-valued. Otherwise, the algorithm proceeds the same way.

The last two tests in Tbl. 1 are explicitly for this type of sublabelled event model. We can use them to turn a conditional intensity matrix from the CTBN into a PCIM tree. Fig. 6 shows the conversion of the "twonode" model.

## 6 EXPERIMENTS

We implement our method as part of an open source code base, and all the code and data will be publicly available.

We perform two sets of experiments to validate our method.

Figure 7: The toroid network and observed patterns [El-Hay et al., 2010].

Figure 8: Number of samples versus KL divergence for the toroid network. Both axes are on a log scale.

First we perform inference with our method on both Markovian and non-Markovian models, and compare the result with the ground-truth statistics. For both we show our result converges to the correct result. Ours is the first that can successfully perform inference tasks on non-Markovian PCIMs. For the second set of experiments, we use ThinnedGibbs in EM for both parameter estimation and structural learning for a non-Markovian PCIM. Our inference algorithm can indeed help producing models that achieve higher data likelihood on holdout test data than several baseline methods.

### 6.1 Verification on the Ising Model

We first evaluate our method, ThinnedGibbs, on a network with Ising model dynamics. The Ising model is a well-known interaction model with applications in many fields including statistical mechanics, genetics, and neuroscience. This is a Markovian model and has been tested by several existing inference methods designed for CTBNs.

Using this model, we generate a directed toroid network structure with cycles following [El-Hay et al., 2010].

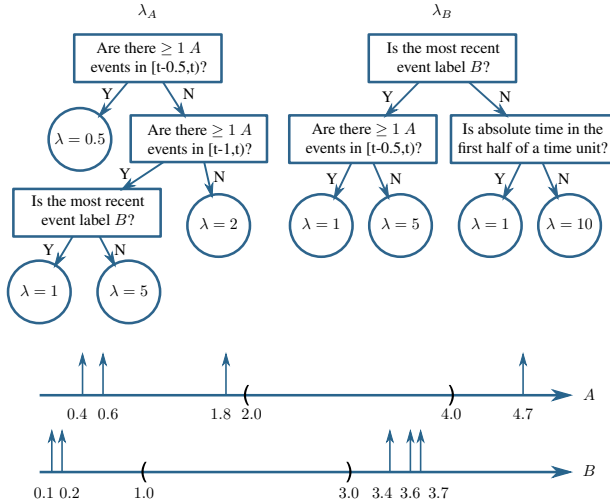

Figure 9: Non-Markovian PCIM and evidence. The ending time is 5.

Nodes can take values  $-1$  and  $1$ , and follow their parents' states according to a coupling strength parameter ( $\beta$ ). A rate parameter ( $\tau$ ) determines how fast nodes toggle between states. We test with  $\beta = 0.5$  and  $\tau = 2$ . The network and the evidence patterns are shown in Fig. 7. The nodes are not observed between  $t = 0$  and  $t = 1$ . We query the marginal distribution of nodes at  $t = 0.5$  and measure the sum of the KL-divergences of all marginals against the ground truth. We compare with the state-of-the-art CTBN Auxiliary Gibbs method [Rao and Teh, 2013]. Other existing methods either produce similar or worse results [Celikkaya and Shelton, 2014]. We vary the sample size between 50 and 5000, and set the burn-in period to be 10% of this value. We run the experiments for 100 times, and plot the means and standard deviations.

Results in Fig. 8 verify that our inference method indeed produces results that converge to the true distribution. Our method reduces to that of [Rao and Teh, 2013] in this Markovian model. Differences between the two lines are due to slightly different initializations of the Gibbs Markov chain and not significant.

## 6.2 Verification on a Non-Markovian Model

We further verify our method on a much more challenging non-Markovian PCIM (Fig. 9). This model contains several non-Markovian EventCountTests. We have observations for event  $A$  at  $t = 0.4, 0.6, 1.8, 4.7$  and for event  $B$  at  $t = 0.1, 0.2, 3.4, 3.6, 3.7$ . Event  $A$  is not observed on  $[2.0, 4.0)$  and event  $B$  is not observed on  $[1.0, 3.0)$ .

In produce ground truth, we discretized time and converted the system to a Markovian system. Note that because the time since the last  $A$  event is part of the state, as the discretization becomes finer, the state space increases. For

Figure 10: Number of samples versus the inferred expected number of events. The horizontal axis is on a log scale.

this small example, this approach is just barely feasible. We continued to refine the discretization until the answer stabilized. The ground-truth expected total number of  $A$  events between  $[0, 5]$  is 22.3206 and the expected total number of  $B$  events is 11.6161. That is, there are about 18.32  $A$  events and 6.62  $B$  events in the unobserved areas. Note that if the evidence is changed to have no events these numbers drop to 1.6089 and 8.6866 respectively and if the evidence after the unobserved intervals is ignored the expectations are 22.7183 and 8.6344 respectively. Therefore the evidence (both before and after the unobserved intervals) is important to incorporate in inference.

We compare our inference method to the exact values, again varying the sample size between 50 and 5000 and setting the burn-in period to be 10% of this value. We ran the experiments 100 times and report the mean and standard deviation of the two expectations. Our sampler has very small bias and therefore the average values match the true value almost exactly. The variance decreases as expected, demonstrating the consistent nature of our method. See Fig. 10. We are not aware of existing methods that can perform inference on this type of model to which we could compare.

## 6.3 Parameter Estimation and Structural Learning

We further test ThinnedGibbs by using it in EM, for both parameter estimation (given the tree structure, estimate the rates in the leaves), and structural learning (learn both the structure and rates). We use Monte Carlo EM that iterates between two steps: First, given a model we generate samples conditioned on evidence with ThinnedGibbs. Second, given the samples, we treat them as complete trajectories and perform parameter estimation and structural learning, which is efficient for PCIM. We initialize the model from

Figure 11: Parameter estimation. Testing log-likelihood as a function of the number of training samples.

Figure 12: Structure and parameter estimation. Testing log-likelihood as a function of the number of training examples.

the partial trajectories, assuming no events occur in the unobserved intervals. EM terminates when the parameters of PCIMs in two consecutive iterations are stable (all rates change less than 10% from the previous ones), or the number of iterations surpasses 10. For structural learning, the structure needs to be the same between iterations.

We use the model in Fig. 1 and generate complete trajectories for time range  $[0, 10]$ . We vary the number of training samples (5, 10, 15, and 20) and use a fixed set of 100 trajectories as the testing data. For each training size, we use the same the training data for all algorithms and runs. We randomly generate an unobserved interval with length  $0.6 \times T$  for both event labels. For each training sample, ThinnedGibbs fills it in to generate a new sample after burning in 10 steps. For each configuration, we run ThinnedGibbs for 5 times. We measure the data likelihood of the holdout testing data on the learned models.

For parameter estimation, we compare with the true model that generated the data, the model learned with only par-

tial data in which we assume no events happened during unseen intervals (Partial Data), and a model learned with complete training data (Complete Data). The results are summarized in Fig. 11. We can see that the model learned by EM algorithm using ThinnedGibbs can indeed produce significantly higher testing likelihood than using only partial data. Of course, we do not do as well as if none of the data had been hidden (Complete Data).

If learning the structure, there is one other possibility: We could use the original fast PCIM learning method, but indicate (by new event labels) when an unobserved interval starts and stops. We augment the bank of possible decisions to include testing if each pseudo-events have occurred most recently. In this way, the PCIM directly models the process that obscures the data. Of course, at test time, branches modeling such unobserved times are not used. Such model should serve as a better baseline than learning from partially observed data, because it can potentially learn unobserved patterns and only use the dependencies in the observed intervals for a better model. We call this model EMUP (explicit modeling of unobserved patterns).

For structure learning, we fix the bank of possible PCIM tests as EventCountTests with  $(l, n, lag1, lag2) \in \{A, B\} \times \{1, 2\} \times \{2, 3, 4, 5, 6\} \times \{0, 1, 2\}$  (omitting tests for which  $lag1 \leq lag2$ ). For EMUP we also allow testing if currently in unobserved interval. The results are summarized in Fig. 12. We can see that EMUP does outperform models using only partial data. However, Structural EM with ThinnedGibbs still performs better. The performance gain is less than that in the parameter estimation task, probably because there are more local optimums for structural EM, especially with fewer training examples.

## 7 DISCUSSION AND FUTURE WORK

We proposed the first effective inference algorithm, ThinnedGibbs, for PCIM. Our auxiliary Gibbs sampling method effectively transforms a continuous-time problem into a discrete one. Our state-vector representation of diverging trajectories takes advantage of state merges and reduces complexity from exponential to linear for most cases. We build the connection between PCIM and CTBN, and show our method generalizes the state-of-art inference method for CTBN models. In experiments we validate our idea on non-Markovian PCIMs, which is the first to do so.

Our method converges to the exact conditional distribution. If the true state of the model grows exponentially, the complexity of ThinnedGibbs follows. We believe this technique could also be applied to other non-Markovian processes. The challenge lies in computing the forward-pass likelihoods when the rate function is not piecewise-constant.

## Abstract

Factored Markov Decision Processes (MDP) are a de facto standard for compactly modeling sequential decision making problems with uncertainty. Offline planning based on symbolic operators exploits the factored structure of MDPs, but is memory intensive. We present new memory-efficient symbolic operators for online planning, prove the soundness of the operators, and show convergence of the corresponding planning algorithms. An experimental evaluation demonstrates superior scalability on benchmark problems.

## 1 INTRODUCTION

The success of online planning in Markov Decision Processes (MDPs) depends crucially on the extent to which the information gathered from search is generalized to unseen states. In the absence of generalization and heuristic guidance, the planner must explore the entire reachable state space. In factored MDPs, the size of the state and action spaces is exponential in the number of state and action variables, causing algorithms that are polynomial in the number of states and/or actions to be impractical. The current state-of-the-art online algorithms based on e.g., Real-Time Dynamic Programming (RTDP) (Barto *et al.*, 1995) and UCT (Kocsis & Szepesvári, 2006), search in terms of atomic or “flat” states. They are unable to take advantage of the factored structure present in the MDP descriptions which allows strong generalization among states (Boutillier *et al.*, 1999).

In contrast, symbolic decision theoretic planners, such as SPUDD (Hoey *et al.*, 1999), do take advantage of the factored structure. These algorithms interleave Dynamic Programming (DP) (Bertsekas & Tsitsiklis, 1996) updates with steps of model minimization (Givan *et al.*, 2003) in a selected representation such as Algebraic Decision Diagrams (ADD) (Bahar *et al.*, 1993). These offline planners some-

times scale to large MDPs, but depend on compactly representing the optimal value function of the entire MDP (Hoey *et al.*, 1999). Due to this requirement, these algorithms exceed practical memory and time limits in many problems of interest.

Symbolic Real-Time Dynamic Programming (sRTDP) (Feng *et al.*, 2002; Feng & Hansen, 2002) aims to combine the benefits of the symbolic methods and online planning by incorporating symbolic state generalization into the computation of the online planner. This effectively imposes state constraints capturing reachability from the current world state into the symbolic computation. However, sRTDP is a general framework, and its performance is sensitive to the definition of generalized states. Existing definitions in prior work lead to algorithms that exceed memory limits in many cases. Despite the aim for generalization, the resulting planner is often inferior to the corresponding algorithms working in the flat state space (e.g. RTDP).

Our main contribution is the introduction of new symbolic generalization operators that guarantee a more moderate use of space and time, while providing non-trivial generalization. Using these operators, we present symbolic online planning algorithms that combine forward search from an initial state with backwards generalized DP updates. The first algorithm, Path Dynamic Programming (PDP) (Section 3.1), samples fixed-length trajectories by acting greedily and refines *one path* in an ADD for each visited state. It uses either an operator based on value invariance (PDP-V) or one based on policy invariance (PDP- $\pi$ ). Both operators yield anytime algorithms that guarantee convergence to the optimal value and action for the current world state, while maintaining bounded growth in the size of the symbolic representation.

In spite of the slow growth of the value function representation, intermediate computations in PDP leading to that representation can potentially exceed memory limits. This motivates our second operator that performs a more careful control of space in its generalization. The resulting planning algorithm, Pruning Path Dynamic Programming (pPDP) (Section 4), applies the pruning procedure of

Raghavan *et al.* (2013) to control the size of intermediate results. The algorithm is convergent and provides generalization only when it does not increase space requirements compared to flat state search. Thus, it is guaranteed not to be worse than flat state space search. It is the first symbolic algorithm to yield a sound generalization while guaranteeing not to use more memory than flat RTDP.

We empirically demonstrate (Section 5) the performance of PDP and pPDP on three benchmark domains from the recent International Probabilistic Planning Competitions (IPPC), where the proposed algorithms scale significantly better than previous results.

## 2 PROBLEM FORMULATION

### 2.1 Algebraic Decision Diagrams (ADD)

An Algebraic Decision Diagram (ADD) (Bahar *et al.*, 1993; Bryant, 1992) represents a real-valued function  $B^n \rightarrow \mathcal{R}$  over  $n$  boolean variables compactly in the form of a rooted Directed Acyclic Graph (DAG), where each interior node has an associated test variable and two outgoing edges labeled by true or false that lead to its children. An example ADD is shown on the right of Figure 1. Every assignment of variables to truth values traces a unique path to a leaf from the root. Each leaf node contains the value of the ADD function for all assignments  $\mathbf{x}$  that reach that node. If  $D$  is the ADD,  $D[\mathbf{x}]$  represents its evaluation on  $\mathbf{x}$ . In the example, the assignment `reboot.c1=0, running.c1=0`, and `running.c1'=0` leads to the value 0.95. A Binary Decision Diagram (BDD) is an ADD with 0/1 leaves.

We assume that the ADD is *ordered* in that there is a fixed total ordering on the variables that all directed paths in the ADD follow. Ordered ADDs have a canonical representation for any function (although their compactness depends on the ordering) and they support polynomial time operations over the functions they represent. The unary “restrict operator” fixes the value of a variable  $x$  to  $x$  or  $\bar{x}$  in ADD  $D$  and returns a new ADD denoted by  $D_{\downarrow x}$ . In general, a binary ADD operation  $C = A \text{ op } B$  gives an ADD such that  $C[\mathbf{x}] = A[\mathbf{x}] \text{ op } B[\mathbf{x}]$  for every  $\mathbf{x}$ . The result  $C$  is computed symbolically and in polynomial time in the size of the ADDs  $A$  and  $B$ . Any binary operation can be used as *op*, for example,  $\{+, -, \times, \div, \max, \min\}$ . Marginalization operations such as  $\max_V D$ ,  $\min_V D$ ,  $\sum_V D$  are defined naturally over all possible restrictions of  $D$  over values of variables in the set  $V$ , e.g.  $\max_x D \equiv \max(D_{\downarrow x}, D_{\downarrow \bar{x}})$ . We also use the operator  $\oplus_C$  for ADDs, where  $A \oplus_C B = (1 - C)A + CB$ , for a binary valued ADD  $C$ . That is, the result takes the values from  $B$  if  $C$  is true and otherwise from  $A$ . This is similar to the ITE(C,B,A) notation in the BDD literature. This operation can cause merging of paths within the ADD due to reduction, e.g. if  $A$  and  $B$  agree on many values.

A partial assignment is a truth assignment to a subset of variables in  $D$ . An assignment is full if it assigns values to all variables. An extension of a partial assignment is a full assignment which is consistent with it. Every path in the ADD from the root to the leaf defines a partial assignment over the internal variables in that path. For example, the path to 0.95 traversed in the example above, defines a partial assignment to three of the variables but leaves other variables, for example `running.c2`, unspecified.

The *path function* for an ADD  $D$  maps a full assignment  $\mathbf{x}$  to the partial assignment defined by the path traced by  $\mathbf{x}$  in  $D$  and is denoted by  $\Phi(D, \mathbf{x})$ . The path function is represented as an ordered BDD that returns 1 for all assignments consistent with the partial assignment and 0 otherwise. For an assignment  $\mathbf{x}$ , ADD  $D$  and  $\phi = \Phi(D, \mathbf{x})$ , let  $\epsilon(\phi)$  denote the set of all extensions of  $\phi$ .

Two additional transformations are useful. The first converts a BDD  $B$  to an ADD  $D$  by mapping the 0-leaf in  $B$  to  $-\infty$ , denoted by  $D = \underline{B}$ . The second, a complementing operation, converts an ADD  $D$  to a BDD  $B$  by mapping the 0-leaf in  $D$  to 1 and all other real-valued leaves to 0, denoted by  $B = \overline{D}$ .

### 2.2 Factored State and Action MDPs

An MDP (Puterman, 2014) is a tuple  $(\mathcal{S}, \mathcal{A}, T, R)$  where  $\mathcal{S}$  is a finite state-space,  $\mathcal{A}$  is a finite action space,  $T : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \rightarrow [0, 1]$  denotes the transition function  $T(s, a, s') = Pr(s'|s, a)$ ,  $R : \mathcal{S} \times \mathcal{A} \rightarrow \mathcal{R}$  denotes the immediate reward of taking action  $a$  in state  $s$ . In this paper, we focus on finite-horizon planning where the goal is to maximize the expected cumulative reward over a specified horizon  $H$ . A non-stationary policy  $\pi = (\pi_1, \dots, \pi_H)$  is a sequence of mappings such that each  $\pi_i : \mathcal{S} \rightarrow \mathcal{A}$  determines the action to take in a state when there are  $i$  steps-to-go. The value function of a policy  $\pi$  with  $i$  steps-to-go is denoted by  $V_i^\pi(s)$ , which gives the expected total reward of following  $\pi$  starting in state  $s$  for  $i$  steps. The value function of the optimal  $i$ -horizon policy is denoted by  $V_i^*(s)$ .

In a factored MDP (Boutilier *et al.*, 1999) the state space  $\mathcal{S}$  and action space  $\mathcal{A}$  are specified by finite sets of state variables  $\mathbf{X} = (X_1, \dots, X_l)$  and action variables  $\mathbf{A} = (A_1, \dots, A_m)$ . We will assume that the variables are discrete and binary so that  $|\mathcal{S}| = 2^l$  and  $|\mathcal{A}| = 2^m$ .

The transition and reward functions are defined in terms of state and action variables using a Dynamic Bayesian Network (DBN), a two-time-step graphical model that captures the variables at time  $t$  that influence the value of each  $X'_i$  at time  $t + 1$  via the conditional probability functions  $P(X'_i | \text{Parents}(X'_i))$ . The reward function is represented as a node at time  $t + 1$ . Following Hoey *et al.* (1999), the functions are represented using ADDs (Bahar *et al.*, 1993) to

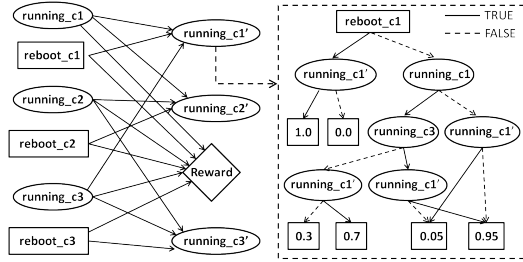

Figure 1: Example of a Factored MDP with Factored Actions. The ADD on the right shows the conditional probability distribution for `running_c1`.

compactly capture sparsity and context-specific dependencies often found in factored MDPs (Boutilier *et al.*, 1999).

For example, Figure 1 shows a DBN for the SysAdmin problem (Guestrin *et al.*, 2001) (see Section 5). The DBN encodes that the computers ‘c1’, ‘c2’ and ‘c3’ are arranged in a directed ring so that the running status of each is influenced by its reboot action and the status of its predecessor. The ADD (right panel) shows that the proposition ‘`running_c1`’ cannot become false if it is ‘rebooted’, and otherwise the next state depends on the status of the neighbors. If currently running, it fails w.p. 0.3 if its neighboring computer ‘c3’ is not operational, and w.p. 0.05 otherwise. A failed computer becomes operational w.p. 0.05.

In previous work we generalized the symbolic approach of SPUDD (Hoey *et al.*, 1999) and introduced algorithms that handle factored states and factored actions. This includes Factored Action Regression (FAR) (Raghavan *et al.*, 2012), a symbolic version of Value Iteration (VI). By leveraging ADD operations (near-)optimal value functions/policies are *deduced* in propositional logic without enumerating the states and actions. Symbolic VI using FAR works by iterating Equation 1,

$$Q = [R + \gamma \sum_{X'_1} P^{X'_1} \times \dots \times \sum_{X'_i} P^{X'_i} \times (V_n)'] \quad (1)$$

with  $V_0 = 0$  and  $V_{n+1} = \max_{A_1 \dots A_m} Q$ . Here  $(V_n)'$  swaps the state variables  $X$  in the diagram  $V_n$  with next state variables  $X'$ , each summation computes the expectation over one  $X'_i$  and marginalizes (and removes)  $X'_i$  from the ADD. Therefore, the ADD  $V_{n+1}$  is the result of one backward DP update for all states.

Below we also use a decision diagram representation of policies. Following (Raghavan *et al.*, 2013) the policy is represented as a BDD over state and action variables and evaluates to 1 on the policy action for a given state. This can be calculated using diagram operations as  $\pi_{n+1} = \overline{\max_A Q - Q}$ , where  $\overline{\phantom{x}}$  is the complementing operator (Section 2.1). Since  $\max_A Q - Q \geq 0$  everywhere and  $> 0$  on paths that include suboptimal actions this identifies the greedy policy with respect to  $Q$ . Below we slightly abuse notation and denote this operation as  $\pi_{n+1} = \arg \max_A Q$ .

Unlike other approaches to factored MDPs based on function approximation (Guestrin *et al.*, 2001; Koller & Parr, 2000), the symbolic algorithms do not require engineered basis functions but rely on compactly representing value functions and policies. FAR and Opportunistic Policy Iteration (Raghavan *et al.*, 2013), a memory-efficient symbolic variant of Modified Policy Iteration (Puterman & Shin, 1978) using FAR, are currently the most effective symbolic algorithms for factored MDPs. As mentioned above, in many cases these methods fail due to the memory exhaustion caused by progressively larger ADDs  $V_n$  as  $n$  increases. Symbolic Online Planning aims to reduce the memory usage by restricting to the state space reachable from the current world state.

### 2.3 Symbolic Online Planning

In order to facilitate the presentation of online symbolic methods we next consider an update that explicitly controls which states are updated. Let  $X$  be a BDD representing some set of states, and let  $\underline{X}$  be the corresponding constraint ADD mapping states in  $X$  to 1, and states not in  $X$  to  $-\infty$ . The operator  $\mathcal{B}^*(V, X)$  performs an exact update (a Bellman backup) for the values of states in  $X$  and copies the values from  $V$  for other states using  $\oplus$ . This operator can be implemented via the ADD expression:

$$\mathcal{B}^*(V, X) \triangleq V \oplus_X [\max_A (R + \gamma E_{X'_1} \dots E_{X'_i} (\underline{X} \times V'))] \quad (2)$$

where multiplication by  $\underline{X}$  is not necessary for correctness but it helps control space. The product of  $V'$  with  $\underline{X}$  fixes the value of states that are not in the set  $X$  to  $-\infty$ . Therefore, the sum and product operations also result in  $-\infty$  without increasing the size of ADDs for these states. The constraint  $\underline{X}$  can be pushed inside the summations due to the distributive property of ADD operations (Raghavan *et al.*, 2013). Note that sRTDP uses an operator equivalent to  $\mathcal{B}^*(V, X)$  via a more memory intensive ADD expression.

We can now explain more general algorithms. Let  $X$  denote a set of states or “a generalized state” and  $s$  denote an atomic state or “flat state”. FAR (Equation 1) uses the backup of Equation 2 with  $X = 1$ , which means it updates the values of all states.

Real-Time Dynamic Programming (RTDP) (Barto *et al.*, 1995) is an online planning algorithm that only updates the values of reachable states. RTDP works by simulating trajectories from a starting state and setting  $X = s$  for each encountered flat state  $s$ . While each update is time and space-efficient, convergence can take a long time in factored MDPs.

sRTDP (Feng *et al.*, 2002) generalizes RTDP updates, uses an update similar to Equation 2 by setting  $X$  to an arbitrary set of states. The set  $X$  is defined by an equivalence relation over states (e.g. the bisimulation relationship (Givan *et al.*, 2003)), which is in practice, heuristically chosen

to trade off the efficiency of the update with the benefit of generalization. An unwise choice of  $X$  in Equation 2 can lead to unreasonable space (or time) requirements. Despite its goal of generalization, the performance of sRTDP can be inferior to RTDP in the online setting where both space and time are limited.

Next we describe our formulations of generalized states  $X$  that lead to efficient updates both in time and space. Convergence of RTDP (and sRTDP) can be retained if  $X$  includes state  $s$ . Efficiency comparable to RTDP can be achieved if the generalized value functions and policies can be captured with about the same amount of memory. We give equivalence relationships that are more restricted than bisimulation (Li *et al.*, 2006), and lead to efficient symbolic online algorithms.

### 3 PDP

Our algorithms are instantiations of Trial-Based Real Time Dynamic Programming (RTDP) (Barto *et al.*, 1995; Keller & Helmert, 2013) with a particular generalized backup function and a fixed trial length. They have two parameters : a lookahead integer  $H > 0$  that is the length of trajectories and a real valued  $\varepsilon$  that controls approximation error in the values of states.

In contrast to most online planners which use a tabular representation, we maintain one value ADD  $V^d$ ,  $d \in [0, H-1]$  per level of the lookahead tree. We chose this over a global ADD (as in sRTDP) because it allows representing non-stationary policies and value functions compactly, as well as allowing different levels of approximation per level, e.g., for increasingly coarse representations of the future. In addition, to simplify the presentation, we explicitly maintain a policy BDD  $\pi^d$ , for each level  $d$ .

Our algorithms start from an initial state and sample a trajectory  $\langle s_0, a_0, \dots, a_{H-2}, s_{H-1} \rangle$  by following the greedy policy  $\pi^0, \dots, \pi^{H-1}$ . Then, the ADDs are updated in the backward direction:  $V^{H-1}$  is updated from the ADD 0,  $V^{H-1}$  is used to update  $V^{H-2}$  and so on till  $V^0$ , which includes  $s_0$  but may be more general.

The general pseudocode for all the algorithms is shown in Figure 2. They have an update of the form  $V = V \oplus_M \max_{\mathbf{A}} Q$ . The algorithm requires three properties: (A)  $M$  is a *path* over state variables (hence the name Path Dynamic Programming), (B)  $Q$  is an ADD over state and action variables with updated values for a super-set of the states in  $M$ . (C) The current state  $s_i$  is included in path  $M$ .

**Proposition 1.** *Any instance of the PDP algorithm (Figure 2) satisfying properties B and C converges to the optimal value (and action) for  $s_0$ .*

**Proof (sketch):** The proof directly follows from the convergence of Trial-Based RTDP (Barto *et al.*, 1995). First,

**Algorithm 3.1:** (ADDs  $V^0, \dots, V^{H-1}, \pi^0, \dots, \pi^{H-1}$ )

```

Initialize each  $V^i \leftarrow (H - i + 1)R_{\max}, \pi^i \leftarrow \text{NoOp}$ .
Sample trajectory  $\langle s_0, a_0, \dots, a_{L-1}, s_L \rangle$  using  $\pi$ .
for  $i \leftarrow L - 1$  downto 0
  if PDP-V then  $(Q, M) \leftarrow$  Equations 4, 5
  if PDP- $\pi$  then  $(Q, M) \leftarrow$  Equations 6, 8
  do  $\left\{ \begin{array}{l} \text{if pPDP then } (Q, M) \leftarrow \text{Equations 9, 11} \\ V^i \leftarrow V^i \oplus_M \max_{\mathbf{A}} Q \\ \pi^i \leftarrow \pi^i \oplus_M \arg \max_{\mathbf{A}} Q \end{array} \right.$ 
  if beyond time or trajectory budget
  then return  $\pi^0(s_0)$ 

```

Figure 2: Pseudocode for Path Dynamic Programming (PDP).  $A \oplus_X B = (1 - X)A + XB$ .

it can be shown that PDP maintains the invariants  $V_i \geq V_i^*$  for all  $i$ . Second, it uses greedy action selection to sample trajectories and each trajectory always includes the state  $s_0$ . Hence if each update is equivalent to DP update on some states, the value and policy at  $s_0$  converge to their optimal values.  $\square$

#### 3.1 PDP-V

The main idea for PDP is to restrict the update to one path in the ADD, instead of one state in RTDP, and PDP-V uses one path in the value ADD. However, this requires a careful control of the set  $M$  as shown below.

$$\mathcal{B}(V, s) = V \oplus_M \max_{\mathbf{A}} Q \quad (3)$$

$$Q = R + \sum_{X'_1} P_1 \times \dots \times \sum_{X'_l} P_l \times (\Phi(V, s) \times V') \quad (4)$$

$$M = \Phi(\max_{\mathbf{A}} Q, s) \wedge \Phi(V, s) \quad (5)$$

For a given state  $s$  and value ADD  $V$ , the values of all states that are extensions of the current path  $\Phi(V, s)$  are updated in the ADD  $Q$  (Equation 4). The ADD  $\max_{\mathbf{A}} Q$  has updated values for the path extensions of  $\Phi(V, s)$  and  $-\infty$  otherwise. But using this update with  $M = \Phi(V, s)$  might lose compactness if many of the extensions of  $\Phi(V, s)$  have different values. Additionally, the new path  $\Phi(\max_{\mathbf{A}} Q, s)$  can be shorter than  $\Phi(V, s)$  whereas only the extensions  $\Phi(V, s)$  have correctly updated values. Sound generalization and compactness are both achieved by restricting the update to the path refinement of  $\Phi(V, s)$  by setting  $M$  to be the intersection of the set of states that share the same path as state  $s$  before and after the update. This is the main difference between PDP and sRTDP. It guarantees that the updated  $V$  has the same number of leaves as the flat state update, an important guarantee for a symbolic method.

**Proposition 2.** *Let  $V$  be an ADD,  $s$  a state,  $W = \mathcal{B}(V, s)$*

and  $M$  the path according to Equation 5.

- (a) For all states  $q \in \epsilon(M)$ ,  $W[q] = \mathcal{B}^*(V, q)[q]$ .  
 (b)  $W$  grows by at most one leaf node over  $V$ .

**Proof (sketch):** (a) follows because ADD  $Q$  is a sound update for states in  $\Phi(V, s)$  (because the constraint  $\Phi(V, s)$  can be pushed inside the summation as in Raghavan *et al.* (2013)). The BDD  $M$  represents a subset of states that satisfy  $\Phi(V, s)$  due to Equation 5<sup>1</sup>. (b) is true because the path  $M$  leads to a leaf in  $\max_{\mathbf{A}} Q$ . For paths in  $1 - M$  the values are copied from  $V$  and do not add leaves to  $W$ .  $\square$

The first part of Proposition 2 guarantees the convergence of PDP-V according to Proposition 1. In practice, it is observed that the paths in symbolic VI often remain unchanged between consecutive iterations while the values have not converged. PDP-V updates these efficiently and succinctly, gaining a speedup proportional to the number of states in the path. However, in order to find the mask  $M$  in PDP-V we have to calculate updated values for all extensions of  $\Phi(V, s)$  in Equation 4, and in some cases this preparatory step exceeds memory limits. Section 4 gives an algorithm that does not have this disadvantage.

### 3.2 PDP- $\pi$

PDP- $\pi$  similarly restricts the update to one path. However, it appeals to the notion of policy irrelevance (Jong, 2005; Li *et al.*, 2006; Hostetler *et al.*, 2014), that captures states having the same optimal action. Recall that PDP maintains a policy representation in addition to the value ADDs. PDP- $\pi$  updates states that share a path in  $\pi$  before and after a DP update to the policy. The memory efficiency of path refinement is retained with respect to the policy representation.

PDP- $\pi$  starts with a trivial policy (e.g. NoOp) and refines the policy for generalized states visited by trajectories. In this way, PDP- $\pi$  behaves more like a policy search method. It is well known that in some cases paths in the policy BDD remain unchanged during iterations of symbolic VI even though the values keep changing. PDP- $\pi$  captures these succinctly (Section 5).

Let  $\pi(s)$  be the policy action, i.e., a complete assignment to action variables for state  $s$  according to BDD  $\pi$ ,  $\pi(s) = \arg \max_{\mathbf{A}} \pi_{\downarrow s}$ . In case of a tie, some action variables are set to false (including the case when they are unspecified by  $\pi_{\downarrow s}$ ). Let  $\Phi_{\pi}(s)$  be the path over state variables according to the greedy action in  $\pi$ ,  $\Phi_{\pi}(s) = \Phi(\pi, s \wedge \pi(s))$ . The update is similar to PDP-V except it uses  $\Phi_{\pi}$  and  $\arg \max$

<sup>1</sup>Note that the proposition does not hold for the path  $\Phi(W, s)$  (rather than  $M$ ) due to the  $\oplus$  operator which might merge an updated path with a path that was not updated.

instead.

$$Q = (R + \sum_{X'_1} P_1 \times \dots \sum_{X'_l} P_l \times (\Phi_{\pi}(s) \times V')) \quad (6)$$

$$\mu = \arg \max_{\mathbf{A}} Q \quad (7)$$

$$M = \Phi_{\mu}(s) \wedge \Phi_{\pi}(s) \quad (8)$$

The ADD  $Q$  contains updated values for the states in  $\Phi_{\pi}(s)$  rather than  $\Phi(V, s)$  as in PDP-V. The mask  $M$  uses  $\mu = \arg \max_{\mathbf{A}} Q$  to denote the greedy policy BDD extracted from  $Q$ . Finally, the policy BDD is updated as  $\pi = \pi \oplus_M \arg \max_{\mathbf{A}} Q$ . Clearly, the property in Proposition 2 (a) holds here as well and therefore by Proposition 1 the algorithm PDP- $\pi$  converges.

## 4 pPDP

The idea in pPDP is to repeatedly prune the intermediate ADDs of Equation 4 so that the ADD  $Q$  has space complexity no larger than the DP update of a flat state. We use the pruning operator proposed in (Raghavan *et al.*, 2013) to control the size of the ADD. Briefly, the pruning operator denoted by  $\mathcal{P}(D, C)$  for an ADD  $D$  and a constraint  $C$  represented as a BDD returns an ADD which is no larger than  $D$ . The result of pruning removes some of the paths from  $D$  that violate the constraint  $C$  but not all.

**Lemma 1.** (Raghavan *et al.*, 2013). *Let  $G = \mathcal{P}(D, \pi)$  then*

- (1) *Every path in  $G$  is a sub-path of a path in  $D$ .*
- (2) *If a path  $p$  in  $G$  does not lead to  $-\infty$ , then for all extensions  $y \in \epsilon(p)$ ,  $G(y) = D(y)$ .*
- (3) *If a path  $p$  in  $G$  does lead to  $-\infty$ , then for all extensions  $y \in \epsilon(p)$  either  $\pi(y) = -\infty$  or  $D(y) = -\infty$ .*

Part (1) gives a strong memory guarantee that  $G$  is no larger than  $D$ . Pruning accomplishes this by leaving some paths in  $G$  unchanged if only some (not all) of their extensions violate the constraint. pPDP uses the flat state  $C = s$  as the constraint. Let  $\mathcal{P}_s(D)$  denote  $\mathcal{P}(D, s)$  for any ADD  $D$  and a flat state  $s$ .

$$Q = \mathcal{P}_s(R + \mathcal{P}_s(\sum_{X'_1} P_1 \times \dots \mathcal{P}_s(\sum_{X'_l} P_l \times V'))) \quad (9)$$

As the expectation is computed over  $X'_i$ , state and action variables are introduced into the paths of  $V'$ . The paths that do not cover the current state are pruned and point to  $-\infty$ . Hence it is efficient to compute the ADD  $Q$  in memory.

**Proposition 3.** (1)  *$Q$  contains  $O(2^m)$  paths over state and action variables that do not lead to  $-\infty$ .*

(2) *Every path  $p$  that does not lead to  $-\infty$  is a DP update for the  $Q$ -value of all states and actions in  $p$ .*

**Proof (Sketch) :** (1) is due to using the state  $s$  as the constraint. Any path that has assignments to state variables

Figure 3: Example illustrating the mask  $M$  in pPDP.  $V$  is set to  $R_{\max}$  initially.  $Q$  is computed using Equation 9 for the state  $s_1 = 1, s_2 = 1$ . The ADD  $\max_{\mathbf{A}} Q$  gives an incorrect value for  $s_1 = 1, s_2 = 0$ , compared to  $W$ , the update using PDP-V (Equation 3).

differing from  $s$  is pruned and leads to  $-\infty$ . The paths that do not lead to  $-\infty$  have different assignments to action variables for a maximum of  $O(2^m)$  paths. (2) is due to part two of Lemma 1 because the pruning operator does not alter the paths that are consistent with state  $s$ .  $\square$

The pruning operator removes portions of the diagram in subtle ways and therefore we have to be careful in choosing the mask  $M$ . Consider using the path  $M = \Phi(\max_{\mathbf{A}} Q, s)$  which at first appears to be a natural choice. Unfortunately, this path does not give sound generalization because of the maximization.

To illustrate this, consider the hypothetical diagram  $Q$  shown on the left of Figure 3 where the state  $s$  assigns  $s_1 = 1$  and  $s_2 = 1$  and paths disagreeing with this assignment have been replaced with  $-\infty$ . The diagram  $\max_{\mathbf{A}} Q$  is shown on the right and gives a value of 10 for state  $s_1 = 1$  and  $s_2 = 0$ . This is incorrect since the true value of  $Q$  from the path  $s_1 = 1, a = 1, s_2 = 0$  can be larger than 10. In  $\max_{\mathbf{A}} Q$  the true value of the states on this path is ignored and assumed to be  $-\infty$ , and therefore the value calculated for the partial assignment  $s_1 = 1$  is not correct for all extensions.

To guarantee correctness we require that all the values in the sub-diagram below the node to be different than  $-\infty$ . Therefore, states whose values are valid in  $\max_{\mathbf{A}} Q$  are those where for all actions  $\mathbf{A}$ , ( $Q \neq -\infty$ ), denoted by the BDD  $\forall_{\mathbf{A}}(Q \neq -\infty)$ . In this example, ( $Q \neq -\infty$ ) when  $\{s_1 = 1, A = 0\} \vee \{s_1 = 1, A = 1, s_2 = 1\}$ , and quantification yields the mask  $M = \{s_1 = 1, s_2 = 1\}$ . Note that the BDDs  $(Q \neq -\infty)$  and  $\forall_{\mathbf{A}}(Q \neq -\infty)$  cannot be zero because all actions are updated in state  $s$ . Therefore, in the worst case, the mask  $M$  is equal to the state  $s$  and the step degenerates to a flat RTDP update. Formally, the operator used in pPDP is

$$\hat{\mathcal{B}}(V, s) = V \oplus_M \mathcal{P}_s(\max_{\mathbf{A}} Q) \quad (10)$$

$$M = \Phi(\forall_{\mathbf{A}}(Q \neq -\infty), s) \quad (11)$$

**Proposition 4.** Given an ADD  $V$  and state  $s$ , let  $W = \hat{\mathcal{B}}(V, s)$  as in Equation 10, and let  $M$  be the path from 11.

Then,  $\forall q \in \epsilon(M), W[q] = \mathcal{B}^*(V, q)[q]$ .

The proof follows from the soundness of pruning (Lemma 1) and the fact that all path extensions of  $M$  lead to a value not equal to  $-\infty$  in  $Q$ . Therefore, by Proposition 1 pPDP converges as well. In cases where PDP exceeds memory limits pPDP can capture some of the sound generalizations, precisely those that can be captured without increasing the size of intermediate  $Q$  ADD. The only overhead in pPDP is the time required for the pruning operations which is negligible.

## 5 EXPERIMENTS

We now evaluate the empirical impact of our proposed generalization operators within the family of RTDP-style algorithms. To do this we compare our algorithms PDP-V, PDP- $\pi$ , and pPDP to the following baselines: 1) **RTDP(Table)** is a simple table-based implementation of RTDP with state values initialized to  $R_{\max}$ . 2) **RTDP(ADD)** is like RTDP(Table) (i.e. no state generalization), except that each state backup is done symbolically using the FAR operator. This can be more efficient for factored actions compared to enumerating actions. 3) **sRTDP** (Feng *et al.*, 2002), where our implementation uses FAR for updates in order to exploit factored actions. 4) **LR<sup>2</sup>TDP** (Kolobov *et al.*, 2012) is an extension of RTDP(Table) to solve finite horizon MDPs using iterative deepening and labeling, which was successful in recent planning competitions. 5) **FAR** (Raghavan *et al.*, 2012) as described above. FAR is limited to 500 minutes of offline planning and then the resulting policy is executed online. This algorithm is only applicable to some of the small problem instances in our experiments and is included to give an optimal baseline value when possible.

All planners were implemented in a common framework, except for LR<sup>2</sup>TDP, for which we used the publicly available code. For PDP-V and pPDP, we initialized each  $V^i$  with  $R_{\max}$  (scaled by  $i$ ). For PDP- $\pi$ , we initialized  $\pi^i$  to the NoOp policy. Planning domains and problems are specified in the Relational Dynamic Influence Diagram Language (RDDI) (Sanner, 2010), which we convert to an ADD-based representation. The ADD variable ordering puts  $\text{parents}(X'_i)$  above  $X'_i$ , where the  $X'_i$ 's are ordered (ascending) by the number of parents that are action variables. Note that the parents include current state variables and action variables so that this defines an ordering over all variables. In all experiments, our symbolic operators allow an approximation error of  $\epsilon = 0.1$  with the upper bound merging strategy (St-Aubin *et al.*, 2001).

Our experiments below are on 5 problem instances of varying sizes from three domains of the 2011 and 2014 International Probabilistic Planning Competitions (IPPCs). A memory limit of 4G is imposed to restrict the size of the

ADDs, beyond which the planner can no longer proceed which we denote as “EML”(Exceeded Memory Limit). A planner is evaluated on a problem by running 30 trials of horizon 40 and averaging the total reward across the trials. We report the averages and 95% confidence intervals for each problem. Planners use a specified time limit per decision and we give results for different time limits. The value functions and policies are reinitialized after each decision.

**Academic Advising Problem:** The Academic Advising domain (Guerin *et al.*, 2012), from IPPC 2014, is a stochastic cost minimization problem that models the process of selecting the courses for a student in order to complete degree requirements, where the courses have complex prerequisite structure. The state space encodes which courses have been taken and whether they were passed or not. The actions at each step correspond to selecting one or more courses to take next. We consider two variants of the domain, a non-concurrent variant, which only allows a single course to be selected at each decision point, and a concurrent version, which allows multiple courses to be selected. The dynamics encode the probability that a course is passed if taken. Missing requirements and retaking of courses are penalized.

Figure 4<sup>2</sup> shows the performance vs. time for the different planners on IPPC 2014 problem instances for the non-concurrent and concurrent variants. All algorithms use a planning lookahead horizon of 16 steps. In the non-concurrent variant and shortest time limit (top left panel), we see that sRTDP fails to scale beyond the two smallest problems, and that FAR is able to solve these two problems as well. In larger instances both of these methods EML. In contrast, PDP-V, PDP- $\pi$  and pPDP are able to give good performance across problem sizes. Moreover, for the smallest instances where FAR is able to compute an optimal policy, these algorithms yield near optimal performance. This result demonstrates the importance of using update operators that attempt to trade-off generalization and memory usage.

The flat search methods RTDP(Table), RTDP(ADD), and LR<sup>2</sup>TDP do not perform well. For the largest three instances, these methods have a return no better than that of a NoOp policy. This shows the importance of generalization across states in order to achieve good performance in reasonable time.

Comparing performance across time limits (increasing time from left to right) we see the following. The flat search methods are not able to improve by much as the time limit is increased. PDP-V, PDP- $\pi$  and pPDP also do not improve significantly with more time. Importantly they are able to avoid EML as more trajectories are sampled with larger time limits. PDP-V shows the most improvement on the largest instance as time increases. This shows that, in this

domain, the use of generalization by our methods is the dominating factor in improving performance, and is even more effective than increasing the time limit.

Figure 4 (bottom) shows results for the same problem instances, but with concurrency (of 5 for the first instance and 2 for others). Here, both sRTDP and FAR (not shown) EML even for the smallest instances. The flat search methods degrade quickly as the problem instances become larger. Our proposed methods (with one exception) outperform the competitors, especially for the larger instances. The exception is PDP- $\pi$  on the largest instance, which results in EML after 18 seconds of planning due to the size of the intermediate ADDs in Equation 6. If we increase the time further (not shown here), PDP-V also does EML. On the other-hand pPDP does not result in EML due to its guarantees on bounding the diagram size (including intermediate diagrams), possibly at the expense of less aggressive generalization.

**SysAdmin Problem :** SysAdmin (Guestrin *et al.*, 2001) models a computer network with  $n$  computers. Computers can fail with some probability, which requires a reboot action to correct. Neighbors of a failed computer have a higher probability of failing. The reward is based on the number of running computers with a cost associated with a reboot action. Unlike the academic advising domain, the number of reachable states in this domain is practically the entire state space. To allow sRTDP to produce non-EML results we consider networks of 10 computers connected in a star network. Following Raghavan *et al.* (2012), we consider problems that vary the maximum number of computers that can be rebooted per decision (1, 3, 5, 7, or 10), which gives a progressively growing factored action space.

Figure 5 gives results for three different time-limit settings. Due to the highly random nature of the problem, we used a short lookahead of four steps for all algorithms. The curve above the bar graphs shows the performance of the optimal policy found by FAR.

sRTDP exhibits interesting behavior in this domain. It performs worse than using no state generalization (i.e. RTDP(ADD)) in the first four instances and then optimally for the largest instance. The increased complexity of the sRTDP backup causes poor performance in the smaller action spaces—sRTDP samples fewer trajectories than our algorithms. On the largest instance as the value ADD becomes more compact (more states have similar values), sRTDP is able to exploit generalization. This shows the difficulty of predicting apriori how much space and time the sRTDP generalization operator may require. In this domain, PDP-V and pPDP scale similarly to RTDP(ADD), because the reward function involves counting the number of computers, which makes the path formula  $\Phi(R, s)$  the same as  $s$ . This means that these algorithms achieve very little state generalization in this domain. However, they

<sup>2</sup>Charts best viewed in color.

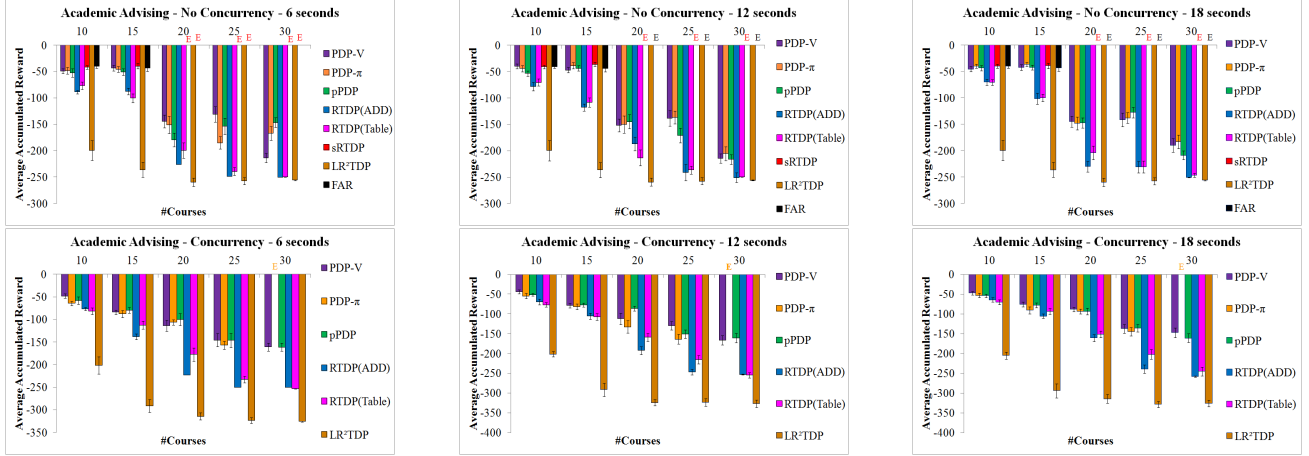

Figure 4: Academic Advising Problem : Performance vs. Time for time limits 6, 12 and 18 seconds per decision without (with) concurrency in the top (bottom) panels respectively. Error bars show 95% confidence intervals. The state space is  $2^{2x}$ ,  $x$  is the number of courses shown on the x-axis.

do outperform RTDP(Table) due to the use of the factored FAR backup compared to a backup based on action enumeration.

In this domain, PDP- $\pi$  clearly outperforms PDP-V and pPDP. In this case, policy irrelevance is able to capture abstract states more succinctly. For example, in the first instance, any state in which the computer at the center of the network is down has the same path formula :  $\sim \text{running}_{c1} \Rightarrow \text{reboot}_{c1}$ . Note that the values of these states are not equal and depend on the status of other computers. As parallelism increases, nodes near the center get added to these rules regardless of the status of nodes farther away. Clearly, in this domain, generalization based on policy irrelevance is more appropriate than value irrelevance.

Finally we see that as the time limit increases there is a small improvement in performance for most algorithms. It is clear that the increase in performance due to larger time limits is not as significant as using the appropriate generalization mechanism, in this case policy irrelevance.

**Crossing Traffic Problem:** This IPPC 2011 domain models the arcade game Frogger, where the agent moves in a 2-D grid to cross a road to reach a goal location, while avoiding right-to-left moving cars that enter the road randomly from the rightmost column. The reward is -1 for each move and -40 for collision.

The boolean encoding of this domain has  $|S| = O(2^{2(n^2)})$  for an  $n \times n$  grid, with two bits per cell for the presence of the agent and car respectively. However, depending on the current location of the agent, many of these bits can be ignored for predicting the optimal value and action.

Figure 6 shows the results for different time limits and problem instances involving 3x3, 4x4, and 5x5 grids. There is larger variance in this domain, compared to the others, due to collisions. We see that sRTDP performs well in the

first three instances and is able to improve with more time per decision. However, in instances 4 and 5 sRTDP exceeds memory limits when given more time. PDP-V and PDP- $\pi$  scale to these instances and times without EML. PDP- $\pi$  performs better than PDP-V initially but PDP-V is able to improve more than PDP- $\pi$  with more time per decision. We see that these algorithms outperform RTDP(ADD), showing that generalization is clearly useful in this domain. Again we see that generalizing appropriately is the dominating factor toward performance compared to increasing the time limit. pPDP never performs worse than the flat search methods RTDP(Table) and RTDP(ADD), and outperforms them in some cases. Its less aggressive generalization, however, leads to overall worse performance compared to our other algorithms.

**Large instances :** The preprocessing of translating RDDDL to propositional logic does not scale for the large instances from the IPPC. For the purpose of showing the scaling of our algorithms, we refactored the RDDDL domain - by decomposing the “robot-at(x,y)” propositions into two independent propositions “robot-at(x)” and “robot-at(y)” because the actions’ effects are independent along  $x$  and  $y$  dimensions. Figure 8 shows the performance of PDP, PDP- $\pi$ , pPDP and sRTDP for grids of sizes  $6 \times 6$  and  $7 \times 7$ .

The algorithms are given much more time per decision to demonstrate the comparative scaling. The charts show the percentage out of 30 trials that the agent reached the goal. We see that in the 6x6 grid (left panel) PDP-V outperforms sRTDP by a large amount. sRTDP is able to scale with time without EML and slowly converges to optimal performance. By comparison, sRTDP does not perform well in the 7 by 7 problem (right panel) whereas PDP-V is able to make progress. PDP- $\pi$  performs worse (better) than sRTDP in the former (latter) instance. The flat search methods are not able to make any progress in this problem due

Figure 5: SysAdmin Problem vs. concurrent actions : The state space is  $2^{10}$  and action space is  $O(2^x)$ ,  $x$  is the maximum number of parallel actions.

Figure 6: Crossing Traffic Problem : The odd numbered instances have  $3 \times 3$ ,  $4 \times 4$ , and  $5 \times 5$  grids arrival probability of 30%. The even numbered instances have the same grid sizes but with arrival probability of 60%.

Performance vs. Time for 6, 12 and 18 seconds per decision. Error bars show 95% confidence intervals.

Figure 8: Crossing Traffic (large instances) : Performance vs. Time with 30, 60, 90 and 120 seconds per decision. Error bars show 95% confidence intervals.

Figure 9: A generalized state discovered by PDP-V in the Crossing Traffic problem. The grid denotes a flat state  $s_0$  and the tiles in blue denote the generalized state  $\Phi(V_0, s_0)$ .

to the large stochastic branching factor. pPDP is able to improve on the flat search in the first instance but falls back to the flat method in the larger problem.

Finally, we present a generalized state found by PDP-V to illustrate the effectiveness of generalization in these problems. Figure 9 shows an instance of the Crossing Traffic problem. All the cells in the grid, including the location of the agent and each car, constitute a flat state. The cells within blue denote the cells that appear in the path formula  $\Phi(V_0, s_0)$  after running PDP-V from  $s_0$ . We see that PDP-

V is able to ignore the assignments to many cells that are irrelevant for optimal online planning.

## 6 SUMMARY

We presented the first fully symbolic planning algorithms for factored MDPs that generalize simulated experience soundly and efficiently. This work is orthogonal to research on improving the anytime performance of RTDP algorithms via smart sampling (McMahan *et al.*, 2005; Walsh *et al.*, 2010) and heuristics (Kolobov *et al.*, 2012; Keller & Helmert, 2013). There were several observations from our experimental results. First, in all domains, we saw that using the appropriate form of generalization was the dominating factor towards good performance compared to increasing the time-limit for algorithms without state generalization. Second, we saw that the most appropriate form of generalization can differ across domains and sometimes problem instances within a domain. This suggests that it is fruitful to investigate mechanisms for tuning or selecting among generalization methods. Third, pPDP never exceeded memory limits, while other generalization approaches did occasionally. Further, previous versions of sRTDP, very frequently exceeded memory limits. This suggests that pPDP is perhaps the safest choice for generalization, especially for large problems and short time limits.

## Abstract

Survival analysis is a core task in applied statistics, which models time-to-failure or time-to-event data. In the clinical domain, for example, meaningful events are defined as the onset of different diseases for a given patient. Survival analysis is limited, however, for analyzing modern electronic health records. Patients often have a wide range of diseases, and there are complex interactions among the relative risks of different events. To this end, we develop the survival filter model, a time-series model for joint survival analysis that models multiple patients and multiple diseases. We develop a scalable variational inference algorithm and apply our method to a large data set of longitudinal patient records. The survival filter gives good predictive performance when compared to two baselines and identifies clinically meaningful patterns of disease interaction.

## 1 INTRODUCTION

Electronic health records enable unprecedented opportunity to understand and form predictions about disease [Jensen et al., 2012, Hripcsak and Albers, 2013]. With historical data about the trajectories of millions of patients, we can learn patterns of disease risk and exploit these patterns to provide better care to future patients.

The classical statistics tool for analyzing the progression of a disease is survival analysis, a method that estimates each patient's hazard or risk for a disease in question [Cox, 1972]. Survival analysis is widely used in medical science to characterize and understand the progression of individual diseases [Shepherd et al., 1995, Stupp et al., 2005].

Classical survival analysis, however, cannot accommodate the complex health data that we now have collected; it is only formulated to analyze one disease at a time. In modern electronic health record data, patients often have several

diseases (called “comorbidities”) with complex interactions among them. Specifically, the occurrence of one disease often affects the progression of others. We need new tools to account for this complexity.

Consider the data in Figure 1, where time is in the x-axis. The top panel shows the setting that classical survival analysis requires. All patients begin at the same time, and we measure one disease outcome. (In this case, it is whether the patient is diagnosed with diabetes.) The bottom panel illustrates the real-world setting of electronic health records. Patients begin at different times and we simultaneously measure many different diseases. These data can potentially reveal interactions between patterns of progression, but classical survival analysis cannot provide such inferences. For example, Patient 1 in the bottom panel illustrates that diabetes and hypertension are significant risk factors for developing a myocardial infarction. A traditional survival analysis may be constructed to capture this specific interaction, but cannot simultaneously capture the relationship between risk factors for diabetes (e.g., obesity) and the onset of diabetes.

We build on survival analysis to develop the survival filter, a new probabilistic model for estimating multivariate risk patterns from large-scale electronic health records. The survival filter is a latent-variable time series model of diagnostic codes. Each patient is represented as a sequence of latent variables. At each time point, a patient's hazards for each disease relates to his or her latent representation.

The survival filter can be thought of as a joint survival analysis model where each patient's sequence of latent representations loosely represents his or her state of health. Given a large data set of patients over time—data of the form of the bottom panel of Figure 1—survival filter inference characterizes each patient and captures complex global patterns of interactions for a large set of diseases.

Using the survival filter, we study 13,000 patients from NewYork-Presbyterian Hospital; these data span over 20 years and contain 8,800 types of diagnoses. It scales well to this size of data and uncovers meaningful relationships be-

tween diseases that would otherwise be difficult to identify.

## 2 SURVIVAL ANALYSIS

In this section we review survival analysis and hazards.

**Survival Analysis.** Survival analysis studies the time duration until the occurrence of an event. Example events include failure of a machine, heart attack, and retirement.

Observations in survival analysis have two types. The first type of observation indicates the event has occurred (called “failure”) at a specific time (failure time). The second type indicates the event has not occurred before the observed time. These observations are called censored observations because the true failure time is censored in the observed data. Formally, the observations in survival analysis can be represented as pairs  $(t, c)$  where  $t$  is a time, and  $c$  is a binary value that indicates whether the observation is censored.

The simplest model for survival analysis assumes that the failure times are drawn from some unknown distribution  $F$  over positive values. The setup assumes that all observations are synchronized at their starts. Given this modeling choice, a nonparametric estimate of the CDF of  $F$ , also denoted by  $F$ , is the Kaplan-Meier estimator [Kaplan and Meier, 1958]. The Kaplan-Meier estimator is the nonparametric maximum likelihood estimator of  $1 - F(t)$ , also called the survival function, in the presence of censored data.

The time measurements in survival analysis can be treated as continuous or discrete (e.g., months or years). In this article we will focus discrete survival times.

**Hazards.** An alternative view of survival analysis is through hazard functions. Hazard functions represent the instantaneous chance of failing at time  $t$  given survival up to time  $t$ . In the discrete time setting, the hazard is the conditional probability of failing at time  $t$  given that the failure occurs at time  $t$  or later,

$$h(t) = P(T = t | T \geq t). \quad (1)$$

The Nelson-Aalen [Nelson, 1972] estimator forms the nonparametric maximum likelihood estimator of the sum of hazard function over time (cumulative hazard). The CDF  $F$  of the underlying distribution implied by the hazards is

$$F(t) = 1 - \exp\left(\sum_{s=0}^t h(s)\right).$$

Unlike the cumulative distribution function and survival function, we can specify the hazard function locally in each discrete time block by a number between zero and one. We will use this property when we develop the survival filter.

## 3 THE SURVIVAL FILTER FOR ELECTRONIC HEALTH RECORDS

In this section we first describe electronic health records and corresponding survival problems. We then describe our model, the survival filter.

**Electronic Health Records.** The Electronic Health Record (EHR) comprises all documentation entered for a patient throughout their interactions with a healthcare institution. It contains a wide range of observations through time, ranging from free-text notes authored by clinicians, medication orders, laboratory test results, procedures, demographic information, and diagnosis codes.

Diagnosis codes (also called billing codes) are structured codes from a standard taxonomy, namely the ICD9 hierarchy (International Classification of Diseases, 9th revision). ICD9 codes are used in all healthcare institutions. While the ICD9 hierarchy contains approximately 16,000 codes, in practice about 9,000 of them are commonly documented. After each visit, a clinician assigns each patient a set of ICD9 codes to reflect the diseases or concerns that were taken care of during the visit.

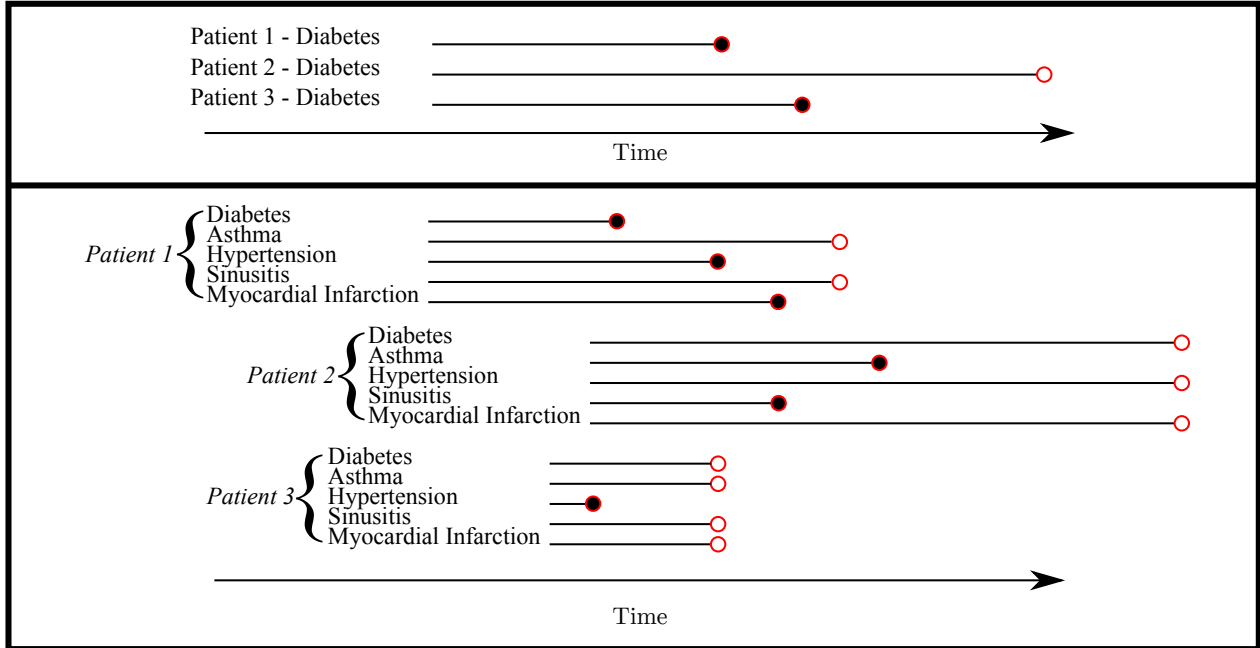

For instance, after a visit to their primary provider, a patient is assigned ICD9 codes for “Essential Hypertension,” and “Diabetes”. At their next visit to their ophthalmologist, the patient can have the ICD9 code for “Nonproliferative Diabetic Retinopathy.” In this example, while the patient has diabetes at both visits, the ICD9 code for diabetes is only observed at the first visit. Furthermore, note that the ICD9 codes are correlated. Retinopathy, an eye condition, is a common complication for patients with diabetes, and hypertension and diabetes are known comorbidities.

EHR data are longitudinal records, represented as a collection of per-patient time series ICD9 codes. Note that an extremely sparse set of ICD9 codes will be used for any given patient.<sup>1</sup> Our goal is to use these data to run a joint survival analysis of every ICD9 code. Specifically, we seek a method that:

- estimates the per-patient risk for all ICD9 codes at any given visit time;
- handles multiple survival problems that are not aligned in time across patients;
- scales to 9,000 ICD9 codes;
- captures interaction between survival problems (e.g., retinopathy, diabetes, and hypertension).

This differs significantly from the setup of traditional survival analysis, where patients are forced to start at the same

<sup>1</sup>In our representation, we use “visit time,” not clock time, as the time unit. Visit time better represents time when studying the temporal course of diseases [Hripcsak et al., 2015].

**Figure 1:** A comparison of standard survival analysis (top frame) and the survival filter (bottom frame). A filled circle represents an observed event, while an empty circle represents a censored one. In the case of standard survival analysis, patients in a cohort are aligned by an event. In the survival filter, patients are not aligned and unlike standard survival analysis, many conditions are considered simultaneously.

time and where we can only analyze a single disease. We now describe the survival filter, a model that addresses these goals to perform large-scale joint survival analysis of EHR.

**Survival Filter.** In the discrete time setting, let the observation pair  $(t, c)$  of time and censoring indicator be represented as a binary vector indexed by the clock with length equal to the observation time. This binary vector has a one in the last entry in the case of failure and is all zero in the case of censoring. We adopt this view of the observations for the survival filter.

Let  $P$  be the number of patients. Let  $n_p$  be the number of time intervals for patient  $p$ , and  $C$  be the number of codes. Then the observation  $x_{p,t,c}$  is one if the code  $c$  is marked in the  $t$ th time interval for patient  $p$  and zero if code  $c$  has not yet occurred for patient  $p$ . To generate this data we propose a latent time series model where each patient has a  $K$  dimensional latent path which along with a  $C \times K$  weight matrix  $W$  produces the hazard for each of the  $C$  codes. Let  $D$  be a distribution over the positive reals. The generative process for this model is

$$\begin{aligned}
 W &\sim D \\
 z_{p,1} &\sim \text{Normal}(z_\mu, \sigma_{z_0}^2) \\
 z_{p,t} &\sim \text{Normal}(z_{p,t-1}, \sigma_z^2) \\
 x_{p,t,c} &\sim \text{Bernoulli}(1 - \exp(-W_c^\top \exp(z_{p,t}))).
 \end{aligned}$$

The hazard of a code  $c$  for patient  $p$  at a time  $t$  is  $1 - \exp(-W_c^\top \exp(z_{p,t}))$ . The positivity of  $W$  and  $\exp(z_{p,t})$  guarantee that  $1 - \exp(-W_c^\top \exp(z_{p,t}))$  is a valid hazard (probability) between zero and one. Larger  $W_{c,k}$  indicate larger hazards for code  $c$  when factor  $k$  is active.

This model handles the criteria described above. First, it provides a simultaneous analysis of all ICD9 codes. Second, it handles misaligned patients by defining the hazards to be a function of the a shared latent space rather than a function of a fixed shared clock  $h(t)$  (as in the classical setting). Third, through the matrix  $W$  it captures the relationship between different survival problems. Specifically, when  $W_{c,k}$  and  $W_{d,k}$  are large, the events  $c$  and  $d$  are more likely to co-occur. Finally, as we will show in Section 4, we can perform efficient computation for the survival filter.

We consider two different priors on  $W$ : the log-normal and the gamma. The gamma distribution is sparsifying when its shape is less than one (this can be seen from the PDF), while the log-normal distribution has a heavier tail. Recent results [Mimno et al., 2014] have shown that log-normal distributions achieve better predictive results and diversity among the weights in a Poisson network model. We derive inference and compare both the log-normal and gamma prior in the experimental section.

**Related Work.** Survival analysis methods have been generalized in many ways beyond the Kaplan-Meier estimator.

One example of such an extension is recurrent event models [Clayton, 1994] which allow for multiple events rather than single events. Cox proportional hazards [Cox, 1972] introduces fixed covariates to scale the patient hazards based on their covariates. Time varying Cox proportional hazard models [Fisher and Lin, 1999] are like Cox proportional hazards, but have a set of covariates that change with time for each patient. Cox-proportional hazard methods are similar to ours in that they define different clocks through the covariates, but differ in that they require covariates and do not capture the relationship between different survival problems. The model with the most similar goal is MEPSUM [Dean et al., 2014]. MEPSUM is a mixture model for multiple kinds of events happening simultaneously. The relationship between events is captured via the latent class label as each latent class contains a nonparametric hazard function for every type of event. Unlike our model, their model assumes that patients are synchronized in time when there are no covariates. Additionally the formulation of their model means that it scales with the number of codes rather than the number of failures, which makes it impractical in large sparse datasets such as those found in electronic health records.

## 4 INFERENCE

The main computational problem in working with the survival filter is computing the posterior distribution of the weights and latent patient trajectory. Computing the posterior of the survival filter analytically is intractable since our likelihood cannot be integrated out. Thus posterior computations require approximations. In this section, we develop a scalable mean field variational inference [Jordan et al., 1999] algorithm to approximate the posterior distribution of the survival filter.

Variational inference transforms the posterior inference problem into an optimization problem. The optimization problem defined by variational inference seeks to find a distribution  $q$  in an approximating family that is close in KL divergence to the posterior distribution. This is equivalent to maximizing the following [Bishop, 2006]:

$$\mathcal{L}(q) := \mathbb{E}_q[\log p(x, z, W) - \log q(z, W)].$$

This function is called the evidence lower bound (ELBO) as it forms a lower bound on  $\log p(x)$ .

**Variational Approximation.** Recall for the survival filter the latent variables are (1)  $z_{pt}$  for all latent states associated with patient  $p$  at time index  $t$  and (2)  $W$ , the matrix shared

across observations. The joint distribution can be written as

$$p(x, z, W) = \prod_{k=1}^K \prod_{c=1}^C p(W_{c,k}) \prod_{p=1}^P p(z_{p,1,k}) \prod_{c:a_{p,1}} p(x_{p,1,c} | z_{p,1}, W) \prod_{t=2}^{n_p} \prod_{k=1}^K p(z_{p,t,k} | z_{p,t-1,k}) \prod_{c:a_{p,t}} p(x_{p,t,c} | z_{p,t}, W).$$

The mean field family posits a variational distribution where the latent variables are independent of each other. Each factorized  $q$  belongs to the same family as in the generative process. Formally, the approximating distribution is

$$q(z, W) = \prod_{k=1}^K \prod_{c=1}^C q(W_{c,k} | \lambda_{c,k}^0, \lambda_{c,k}^1) \prod_{p=1}^P \prod_{t=1}^{n_p} \prod_{k=1}^K p(z_{p,t,k} | \mu_{p,t,k}, \sigma_{p,t,k}^2),$$

where  $\lambda_{c,k_0}$ ,  $\lambda_{c,k_1}$ ,  $\mu_{p,t,k}$ , and  $\sigma_{p,t,k}$  are variational parameters. These variational parameters are then set via an optimization procedure to maximize the ELBO.

**Classical Optimization.** Typical optimization methods for mean field variational inference iteratively optimize the variational parameters associated with each latent variable by holding the others fixed. These updates are easy to derive when the model’s log complete conditional (the log of the distribution of each latent variable conditioned on the rest) has analytic expectation with respect to the variational approximation. This analytic property most commonly occurs in conditionally conjugate exponential families models where the complete conditional is in the exponential family [Ghahramani and Beal, 2001]. Unfortunately, none of the latent variables in our model fall into this class. Instead, we derive a variational algorithm based on sampling from the variational approximation [Salimans and Knowles, 2013, Kingma and Welling, 2014, Rezende et al., 2014, Ranganath et al., 2014, Titsias and Lázaro-Gredilla, 2014].

**Sampling based Variational Inference.** We briefly review stochastic optimization before discussing sampling based variational inference. In the following, we use  $\lambda$  as an example parameter. Let  $\mathcal{L}(\lambda)$  be a function to be maximized and let  $\hat{\nabla}_\lambda \mathcal{L}(\lambda)$  be a draw from a random variable whose expectation is the true gradient  $\nabla_\lambda \mathcal{L}(\lambda)$ . Let  $\rho_t$  be the learning rate, then stochastic optimization updates to the current parameter  $\lambda_t$  can be made with

$$\lambda_{t+1} = \lambda_t + \rho_t \hat{\nabla}_\lambda \mathcal{L}(\lambda).$$

---

**Algorithm 1** Stochastic Variational Inference for the Survival Filter
 

---

**Input:** data  $X$   
**Initialize**  $\lambda$  randomly,  $t = 1$ .  
**repeat**  
 Sample a batch of datapoint  $x_{1...B}$   
**for**  $b = 1...b$  in parallel **do**  
 Use stochastic optimization with Eq. 4 to find the optimal  $\mu_{b,v}$  and  $\sigma_{b,v}$   
**end for**  
 Compute the noisy global gradient for  $\lambda$  (Example: Eq. 8)  
 Update  $\lambda$  with RMSProp  
**until** change in validation metric is small

---

This update converges to a local maximum when the learning rate satisfies the Robbins Monro conditions

$$\sum_{t=1}^{\infty} \rho_t = \infty$$

$$\sum_{t=1}^{\infty} \rho_t^2 < \infty.$$

Stochastic optimization has become a widely used tool in variational inference.

Returning to variational inference, the variational objective is an expectation with respect to the variational approximation. Sampling based variational inference works by writing the gradient of the ELBO as an expectation followed by a stochastic optimization driven by Monte Carlo estimates of the gradient written as an expectation. The gradient as an expectation step comes in two main flavors: (1) those based on transformations and (2) those based on the score function (gradient of the log probability) of the variational approximation. We use both of these techniques to derive an inference algorithm for the survival filter (See the appendix for derivation details).

**Algorithm.** Algorithm 1 summarizes the parallelized stochastic variational inference algorithm we use to approximate posteriors of the variational approximation.

**Scalability** To scale to a large number of censored codes, we need to be able to efficiently compute the likelihood for a patient  $p(x_p)$ . Let  $a_{p,t}$  be the set of codes that have not occurred before time  $t$  for patient  $p$ . Define  $R_{p,t}$  as the relative log likelihood of the failed codes minus the previously failed codes:

$$R_{p,t} = \sum_{c: x_{p,t,c}=1} \log p(x_{p,t,c}=1) - \log p(x_{p,t,c}=0)$$

$$- \sum_{c:[C] \setminus a_{p,t}} \log p(x_{p,t,c}=0).$$

Note that  $R_{p,t}$  can be computed on the order of the number of failures for patient  $p$

By the generative process, we have that the likelihood is

$$\log p(x_p) = \sum_{t=1}^{n_p} \sum_{c \in a_{p,t}}^C \log p(x_{p,t,c})$$

$$= \sum_{t=1}^{n_p} \sum_{c=1}^C \log p(x_{p,t,c}=0) + R_{p,t}$$

$$= \sum_{t=1}^{n_p} \sum_{c=1}^C \log(1 - (1 - \exp(-W_c^\top \exp(z_{p,t})))) + R_{p,t}$$

$$= \sum_{t=1}^{n_p} \sum_{c=1}^C -W_c \exp(z_{p,t}) + R_{p,t}$$

$$= - \left( \sum_{c=1}^C W_c \right) \left( \sum_{t=1}^{n_p} \exp(z_{p,t}) \right) + \sum_{t=1}^{n_p} R_{p,t}. \quad (2)$$

This means that the likelihood for a patient can be computed in time  $O((C + n_p)K + n_p s_p K)$  where  $s_p$  is the number of failures for patient  $p$  instead of of  $O(C n_p K)$ . Thus the runtime scales with the number of uncensored codes rather than by the total number of codes. This efficiency in computing the likelihood will allow for the construction of efficient inference algorithms that scale with the number of failures in the data.

## 5 EMPIRICAL STUDY

In this section, we describe our experimental setup and results.

**Datasets.** Our dataset comprises the longitudinal records of 13,180 patients from a large, metropolitan healthcare institution, NewYorkPresbyterian Hospital. IRB approval was obtained for these experiments. The patient records contain documentation pertaining to all visit types, including outpatient visits, emergency department visits, as well as hospital admissions and intensive care stays (thus with varying ICD9 codes through time for a given patient). The only criteria to include patients in the dataset was at least 5 visits overall to the institutions and among them at least 3 to a primary provider care clinic. We truncated the longitudinal records of patients to 50 visits at most, and thus the mode of the visits was 50. Note that even though the time unit for our analysis is visit, the patient records actually have a wide range of durations (mean 14.5 years; std dev 8 years; median 15.5 years).

For the 13,180 patients, there were overall 8,722 unique ICD9 codes present in at least one visit. On average, each visit had 3.61 ICD9 codes assigned (std dev 2.28; median 3.05), and patients had an average of 189 (std dev 178; median 138) ICD9 codes in their longitudinal records, corre-

sponding to 57 unique codes on average (std dev 36; median 49).

Thus, our dataset represents a large set of patients with a wide range of conditions, as reflected by the large number of ICD9 codes in the dataset.

For our experiments, we held out 100 patient records for validation and parameter tuning and 1,000 patient records for testing purposes.

**Evaluation Metrics.** Standard evaluations in traditional survival analysis rely on concordance; essentially how well can the model rank patients according to the order in which the outcome is observed. This assumes a common clock, or  $t_0$  for all patients, an assumption not held for the survival filter model. Instead, we propose the following three metrics: predictive log likelihood on held out data to assess model fitness, and two metrics well defined in the case of multiple, simultaneous survival analyses. All three metrics are computed by looking forward in the patient time series. We keep the approximate posterior of the shared weights from the training cohort fixed throughout testing.

The first metric computes the log likelihood of all ICD9 codes that have not yet occurred at each visit conditional on all the patient history prior to the visit. Thus, log likelihood is:

$$\log p(x_{c,p,t}) = -W_c^\top z_{p,t-1} \mathcal{I}(x_{c,p,t} = 0) + \log(1 - \exp(-W_c^\top z_{p,t-1})) \mathcal{I}(x_{c,p,t} = 1),$$

where  $\mathcal{I}$  is the indicator function. For each patient in the test set, the predictive log likelihood is computed at each visit after the third visit. Procedurally, this means that we test at visit 4 conditioning on the first three visit, followed by testing at visit 5, conditioning on the first four, and so on.

The second metric computes the Mean Average Ranking of the codes that failed (i.e., first time observed) at visit  $t$  in the set of all ICD9 codes that have not yet failed (i.e., not yet observed) at that visit. The ICD9 ranks are computed by ordering the hazards the model assigns to each code at visit  $t$  based on the patient’s latent state at visit  $t - 1$ .

The third metric is Recall at D (in our experiments, D is set to 10). Recall at D computes how many failed codes (i.e., first time observed) are in the top D codes, as ordered by the hazards assigned by the model to each code.

**Baselines** We consider two baselines for this problem. The first baseline, which we call Mean Disease Risk, considers the frequency of ICD9 codes over the entire population. Given the training set of longitudinal records, a mean hazard is computed for each ICD9 code. Thus, this baseline outputs a fixed hazard prediction through time for any new patient visit.

The second baseline is patient specific, and is called Person Disease Risk. It computes a single hazard for all ICD9 codes

| Factor A  | Factor B  |
|---|---|
| Lumbago<br>Osteoarthritis<br>Myalgia and myositis<br>Pain in joint<br>Pain in limb<br>Backache<br>Arthropathy<br>Pain in joint involving lower leg<br>Cervicalgia<br>Pain in joint involving shoulder region  | Depressive disorder<br>Anxiety state<br>Major depressive disorder, recurrent<br>Major depressive disorder, single episode<br>Dysthymic disorder<br>Adjustment disorder<br>Unknown cause of morbidity or mortality<br>Panic disorder without agoraphobia<br>Unspecified personality disorder<br>Palpitations |
| Factor C  | Factor D  |
| HIV counseling<br>Pregnant state, incidental<br>Vaginitis<br>Special gynecological examination<br>Routine gynecological examination<br>Counseling and advice on contraception<br>Mother with single liveborn<br>Supervision of other normal pregnancy<br>Normal delivery<br>Leiomyoma of uterus | Headache<br>Dizziness and giddiness<br>Migraine<br>Disorder of optic nerve and visual pathways<br>Visual field defect<br>Unspecified endocrine disorder<br>Cushing's syndrome<br>Optic atrophy<br>Neoplasm of endocrine glands<br>Visual discomfort   |

**Figure 3:** Example factors for the survival filter represented by the ICD9 codes with highest hazard for each factor.

based on the empirical frequency of failures at all previous visits. This baseline captures in essence the level of sickness of a patient, as sicker patients experience more code failures (i.e., observe more ICD9 codes).

**Hyperparameters.** We set the prior variance on the initial state of the latent trajectories to 10 and the prior mean  $-3$ . The large variance accounts for the fact that patient’s records start at different points. We set the transition variance to  $.1$ . For log-normal weights we set the log scale to  $\log(10^{-10})$ , and the shape to 30. This distribution places a lot of mass near zero. To encourage sparsity of the gamma weights, we set the shape to  $.02$  and the rate to  $0.3$ .

RMSProp also contains a scaling parameter. For the local maximization step we use a decreasing schedule given by  $(1 + t)^{-.8}$  and for the global gradients we set the constant to  $.1$ .

We explore several different sizes for the latent space ranging from  $K = 5$  to  $K = 100$ .

**Results.** Figure 2 plots the evaluation metrics as a function of  $K$  for the log-normal model. We find that the model with  $K = 25$  does best with the best predictive log likelihood and a nearly best performance on Mean Average Ranking. All of the models outperform the plotted mean disease risk baseline on all metrics. We find that the gamma models performs worse than the log-normal model for all  $K$  with a best test log likelihood of  $-284874$ . Finally, all of the models outperform the person disease risk baseline on log likelihood ( $-359079$ ).

Figure 3 displays four of the factors found by the log-normal survival filter with  $K = 25$ . These components represent clinically meaningful groups of conditions.

**Figure 2:** The survival filter (blue dots) outperforms the mean disease risk baseline (dashed red line) for all values of  $K$  on all metrics.

## 6 DISCUSSION

In this paper, we have developed the survival filter, a latent timeseries model for joint survival analysis. The main advantages of the survival include jointly modeling time-to-event data for a large set of events and without specifying alignment across individuals, and an efficient mean field variational inference algorithm that scales in the number of events. We demonstrated the use of the survival filter by measuring the predictive likelihood on a real-world clinical data set and demonstrate superior performance relative to baselines and interpretable latent factors.

The survival filter is a general joint survival analysis model and can be used to study survival problems beyond those in electronic health records. It can be used in any situation where there are multiple simultaneous survival problems that are not necessarily aligned by a true clock. For example, the survival filter can be used to make movie recommendations. In this setting the codes are movies, and the patients are the users. Here, failure of a particular code at time  $t$  means that a movie was watched at time  $t$  and the hazards capture the chance that a movie is watched by a user at time  $t$ .

## 7 APPENDIX

**Sample-based gradients** Transformation based approaches [Kingma and Welling, 2014, Rezende et al., 2014, Titsias and Lázaro-Gredilla, 2014] write the ELBO as an expectation with respect to the a standard distribution without variational parameters and moves the differential operator inside of the expectation. Formally let  $r(y)$  be a standard distribution and let  $T$  be a transformation such that  $T(y, \lambda)$  is distributed as  $q_\lambda$ , then the ELBO can be written as

$$\mathcal{L}(\lambda) = \mathbb{E}_r[\log p(x, T(y, \lambda)) - \log q(T(y, \lambda))].$$

When  $T$  and the model and approximation are differentiable the gradient of the ELBO is given by the ELBO as

$$\nabla_\lambda \mathcal{L}(\lambda) = \mathbb{E}_r[\nabla_z [\log p(x, T(y, \lambda)) - \log q(T(y, \lambda))] \nabla_\lambda T].$$

See Kingma and Welling [2014] for a complete derivation of this identity. In our use below,  $r$  will be the standard normal transformation and  $T$  will be  $z = \sigma y + \mu$ .

Score function based approaches [Ranganath et al., 2014, Mnih and Gregor, 2014] are based on the following identity

$$\nabla_\lambda \mathcal{L}(\lambda) = \mathbb{E}_q[\nabla_\lambda \log q(z|\lambda)(\log p(x, z) - \log q(z))]. \quad (3)$$

See Ranganath et al. [2014] for a derivation of this.

The convergence time of stochastic optimization is related to its noise, so in the sequel we derive analytically when possible.

**Gradient for  $q(z_{p,t})$ .** The variational approximation  $q(z_{p,t,k} | \mu_{p,t,k}, \sigma_{p,t,k}^2)$  is a normal distribution with mean  $\mu_{p,t,k}$  and variance  $\sigma_{p,t,k}^2$ . The gradient for the variational parameters can be mostly computed analytically.

$$\begin{aligned} \nabla_{\mu_{p,t,k}} \mathcal{L} &= -\exp(\mu_{p,t,k} + \frac{1}{2}\sigma_{p,t,k}^2) \sum_{c=1}^C \mathbb{E}[W_c] \\ &\quad - \frac{1}{\sigma_z^2} (2\mu_{p,t,k} - \mu_{p,t-1,k} - \mu_{p,t+1,k}) \\ &\quad + \nabla_{\mu_{p,t,k}} \mathbb{E}[R_{p,t}], \\ \nabla_{\sigma_{p,t,k}^2} \mathcal{L} &= -\frac{1}{2} \exp(\mu_{p,t,k} + \frac{1}{2}\sigma_{p,t,k}^2) \sum_{c=1}^C \mathbb{E}[W_c] \\ &\quad - \frac{1}{\sigma_z^2} - \nabla_{\sigma_{p,t,k}^2} \mathbb{E}[R_{p,t}] + \frac{1}{2\sigma_{p,t,k}^2}. \end{aligned} \quad (4)$$

$\mathbb{E}[W_c]$  can be computed analytically for both the gamma and log-normal distribution. Recall the definition of  $R_{p,t}$

$$\begin{aligned} R_{p,t} &= \sum_{c: x_{p,t,c}=1} \log p(x_{p,t,c}=1) - \log p(x_{p,t,c}=0) \\ &\quad - \sum_{c:[C] \setminus a_{p,t}} \log p(x_{p,t,c}=0). \end{aligned}$$

Its expected value is

$$\begin{aligned} \mathbb{E}_q[R_{p,t}] &= \sum_{c:x_{p,t,c}=1} \mathbb{E}[\log p(x_{p,t,c} = 1)] \\ &+ \mathbb{E}[W_c]^\top \mathbb{E}[\exp(z_{p,t})] \\ &+ \sum_{c:[C]\setminus a_{p,t}} \mathbb{E}[W_c]^\top \mathbb{E}[\exp(z_{p,t})]. \end{aligned}$$

Its derivative with respect to its mean is computed by the transformation approach using the identity  $z = y\sqrt{\sigma_{p,t,k}^2} + \mu_{p,t,k}$  where  $y$  is drawn from a standard normal  $\mathcal{N}$ .

$$\begin{aligned} \nabla_{\mu_{p,t,k}} \mathbb{E}_q[R_{p,t}] &= \sum_{c:x_{p,t,c}=1} \mathbb{E}_q(W_c) \mathbb{E}_{y \sim \mathcal{N}} \left[ \frac{W_{c,k} \exp(z)}{\exp(-W_c^\top \exp(z)) - 1} \right] \\ &+ \mathbb{E}[W_{c,k}] \exp(\mu_{p,t,k} + \frac{1}{2}\sigma_{p,t,k}^2) \\ &+ \sum_{c:[C]\setminus a_{p,t}} \mathbb{E}[W_{c,k}] \exp(\mu_{p,t,k} + \frac{1}{2}\sigma_{p,t,k}^2). \end{aligned}$$

Similarly it's derivative with respect to the variance is given as

$$\begin{aligned} \nabla_{\sigma_{p,t,k}^2} \mathbb{E}_q[R_{p,t}] &= \frac{1}{2} \left( \sum_{c:x_{p,t,c}=1} \mathbb{E}_q(W_c) \mathbb{E}_{y \sim \mathcal{N}} \left[ \frac{y W_{c,k} \exp(z)}{\exp(-W_c^\top \exp(z)) - 1} \right] \right. \\ &+ \mathbb{E}[W_{c,k}] \exp(\mu_{p,t,k} + \frac{1}{2}\sigma_{p,t,k}^2) \\ &+ \left. \sum_{c:[C]\setminus a_{p,t}} \mathbb{E}[W_{c,k}] \exp(\mu_{p,t,k} + \frac{1}{2}\sigma_{p,t,k}^2) \right). \end{aligned}$$

We can compute noisy, unbiased estimates of this gradient by sampling from the variational approximation for  $W_{c,k}$  and sampling  $y$  from the standard normal.

The gradient can be computed in time  $O((C + n_p)K + n_p s_p K)$  rather than  $O(Cn_p K)$ . The only portion of the gradient that we cannot compute analytically is the portion associated with failing codes. This portion requires sampling from the variational approximation. This means we can exploit the sparsity of the failures as we only have to sample small fractions of the  $W$  matrix rather than the entire  $W$  matrix. This results in an order of magnitude less samples from the underlying random generator for each noisy gradient and produces lower variance gradients than sampling entirely.<sup>2</sup>

The gradient of the variational parameters of the first and last point can be expressed similarly.

<sup>2</sup>Variance can be a problem in sampling based variational approximations [Kingma and Welling, 2014, Rezende et al., 2014, Ranganath et al., 2014].

**Gradients for Log-Normal  $W$ .** Similar to the time series  $z_{p,t}$ , the only component of the gradient of the variational parameters of  $W$  that is not analytically tractable is due to the failures. To symmetrize this update with the latent time series, we represent the log-normal distribution as an exponentiated normal. That is  $W_{c,k} = \exp(\tilde{W}_{c,k})$ , where  $\tilde{W}_{c,k}$  is normally distributed with mean  $\mu_w$  and variance  $\sigma_w^2$ . In this setup, the variational approximation for  $\tilde{W}_{c,k}$  is normally distributed with variational parameters  $\lambda_{c,k}^0$  (the mean) and  $\lambda_{c,k}^1$  (the variance). The gradient for the mean of the variational approximation is given by

$$\nabla \lambda_{c,k}^0 = -\frac{1}{\sigma_w^2} (\mu_w - W_{c,k}) \quad (5)$$

$$- \exp(\lambda_{c,k}^0 + \frac{1}{2}\lambda_{c,k}^1) \sum_{p=1}^P \sum_{v=1}^{n_p} \mathbb{E}[\exp(z_{p,t,k})] \quad (6)$$

$$+ \nabla \lambda_{c,k}^0 \mathbb{E}[R_{p,t}]. \quad (7)$$

and the gradient of the variance is

$$\begin{aligned} \nabla \lambda_{c,k}^1 &= -\frac{1}{2\sigma_w^2} \\ &- \exp(\lambda_{c,k}^0 + \frac{1}{2}\lambda_{c,k}^1) \sum_{p=1}^P \sum_{v=1}^{n_p} \frac{1}{2} \mathbb{E}[\exp(z_{p,t,k})] \\ &+ \nabla \lambda_{c,k}^1 \mathbb{E}[R_{p,t}] + \frac{1}{2\lambda_{c,k}^1}. \end{aligned}$$

The gradients of  $R$  are symmetric to the time series updates for both the mean and variance parameter.

Note that the gradient can be computed in time proportional to the number of failures ( $O((C + n_p)K + (\sum_{p=1}^P n_p s_p) K)$ ) rather than the number of codes multiplied by the number of visits ( $O(CK \sum_{p=1}^P n_p)$ ) as sum of  $\mathbb{E}[\exp(z_{p,t,k})]$  across all patients and visits can be shared for each code.

**Gradients for Gamma  $W$**  Finally, we consider the gradient of the parameters of the variational approximation of  $W$  when  $W$  is drawn from a gamma distribution in the generative process. In this setup, the variational approximation for each entry in the weight matrix is gamma distributed with shape  $\lambda_{c,k}^0$  and scale  $\lambda_{c,k}^1$ . Similarly the only part of the gradient for this approximation that cannot be computed analytically is due to the failures. The gradient with respect to the shape is

$$\begin{aligned} \nabla \lambda_{c,k}^0 &= -\beta_w \lambda_{c,k}^1 + (\alpha_w - 1) \Psi^{(1)}(\lambda_{c,k}^0) + 1 \\ &+ (1 - \lambda_{c,k}^0) \Psi^{(1)}(\lambda_{c,k}^0) \\ &- \lambda_{c,k}^1 \sum_{p=1}^P \sum_{v=1}^{n_p} \frac{1}{2} \mathbb{E}[\exp(z_{p,t,k})] \\ &+ \nabla \lambda_{c,k}^0 \mathbb{E}[R_{p,t}]. \end{aligned}$$

where  $\Psi$  is the digamma function and  $\Psi^{(1)}$  is its derivative. The gradient with respect to the scale parameter is

$$\begin{aligned} \nabla_{\lambda_{c,k}^1} &= \beta_w \lambda_{c,k}^0 + \frac{(\alpha_w - 1)}{\lambda_{c,k}^1} + \frac{1}{\lambda_{c,k}^0} \\ &\quad - \lambda_{c,k}^0 \sum_{p=1}^P \sum_{v=1}^{n_p} \frac{1}{2} \mathbb{E}[\exp(z_{p,t,k})] \\ &\quad + \nabla_{\lambda_{c,k}^1} \mathbb{E}[R_{p,t}]. \end{aligned}$$

Similar to the log-normal case this gradient scales with number of failures, and the  $\log p(x = 0)$  terms can be computed analytically.

Rather than using transformations to compute gradient of the expected value of  $\log p(x = 1)$ , we use score style gradients. We already know how to evaluate  $\log p(x = 1)$ , so the all we need to compute the gradient is the score function of the gamma distribution for both the shape  $\alpha$  and the scale  $\kappa$ . The score function of the shape is

$$\nabla_{\lambda_{c,k}^0} \log q(w_{c,k}) = -\log(\lambda_{c,k}^1) - \Psi(\lambda_{c,k}^0) + \log(w_{c,k})$$

The score function of the scale is

$$\nabla_{\kappa} \log q(w_{c,k}) = -\frac{\lambda_{c,k}^0}{\lambda_{c,k}^1} + \frac{w_{c,k}}{\lambda_{c,k}^1{}^2}.$$

Plugging this into Eq. 3 and approximating the expectation by Monte Carlo yields a noisy gradient of the ELBO.

**Data subsampling.** Given the noisy gradients just derived, we can use stochastic optimization to maximize the ELBO. This procedure is inefficient in that every single observation has to be iterated over in order to compute the gradient of the variational parameters for shared  $W$ . Another way this procedure is computationally wasteful is that at early iterations work done on all of the local parameters is based on the randomly initialized variational parameters for shared structure. These inefficiencies can be prohibitive when dealing with large datasets or large data instances.

Stochastic variational inference (SVI) [Hoffman et al., 2013] addresses this by using stochastic optimization. SVI works by first identifying local parameters, latent variables associated with a datapoint, and global parameters, shared latent variables. Next a datapoint is sampled, the optimal variational distribution for the local parameters is computed based on the current value of the global parameters, and a noisy gradient based on the sampled data point is computed. SVI generalizes this to drawing batches of datapoints rather than drawing a single datapoint at each update.

In the survival filter the global parameters are the weights and the local parameters are the latent trajectory. For a fixed variational approximation on  $W$ , we compute the optimal local variational parameters by running a stochastic optimization procedure with noisy gradient given by Eq. 4. An

example global gradient for log-normal weights is given by

$$\begin{aligned} &-\frac{1}{\sigma_w} (\mu_w - W_{c,k}) \\ &\quad - \frac{P}{B} (\exp(\lambda_{c,k}^0 + \frac{1}{2} \lambda_{c,k}^1) \sum_{b=1}^B \sum_{v=1}^{n_{p_b}} \mathbb{E}[\exp(z_{p_b,t,k})] \\ &\quad + \nabla_{\lambda_{c,k}^0} \mathbb{E}[R_{p_b,t}]). \end{aligned} \tag{8}$$

where we have reweighted the data term to maintain unbiasedness of the gradient.

Our approach differs from standard SVI in that we use stochastic optimization to compute the optimal local variational parameters. This approach allows differs from the double stochastic approaches in sampling based variational methods [Titsias and Lázaro-Gredilla, 2014, Ranganath et al., 2014] in that we do run a complete maximization procedure for each data point that is sampled rather than simply follow a noisy gradient. This maximization step can be time consuming, so we find the optimal local variational approximation in parallel.

**Learning Rates.** The standard robbins monro learning rate can be challenging to set in that it does not account for varying length scales or different amounts of noise in each gradient of the coordinate. We instead use RMSProp<sup>3</sup> which scales the gradient by the square root of a running average of the squared gradient. This handles varying length scales as multiplying the objective by a constant does not change the step. RMSProp controls for noise as the moving average of the squared gradient is larger when the variance of the gradient is larger.

## Abstract

In this paper, we study the problem of empirical loss minimization with  $l_2$ -regularization in distributed settings with significant communication cost. Stochastic gradient descent (SGD) and its variants are popular techniques for solving these problems in large-scale applications. However, the communication cost of these techniques is usually high, thus leading to considerable performance degradation. We introduce a novel approach to reduce the communication cost while retaining good convergence properties. The key to our approach is the construction of a small summary of the data, called *coreset*, at each iteration and solve an easy optimization problem based on the coreset. We present a general framework for analyzing coreset-based optimization and provide interesting insights into existing algorithms from this perspective. We then propose a new coreset construction and provide its convergence analysis for a wide class of problems that include logistic regression and support vector machines. Preliminary experiments show encouraging results for our algorithm on real-world datasets.

## 1 INTRODUCTION

Empirical loss minimization is one of the most fundamental principles in supervised learning. The key idea is to minimize the loss on the training data subject to some regularization on the model that is being learned. More formally, given the training data  $P = \{(x_1, y_1), \dots, (x_n, y_n)\}$  from a probability distribution on  $\mathcal{X} \times \mathcal{Y}$ , we are interested in the following generic optimization problem:

$$\min_w f(w) \equiv \frac{\lambda}{2} \|w\|^2 + \frac{1}{n} \sum_{i=1}^n \ell(x_i, y_i, w) \quad (1)$$

Throughout this paper we assume that  $\ell$  is convex. Furthermore, we assume that  $\mathcal{X} = \mathbb{R}^d$  and  $\mathcal{Y} = \mathbb{R}$ . Note that the objective function above is strongly convex (a function  $f$  is strongly convex with modulus  $\lambda$  if  $f(w) - \frac{\lambda}{2} \|w\|^2$  is a convex function). Problems conforming to Equation (1) include popular supervised learning algorithms like support vector machines and regularized logistic regression. For example, when  $x_i \in \mathbb{R}^d$ ,  $y_i \in \{-1, 1\}$  and  $\ell(x_i, y_i, w) = \log(1 + \exp(-y_i w^\top x_i))$  (logistic loss), the optimization problem in Equation (1) corresponds to regularized logistic regression. The loss function  $\ell$  is not necessarily smooth as in, for example, support vector machines (SVM) where  $\ell(x_i, y_i, w) = \max(0, 1 - y_i w^\top x_i)$  (hinge loss).

Several algorithms have been proposed in the literature for solving optimization problems of the aforementioned form. We will briefly review a few key approaches in Section 2; however, the algorithms are either largely synchronous or communication intensive. For example, one of the popular approaches for solving such optimization problems is stochastic subgradient descent. At each iteration of the algorithm, a single training example is chosen at random and used to determine the subgradient of the objective function. While such an approach reduces the computation complexity at each iteration, the communication cost is prohibitively expensive in distributed environment.

In this paper, we study the problem described in Equation (1) in the setting where the data is distributed across nodes and hence, communication is expensive in comparison to the computation time. *The main theme of this paper is to reduce communication cost by constructing and optimizing over a small summary of the training data — which acts as a proxy for the entire data set.* Such a summary of the training points is called a *coreset*. While this methodology has been successfully applied to data clustering problems like k-means and k-median (we refer the reader to [4, 5] for a comprehensive survey), it remains largely unexplored for supervised learning and optimization problems. The goal of this paper is to advance the frontier in this direction. In light of the above, the primary contributions of this paper are as follows:

- We describe a general framework for designing coreset-based algorithms. This also provides insights into existing algorithms from the coresets viewpoint.
- We propose a novel coreset-based algorithm with low communication cost and provable guarantees on the convergence to the optimal solution.
- We demonstrate the efficiency of the proposed algorithm on a few real-world datasets. In particular, we show that the proposed approach reduces the communication cost significantly.

Our paper is structured as follows. We begin with a discussion on the related work in Section 2. In Section 3, we describe a general framework for the coreset-based methodology. We then propose a coreset-based algorithm in Section 4 and provide its convergence analysis. We finally conclude by demonstrating the empirical performance of the algorithm in Section 5.

## 2 RELATED WORK

As noted earlier, problem in Equation (1) arises frequently in the machine learning and optimization literatures and hence has been a subject of extensive research. Consequently, we cannot hope to do full justice to all the related work. We instead mention the key relevant works here and refer the reader to the appropriate references for a more thorough coverage.

**First-order methods:** In large-scale machine learning and convex optimization applications, first-order methods are popular due to their cheap iteration cost. The classic approach in first order methods is the gradient descent approach. For strongly convex functions  $f$  with  $L$ -lipschitz gradient, gradient descent has linear convergence rate i.e.,  $f(w_t) - f(w_*) \leq \epsilon$  in  $O(\log(1/\epsilon))$  iterations where  $w_t$  and  $w_*$  are the  $t^{\text{th}}$  iterate of gradient descent and the optimal solution respectively [10]. The constants can be further improved by the means of accelerating techniques [10]. On the other hand, when  $\ell$  is non-smooth, gradient descent methods have sub-linear convergence rates.

While gradient descent methods have appealing convergence properties, they have two major shortcomings: (1) they require evaluation of  $n$  gradients at each iteration, typically leading to high computational cost, and (2) the communication costs is also high. A popular modification of this algorithm in large-scale settings is the stochastic gradient descent. While the computational cost per iteration decreases, the linear convergence property is lost. This is due to the variance introduced by stochasticity of the approach. Recently, there has been a surge in interest to address this issue by incremental methods (see [13, 7]). By reducing the variance, these approaches achieve low iteration complexity while retaining the good convergence properties. How-

ever, all these approaches still do not address the other major shortcoming — namely, high communication cost.

**Active Set & Cutting plane Methods:** Our approach is also related to the classic active set and cutting plane methods used in the optimization and the machine learning literatures [11]. The basic idea is to find a *working set* of constraints, i.e., those inequality constraints of the optimization problem that are either fulfilled with equality or are otherwise important to the optimization problem. These methods are particularly popular in the SVM literature. Scheinberg et al. [12] and Joachims et al. [6] provide more details on these approaches. However, these approaches are inherently sequential and not communication friendly. Moreover, it is observed that these approaches are typically outperformed by subgradient methods [14]. While the basic theme of these methods is similar to that of ours insofar that we compute a similar *summary* of the training data at each iteration, the key distinction is the approach and methodology used in constructing the summary. Moreover, our approach is much more general and can be applied to a wide range of loss functions.

**Coresets:** Our approach is closely related to the paradigm of coresets used in the theory literature [2, 4, 5]. The basic idea of coresets is to extract a small amount of relevant information from the given data and work on this extracted data. Coresets have been proposed on a variety of data clustering problems such as  $k$ -means,  $k$ -medians, and projective clustering. This approach is particularly important for NP-hard problems like  $k$ -means. For example, coresets of size  $O(k/\epsilon^4)$  and independent of  $n$  (number of the data points) have been proposed for the  $k$ -means problem [2, 4]. If  $k$  is small, such an approach makes it possible to find optimal solution of  $k$ -means simply by an exhaustive search. Furthermore, coresets can seamlessly handle distributed and streaming settings and hence, are suitable to large-scale real-world applications. We refer the reader to the excellent (but outdated) survey on coresets [1] for more details. Recently, a unifying coreset framework has been proposed for data clustering problems [4], which provides a more comprehensive treatment; interested readers may also refer to the references therein. While there has been some progress in borrowing ideas from coresets in the context of SVMs [15], this intersection remains largely unexplored.

**Distributed Methods:** Owing to large-scale machine learning applications, there has been a recent surge of interest in distributed training of models. The basic idea is to solve subproblems in parallel, followed by averaging at each iteration. For example, [17, 9] propose an algorithm with a trade-off between computation and communication costs. The Alternating Direction Method of Multipliers (ADMM) [3] and its variants are also popular approaches that fall in this category. However, these strategies are either synchronous and communication unfriendly since no communication occurs during the compu-

tation phase. Mini-batch approaches have received considerable attention recently. We refer the reader to [8] and references therein for a more thorough analysis of mini-batch approaches based on stochastic gradient descent.

### 3 A GENERAL FRAMEWORK

We describe our general methodology in this section. Before delving into the details of the framework, we introduce a few definitions and notations in order to simplify our exposition. We denote the objective function in Equation (1) by  $f(w; P)$ . Recall that  $P$  is the training set. The optimal solution of Equation (1) is denoted by  $w_*$  i.e.,

$$w_* = \operatorname{argmin}_w f(w; P) \equiv \frac{\lambda}{2} \|w\|^2 + \frac{1}{n} \sum_{i=1}^n \ell(x_i, y_i, w).$$

We use  $R_*$  to denote  $\|w_* - w_0\|$ , the distance of optimal solution from the initial point. Next, we define the key ingredient in our approach.

**Definition 1.** (Coreset) For given functions  $f$  and  $g$ , we call a set  $C$  an  $\epsilon$ -coreset of  $P$  on a set  $\Omega$  if  $|g(w; C) - f(w; P)| \leq \epsilon$  for all  $w \in \Omega$ .

Note that the above definition is slightly different from the one typically used in the coreset literature (see [4]) in two ways: (i) the set  $C$  is not necessarily a subset of  $P$ . In particular, when the function is of the form described in Equation 1, typically, coresets are constructed for the specific function of  $g$  being the weighted sum of loss and coreset  $C$  being a subset of  $P$ . However, this is not necessarily the case here. (ii) the coreset is restricted to the domain  $w \in \Omega$ . Another noteworthy point is that while coresets are classically defined as a multiplicative approximation, we use the notion of additive approximation. All these relaxations allow us to view other related algorithms through the lens of coresets. The key desirable property of a coreset is that the cardinality of the set  $C$  is small, which will help us reduce the overall communication complexity of the algorithm. For brevity, we drop  $C$  and  $P$  from the notations  $g(w; C)$  and  $f(w; P)$  respectively whenever  $C$  and  $P$  are clear from the context.

With this background we are ready to state our algorithm. At each iteration of the algorithm, the key component of our framework is to compute a new coreset-based on the current solution and solve the optimization problem based on that coreset. The pseudocode is given as Algorithm 1.

First, we note that algorithm is still abstract because it does not specify details about the function  $g_{t-1}(w; C_{t-1}, w_{t-1})$  and coreset  $C_{t-1}$ . Furthermore, feasible region of the subproblem  $\Omega(w_{t-1}, R_{t-1})$  at each iteration is unspecified. These details depend on the specific coreset construction and hence, are explained during the description of the coreset. We now state a general result on performance of Algorithm 1 based on some important properties of the coreset.

---

#### Algorithm 1 Generic Iterative Coreset Algorithm

---

**INPUT:** Initial  $w_0$ , coefficients  $\{\gamma_1, \dots, \gamma_T\}$

- 1: **for**  $t = 1$  to  $T$  **do**
- 2:   Compute the coreset  $C_{t-1}$  with the corresponding function  $g_{t-1}(w; C_{t-1}, w_{t-1})$
- 3:   Solve the following subproblem

$$w_t = \operatorname{argmin}_{w \in \Omega(w_{t-1}, R_{t-1})} g_{t-1}(w; C_{t-1}, w_{t-1})$$

- 4:    $R_t = \gamma_t \cdot R_{t-1}$
  - 5: **end for**
- 

For ease of analysis, throughout the paper, we assume that  $\gamma_t$  is chosen in such a way that  $R_t = \|w_t - w_*\|$ . The analysis for the case where  $R_t$  is an upper bound on  $\|w_t - w_*\|$  is similar.

**Theorem 1.** Suppose we have the following conditions on the function  $g_{t-1}$  for  $1 \leq t \leq T$ :

1.  $g_{t-1}$  is an upper bound on  $f$  and is strongly convex with modulus  $\lambda'_{t-1}$ , for some  $\lambda'_{t-1} > 0$ .
2. The feasible region  $\Omega(w_{t-1}, R_{t-1})$  is convex and contains the optimal solution  $w_*$ .
3.  $C_{t-1}$  is an  $\Delta_{t-1}$ -coreset of  $P$  on  $\Omega(w_{t-1}, R_{t-1})$  with respect to functions  $g_{t-1}$  and  $f$ . More precisely, we need  $g_{t-1}(w; C_{t-1}, w_{t-1}) \leq f(w; P) + \Delta_{t-1}$  for all  $w \in \Omega(w_{t-1}, R_{t-1})$ .

Then for the iterates  $\{w_t\}_{t=1}^T$  of Algorithm 1 we have,

$$R_t = \|w_t - w_*\| \leq \sqrt{\frac{2\Delta_{t-1}}{\lambda + \lambda'_{t-1}}}.$$

*Proof.* We have the following inequalities:

$$\begin{aligned} g_{t-1}(w_*) &\leq f(w_*) + \Delta_{t-1}, \\ g_{t-1}(w_t) + \langle \partial g_{t-1}(w_t), w_* - w_t \rangle \\ &\quad + \frac{\lambda'_{t-1}}{2} \|w_t - w_*\|^2 \leq g_{t-1}(w_*) \end{aligned}$$

The first inequality follows from condition 3 of the theorem. The second inequality follows from the fact that  $g_{t-1}$  is strongly convex with modulus  $\lambda'_{t-1}$  (condition 1). Adding the above two inequalities we get

$$\begin{aligned} g_{t-1}(w_t) + \langle \partial g_{t-1}(w_t), w_* - w_t \rangle \\ + \frac{\lambda'_{t-1}}{2} \|w_t - w_*\|^2 \leq f(w_*) + \Delta_{t-1}. \end{aligned} \tag{2}$$

Because  $f$  is strongly convex with modulus  $\lambda$ , we have

$$f(w_*) + \langle \partial f(w_*), w_t - w_* \rangle + \frac{\lambda}{2} \|w_t - w_*\|^2 \leq f(w_t).$$

Combining it with the fact that  $g_{t-1}$  is an upper bound on function  $f$  (condition 1), we have

$$f(w_*) + \langle \partial f(w_*), w_t - w_* \rangle + \frac{\lambda}{2} \|w_t - w_*\|^2 \leq g_{t-1}(w_t). \quad (3)$$

Adding Equations (2) and (3), we get the following.

$$\langle \partial g_{t-1}(w_t), w_* - w_t \rangle + \langle \partial f(w_*), w_t - w_* \rangle + \frac{(\lambda + \lambda'_{t-1})}{2} \|w_t - w_*\|^2 \leq \Delta_{t-1} \quad (4)$$

To complete the proof we need the following intermediate result.

**Lemma 1.** *Suppose  $g_{t-1}$  satisfies the conditions in Theorem 1, then for iterates  $w_t$ , for  $1 \leq t \leq T$ , of Algorithm 1 we have*

$$\langle \partial g_{t-1}(w_t), w_* - w_t \rangle \geq 0 \quad (5)$$

$$\langle \partial f(w_*), w_t - w_* \rangle \geq 0 \quad (6)$$

*Proof.* We prove the inequality in Equation (5). The inequality in Equation (6) can be proved in a similar manner. Let  $A = \Omega(w_{t-1}, R_{t-1})$  and  $\mathbb{I}_A : \mathbb{R}^d \rightarrow \mathbb{R}^+$  be the indicator function corresponding to  $A$  i.e.,

$$\mathbb{I}_A(w) = \begin{cases} 0 & \text{if } w \in A \\ +\infty & \text{if } w \notin A \end{cases}$$

Recall that the  $w_t$  is the optimal solution of the following:

$$w_t = \operatorname{argmin}_{w \in A} g_{t-1}(w).$$

From the optimality condition of  $w_t$ , we have  $\partial g_{t-1}(w_t) + \partial \mathbb{I}_A(w_t) = 0$ . Therefore, we have

$$\langle \partial g_{t-1}(w_t), w_* - w_t \rangle = \langle -\partial \mathbb{I}_A(w_t), w_* - w_t \rangle \quad (7)$$

Since  $A$  is convex (condition 2 of Theorem 1), the subgradient will be the normal cone of  $A$ . Using the fact that  $w_*, w_t \in A$  (condition 2 of Theorem (1)) and from the definition of the normal cone, we have

$$\langle -\partial \mathbb{I}_A(w_t), w_* - w_t \rangle \geq 0.$$

Using the above inequality in Equation (7), we get the required result.  $\square$

Using the inequalities from Lemma 1 in Equation (4) it is easy to see that the result follows.  $\square$

The above result gives an upper bound on the distance of the iterate  $w_t$  in Algorithm 1 from the optimal solution  $w_*$ . Note that the bound depends on  $\Delta_{t-1}$  which in turn typically depends on the optimality of  $w_{t-1}$ . It is easy to see that convergence to the optimal solution is possible as long

as  $\lim_{t \rightarrow \infty} \Delta_t = 0$ . It is also worth noting that result does not assume anything on the size of the coreset  $C_t$ . However, as we shall see, the communication and computation complexity of the algorithm will critically depend on  $|C_t|$  at each iteration.

Before discussing our algorithm based on this framework, we consider a popular instantiation of this framework — gradient descent. For this discussion, we assume that the loss function  $\ell$  is differentiable and has  $L$ -lipschitz gradient i.e.,  $\|\partial \ell(x_i, y_i, w) - \partial \ell(x_i, y_i, w')\| \leq L\|w - w'\|$ . This smoothness condition on the gradient gives us the following useful result.

**Lemma 2.** [10] *For any function  $h : \mathbb{R}^d \rightarrow \mathbb{R}$  with  $L$ -Lipschitz continuous gradient  $\partial h$ , we have*

$$h(x) \leq h(y) + \langle \partial h(y), x - y \rangle + \frac{L}{2} \|x - y\|^2, \quad \forall x, y \in \mathbb{R}^d.$$

The update for gradient descent is the following:

$$w_{t+1} = w_t - \gamma \partial f(w; P), \quad (8)$$

where  $\gamma$  is the learning rate and is typically set to  $1/L$ . Such an update can be obtained by minimizing the upper bound on  $f$  in Lemma 2. We briefly explain how gradient descent like method fits our framework. We choose the coreset<sup>1</sup>  $C_t = \partial f(w_t; P)$  and the function  $g_t$  as follows:

$$g_t(w; C_t, w_t) = f(w_t; P) + \langle \partial f(w_t), w - w_t \rangle + \frac{L + \lambda}{2} \|w - w_t\|^2 \quad (9)$$

First note that the function  $g_t$  is an upper bound of  $f$  and is strongly convex with modulus  $L + \lambda$ . This can be obtained from Lemma 2. Hence,  $g_t$  satisfies condition 1 of Theorem 1. Next, we set  $\Omega(w_t, R_t) = \mathcal{B}(w_t, R_t)$  where  $\mathcal{B}(w, R)$  represents a ball of radius  $R$  centered around  $w$ . Since this is convex and  $R_t = \|w_t - w_*\|$ , it is easy to see that condition 2 of Theorem 1 holds.

Finally,  $g_{t-1}$  is an  $\Delta_{t-1}$ -coreset with  $\Delta_{t-1} \leq LR_{t-1}^2/2$ . This can be obtained by a straightforward reasoning based on the Taylor expansion of  $f$  and Lemma 2. Thus all the conditions of Theorem 1 hold. Hence, using Theorem 1 we obtain the following corollary.

**Corollary 1.** *The iterates  $w_t$  of gradient descent algorithm like algorithm (minimizing upper bound in Equation 9 subject to the constraint on  $w \in \Omega(w_t, R_t)$ ) satisfy*

$$R_t = \|w_t - w_*\| \leq \sqrt{\frac{2LR_{t-1}^2}{2(L + 2\lambda)}} = R_{t-1} \sqrt{\frac{1}{(1 + \frac{2\lambda}{L})}}.$$

<sup>1</sup>Recall that the coreset could be any summary of the data, and not necessarily one of its subsets.

In general, dropping the constraint that  $w \in \Omega$ , recovers the gradient descent algorithm. The above corollary reproduces the well-known linear convergence rate for gradient descent [10]. Note the dependence of the convergence rate on the condition number  $L/\lambda$ . While the result does not lead to any new convergence rates, it provides an interesting insight that gradient descent can be viewed as solving an optimization problem on a *coreset* based on the gradients at each iteration. However, it is important to note that the communication cost is still high when the condition number is large since the gradient needs to be communicated at each iteration. Hence, gradient descent is not suitable for settings of our interest — that is, distributed settings where communication is expensive.

A natural question that arises is whether we can construct more interesting coresets than the gradients of the function. We provide an affirmative answer to this question in the next few sections.

## 4 CORESET ALGORITHM

In this section, we propose a new coreset-based algorithm. Before discussing the details of the coreset contribution, it is worth mentioning two additional assumptions; however, we should emphasize that the first assumption is only for the ease of exposition.

1. The loss function  $\ell$  is of the form  $\ell(x_i, y_i, w) = \ell(y_i w^\top x_i)$ . Note the slight abuse of notation in the usage of  $\ell$ . In what follows, the quantity  $y_i w^\top x_i$  is referred to as *margin*.
2.  $\ell$  is  $L$ -lipschitz continuous i.e.,  $|\ell(y_i w^\top x_i) - \ell(y_i w'^\top x_i)| \leq L|y_i w^\top x_i - y_i w'^\top x_i|$ .

Loss functions that satisfy the above properties include popular choices such as logistic loss (used in logistic regression) and hinge loss (used in SVM). The significance of these assumptions will become clear as we proceed. We also need the following definitions for our discussion.

**Definition 2.** (Cover) We call a set of points  $S$  as  $\epsilon$ -cover of a set of points  $Q$  if for all  $q \in Q$  there exists a point  $s \in S$  such that  $\|s - q\| \leq \epsilon$ .

Let  $N(x)$  for a point  $x$  in the cover denote the set of points in  $Q$  that are closer to  $x$  than any other point in the cover  $S$ . With slight abuse of notation, let  $\epsilon(Q) = [S, \beta]$ , where  $S$  is an  $\epsilon$ -cover of  $Q$ , and  $\beta$  is the vector of cardinalities of the sets  $\{N(x)|x \in S\}$ . Note that  $\|\beta\|_1 = |Q|$ .

The key insight to our coreset construction of the algorithm is that typically at each iteration there exist only a few *important* data points that are critical from the optimization perspective. For example, consider an iterative algorithm for SVMs. Intuitively, at each iteration, the points that are

close to the margin are crucial in comparison to those away from it. Furthermore, due to the piecewise linear nature of the hinge loss, the points far away from the margin can be represented by a linear function precisely. Hence, it is possible to obtain a good summary of the data through few points near the margin and a linear function. With this intuition, we now present our coreset construction.

We define the set  $P' = \{x'_i\}_{i=1}^n$  where  $x'_i = y_i x_i$ . Our coreset construction consists of two primary steps:

**Step 1:** Identify points whose loss can be approximated by a linear function and construct a *single* linear function as a coreset for these points. Generally, these are points where gradient approximation is good. We denote such a function by `LINEARAPPROX`. The description of this function will depend on  $\ell$ .

**Step 2:** Construct a cover or equivalent functional approximation for the rest of the points in the set  $P'$ . Since  $\ell$  is assumed to be lipschitz, such a cover also provides approximation guarantees on the empirical loss on  $P'$ .

It should be emphasized that while we use the concept of cover for simplicity, a similar analysis can be carried out for clustering based algorithms. In fact, as we will see later, all our experiments are based on clustering. At each iteration, we use disjoint sets  $G_t$  and  $E_t$  to denote the points concerned with these two steps respectively. Note that  $G_t \cup E_t = P'$ . We use  $l_t \in \mathbb{R}^d$  to denote the linear approximation of loss for points in  $G_t$ . Our coreset is  $C_t = (I_t, \beta_t, l_t)$  where  $[I_t, \beta_t] = \epsilon_t(E_t)$  and function  $g_t$  in Algorithm 1 is as follows.<sup>2</sup>

$$g_t(w; C_t) = \frac{\lambda}{2} \|w\|^2 + \frac{1}{n} \left( \sum_{x_e \in I_t} \beta_t^e \ell(w^\top x_e) + w^\top l_t \right) + h_t \tag{10}$$

where  $h_t = (2LR_*|E_t|\epsilon + |G_t|\delta + c)/n$  for some  $\delta > 0$  and constant  $c$ . The pseudocode, based on the above key steps, is given as Algorithm 2. The size of the coreset  $C_t$  depends on the cardinality of set  $E_t$ .

For simplicity, we assume that  $w_0 = 0$  for our analysis. In this case, we have  $R_* = \|w_*\|$ . One of the key components of Algorithm 2 is the function `LINEARAPPROX`. As mentioned earlier, in general, this function depends on the loss function  $\ell$ . We choose  $\Omega(w_0, R_0) = \mathcal{B}(w_0, R_0)$  and  $\Omega(w_t, R_t) = \Omega(w_{t-1}, R_{t-1}) \cap \mathcal{B}(w_t, R_t)$  for  $t \in [1, \dots, T-1]$ . Recall that we assume the coefficients  $\{\gamma_1, \dots, \gamma_T\}$  are chosen in a way such that  $R_t = \|w_t - w_*\|$ . We prove the following result for Algorithm 2. The proof of Theorem 2 relies on result of the generic coreset algorithm, Theorem 1.

**Theorem 2.** Suppose  $g_t$  is as defined in Equation (10) and

<sup>2</sup>Hereinafter we include the parameter  $w_t$  in the coreset description  $C_t$ .

---

**Algorithm 2** Iterative Coreset Algorithm
 

---

**INPUT:** Initial  $w_0$ , coefficients  $\{\gamma_1, \dots, \gamma_T\}$  and  $\{\epsilon_1, \dots, \epsilon_T\}$

- 1: **for**  $t = 1$  to  $T$  **do**
- 2:    $[G_{t-1}, l_{t-1}] = \text{LINEARAPPROX}(P', w_{t-1}, R_{t-1})$
- 3:    $[I_{t-1}, \beta_{t-1}] = \epsilon_{t-1}(P' \setminus G_{t-1})$
- 4:   Coreset  $C_{t-1} = (I_{t-1}, \beta_{t-1}, l_{t-1})$
- 5:   Solve the following subproblem

$$w_t = \underset{w \in \Omega(w_{t-1}, R_{t-1})}{\text{argmin}} g_{t-1}(w; C_{t-1})$$

- 6:    $R_t = \gamma_t \cdot R_{t-1}$
  - 7: **end for**
- 

LINEARAPPROX satisfies the following condition:

$$\max_{w \in \mathcal{B}(w_t, R_t)} \left| \sum_{x_g \in G_t} \ell(w^\top x_g) - [w^\top l_t + c] \right| \leq |G_t| \delta \quad (11)$$

where  $[G_t, l_t] = \text{LINEARAPPROX}(P', w_t)$  and  $c \in \mathbb{R}^d$  and for all  $t \in \{0, \dots, T-1\}$ , then we have

$$R_{t+1} = \|w_{t+1} - w_*\| \leq \sqrt{\frac{2LR_*|E_t|\epsilon_t + |G_t|\delta}{\lambda n}}.$$

*Proof.* We first observe that  $g_t$  (in Equation (10)) is strongly convex with modulus  $\lambda$ . Moreover,  $g_t$  is an upper bound on  $f$  due to the following relation:

$$\begin{aligned} & \frac{1}{n} \left( \sum_{x_e \in I_t} \beta_t^e \ell(w^\top x_e) + w^\top l_t \right) + h_t \\ &= \frac{1}{n} \left( \sum_{x_e \in I_t} \beta_t^e \ell(w^\top x_e) + w^\top l_t + 2LR_*|E_t|\epsilon_t + |G_t|\delta + c \right) \\ &\geq \frac{1}{n} \left( \sum_{x_e \in I_t} \beta_t^e \ell(w^\top x_e) + 2LR_*|E_t|\epsilon_t + \sum_{x_g \in G_t} \ell(w^\top x_g) \right) \\ &\geq \frac{1}{n} \left( \sum_{x_p \in E_t} \ell(w^\top x_p) + \sum_{x_g \in G_t} \ell(w^\top x_g) \right) = \frac{1}{n} \sum_{x \in P'} \ell(w^\top x) \end{aligned}$$

The first inequality follows from the definition of  $h_t$ . The second step follows from the condition on LINEARAPPROX in the theorem statement. The third step follows from the fact that  $\ell$  is  $L$ -lipschitz continuous and  $\|\beta_t\|_1 = |E_t|$ . Combining the above with regularization term proves the fact that  $g_t$  is an upper bound on  $f$ .

It is easy to see that the feasible region  $\mathcal{B}(w_t, R_t)$  is convex and contains the optimal solution  $w_*$ . To obtain an upper

bound on the function  $g_t$ , we observe the following:

$$\begin{aligned} & \frac{1}{n} \left( \sum_{x_e \in I_t} \beta_t^e \ell(w^\top x_e) + w^\top l_t \right) + h_t \\ &\leq \frac{1}{n} \left( \sum_{x_e \in I_t} \beta_t^e \ell(w^\top x_e) + 2LR_*|E_t|\epsilon_t \right. \\ &\quad \left. + \sum_{x_g \in G_t} \ell(w^\top x_g) + 2|G_t|\delta \right) \\ &= \frac{1}{n} \left( \sum_{x \in P'} \ell(w^\top x) + 4LR_*|E_t|\epsilon_t + 2|G_t|\delta \right) \end{aligned}$$

The first and second inequalities follow from the condition of the theorem statement and the lipschitz continuous nature of the loss function  $\ell$ .

Therefore,  $C_t$  with the corresponding function  $g_t$  is an  $\Delta_t$ -coreset where  $\Delta_t \leq (4LR_*|E_t|\epsilon_t + 2|G_t|\delta)/n$ . The above reasoning shows that the function  $g_t$  satisfies all the conditions of Theorem 1. Applying Theorem 1 on the function  $g_t$ , we get the required result.  $\square$

It can be observed that the conditions  $\epsilon_T \rightarrow 0$  and  $\delta \rightarrow 0$  as  $T \rightarrow \infty$  ensure convergence of the algorithm to the optimal solution. In general, we can guarantee that our solution is arbitrary close to the optimal solution by choosing  $\delta$  and  $\epsilon_t$  appropriately. Furthermore, we can ensure linear convergence of our algorithm by decreasing  $\epsilon_t$  by a constant factor at each iteration.

It is also important to study the coreset size and the design choice of  $\epsilon_t$  and  $\delta$  since they determine the communication cost of our algorithm. Let  $\delta = 2LR_* \min\{\epsilon_1, \dots, \epsilon_T\}$ . For this value of  $\delta$ , we observe the following:

1. The size of the coreset depends on the cardinality of  $G_t$ . In general, larger the cardinality of  $G_t$ , smaller is the size of the coreset. Furthermore, as a general rule of thumb, if  $\ell$  is asymptotically linear i.e.,  $\lim_{|m| \rightarrow \infty} |\ell(m) - (cm + d)| = 0$  for some constants  $c, d$ , the performance of our algorithm will depend on the rate of asymptotic linearity.
2. We typically require  $\epsilon_{t+1} \leq \epsilon_t$  for all  $t \in \{0, \dots, T-1\}$ . With such a choice, if  $|G_t|$  does not decrease, size of the coreset may increase. However, observe that  $R_t$  decreases. Thus, typically more points satisfy Equation (11), and the cardinality of  $G_t$  usually decreases.
3. Suppose a subset of  $P'$  satisfies Equation (11) at iteration  $t$  then it will always satisfy the condition in future iterations. This is due to the fact that feasible region shrinks at each iteration. Hence, size of the coreset is always non-increasing.

While the above remarks provide informal reasoning for the size of the coreset, it does not provide a formal analysis.

In order to gain a better understanding, we discuss the implementation of this algorithm and provide a more formal analysis in the case of logistic regression and SVMs. To this end, let us first discuss the function LINEARAPPROX for specific cases.

**LINEARAPPROX for differentiable loss functions:** The linear approximation in the differentiable case can be obtained through the first-order Taylor expansion of the loss function. More formally, we have

$$\ell(w^\top x_k) = \ell(w_t^\top x_k) + \partial\ell(w_t^\top x_k)(w^\top x_k - w_t^\top x_k) + \frac{\partial^2\ell(z)}{2}(w^\top x_k - w_t^\top x_k)^2$$

for some  $z = \tilde{w}_t^\top x$  where  $\|\tilde{w}_t - w_t\| \leq R_t$  since our feasible region satisfies  $\|w - w_t\| \leq R_t$ . The key step is to bound the term  $\partial^2\ell(z)$ . This bound will depend on the structure of the loss function. We now derive these bounds for logistic regression. We want the following to ensure that the condition in Theorem 2 with  $l_t = \sum_{x_k \in G_t} \partial\ell(w_t^\top x_k)x_k$  and  $c = \sum_{x_k \in G_t} [\ell(w_t^\top x_k) - \partial\ell(w_t^\top x_k)w_t^\top x_k]$ :

$$\frac{\partial^2\ell(z)}{2}(w^\top x_k - w_t^\top x_k)^2 \leq \delta$$

for all  $x_k \in G_t$ . The above statement is true when

$$\frac{\partial^2\ell(z)}{2}R_t^2\|x_k\|^2 \leq \delta \quad (12)$$

This can be obtained by a straightforward application of the Cauchy-Schwartz inequality. The final step is to derive an upper bound on  $\partial^2\ell(z)$ . For logistic loss we have

$$\partial^2\ell(z) = \frac{1}{(1 + \exp(-z))(1 + \exp(z))}.$$

Without loss of generality, we can assume  $z > 0$ . Then we have  $\partial^2\ell(z) \leq 1/(1 + \exp(z))$ . Using the above inequality it is easy to see that Equation (12) is satisfied if

$$\frac{R_t^2\|x_k\|^2}{2(1 + \exp(z))} \leq \delta.$$

We observe that

$$\begin{aligned} \frac{R_t^2\|x_k\|^2}{2(1 + \exp(z))} &= \frac{R_t^2\|x_k\|^2}{2(1 + \exp(w_t^\top x_k + z - w_t^\top x_k))} \\ &\leq \frac{R_t^2\|x_k\|^2}{2(1 + \exp(w_t^\top x_k) \exp(-R_t\|x_k\|))} \end{aligned}$$

This follows from the fact that  $z = \tilde{w}_t^\top x$  where  $\|\tilde{w}_t - w_t\| \leq R_t$ . Hence, for logistic regression, the goal of LINEARAPPROX is to identify all points satisfying

$$V_t(x_k) = \frac{R_t^2\|x_k\|^2}{2(1 + \exp(w_t^\top x_k) \exp(-R_t\|x_k\|))} \leq \delta$$

and place these points in the set  $G_t$ . The linear function to be used for approximation is obtained from the first-order Taylor expansion. The pseudocode for LINEARAPPROX in case of logistic regression is given in Algorithm 3.

---

**Algorithm 3** LINEARAPPROX for Logistic Regression

---

**INPUT:**  $P', w_t, R_t$

- 1:  $G_t = \{x_k \in P' \mid V_t(x_k) \leq \delta\}$
  - 2:  $l_t = -\sum_{x_k \in G_t} \frac{x_k}{(1 + \exp(w_t^\top x_k))}$
- 

Furthermore, we can also obtain a relationship between the margin of  $x_k$  with respect to the optimal solution and the iteration at which the point  $x_k$  moves to the set  $G_t$ . We note the following:

$$\begin{aligned} \frac{R_t^2\|x_k\|^2}{2(1 + \exp(z))} &= \frac{R_t^2\|x_k\|^2}{2(1 + \exp(w_*^\top x_k + z - w_*^\top x_k))} \\ &\leq \frac{R_t^2\|x_k\|^2}{2(1 + \exp(M_k^* \exp(-2R_t\|x_k\|))} \\ &\leq \frac{R_t^2\|x_k\|^2 \exp(2R_t\|x_k\|)}{2 \exp(M_k^*)} \leq \frac{\exp(3R_t\|x_k\|)}{2 \exp(M_k^*)} \end{aligned}$$

where  $M_k^* = |w_*^\top x_k|$ . The first step follows from triangle inequality and the fact that  $z = \tilde{w}_t^\top x$  where  $\|\tilde{w}_t - w_t\| \leq R_t$  and  $\|\tilde{w}_t - w_t\| \leq R_t$ . The final step follows from the fact that  $x^2 \leq \exp(x)$  for  $x \geq 0$ . Therefore, from above inequality it is easy to see that Equation (12) is satisfied when the following holds

$$R_t \leq \max \left\{ \frac{\sqrt{\delta}}{\|x_k\|}, \frac{M_k^* + \log(2\delta)}{3\|x_k\|} \right\}. \quad (13)$$

**LINEARAPPROX for SVM**

For SVM, the implementation of LINEARAPPROX is pretty straightforward. Due to the piecewise linear nature of the hinge loss, the condition in Equation (10) is satisfied with  $\delta = 0$  if  $w^\top x_k$  is greater than 1 (or less than 1) for the whole feasible region  $\|w - w_t\| \leq R_t$ . This is satisfied when

$$R_t \leq \frac{|1 - w_t^\top x_k|}{\|x_k\|}$$

The pseudocode for LINEARAPPROX in case of SVM is given in Algorithm 4.

---

**Algorithm 4** LINEARAPPROX for SVM

---

**INPUT:**  $P', w_t, R_t$

- 1:  $G_t = \{x_k \in P' \mid R_t \leq |1 - w_t^\top x_k|/\|x_k\|\}$
  - 2:  $l_t = -\sum_{x_k \in G_t} \mathbb{I}(w_t^\top x_k < 1)x_k$
- 

Similarly to the case of logistic regression, we analyze how the margin of  $x_k$  affects when it get included in the set  $G_t$ . For this, note the following:

$$1 - w_t^\top x_k = 1 - w_*^\top x_k - (w_t - w_*)^\top x_k$$

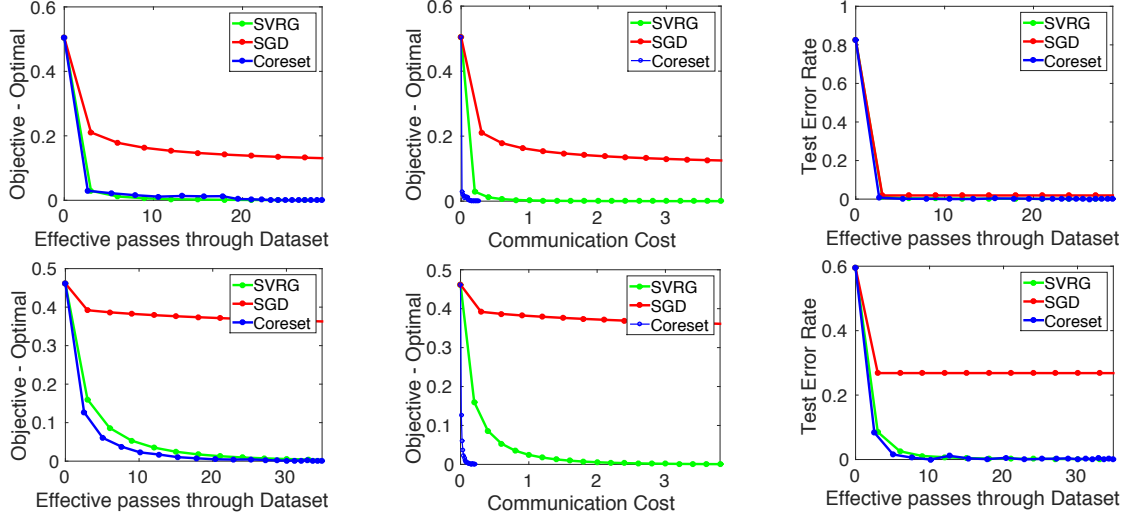

Figure 1:  $l_2$ -regularized logistic regression on ijcnn1 (top) and cod-rna (bottom) datasets. We compare our algorithm with mini-batch SVRG and SGD. Training loss residual is shown with respect to passes through the dataset and communication cost (left and central columns). Test error with respect to the passes through the dataset is shown in the right column.

Again, the above quantity will not change sign when  $w^\top x_k$  is greater than 1 (or less than 1) for the whole feasible region  $\|w - w_t\| \leq R_t$ . Based on the expression above, this is satisfied when

$$\|w_t - w_*\| \|x_k\| \leq |1 - w_*^\top x_k| = M_k^*$$

It is obtained by application of the Cauchy-Schwartz inequality. Note the difference in the definition of  $M_k^*$  in comparison to logistic regression. Hence, condition in Equation (10) will be satisfied when

$$R_t \leq \frac{M_k^*}{\|x_k\|} \quad (14)$$

Let us make a final remark before proceeding to the experimental section. It should be emphasized that based on Equations (13) and (14), the cardinality of  $G_t$  critically depends on the margin of the training points. If the margin of the training points is large, then the coreset size is small and consequently the communication and computation costs are low. Hence, our algorithm is naturally adaptive to the hardness of the optimization problem.

## 5 EXPERIMENTS

We present our empirical results in this section. To evaluate the performance of our algorithm, we focus on the task of regularized logistic regression. Recall that Equation (1) in this case is of the following form:

$$\min_w f(w) \equiv \frac{\lambda}{2} \|w\|^2 + \frac{1}{n} \sum_{i=1}^n \log(1 + \exp(-y_i w^\top x_i)).$$

In our Matlab implementation, we measure simulated communication costs. We use the following datasets.

| Dataset | # examples | # features |
|---------|------------|------------|
| ijcnn1  | 49,990     | 22         |
| cod-rna | 59,535     | 8          |
| w8a     | 64,700     | 300        |
| covtype | 581,012    | 54         |

All these datasets can be accessed from the LIBSVM website.<sup>3</sup> Similarly to [7], each dataset is scaled to  $[-1, 1]$ . We split each dataset in 3:1 ratio for training and testing purposes respectively.

The regularization parameter  $\lambda$  in Equation (1) is  $1/n$ . Recall that  $n$  is the size of the training set. This results in a high condition number and consequently increases the difficulty of the problem [10]. All the experiments were conducted for 10 random seeds and results are reported by averaging over these 10 runs.

We use PROXSVRG [16] for solving the subproblems of Algorithm 2 at each iteration. SVRG is an incremental first-order method that can be used for solving optimization problems conforming to Equation (1). The origin is used as the initial point for the for all our experiments. The number of “inner iterations” in the PROXSVRG algorithm is set to the recommended value of  $m = 2n$ . The step size parameter for each dataset is chosen so as to give the fastest convergence for PROXSVRG.

For our experiments, we choose  $T = 20$  and  $\gamma_1 = \gamma_2 = \dots = \gamma_T = \gamma$  in Algorithm 2 where  $\gamma$  is chosen such that upper bound on  $R_T$  is 0.01. Such a choice is rea-

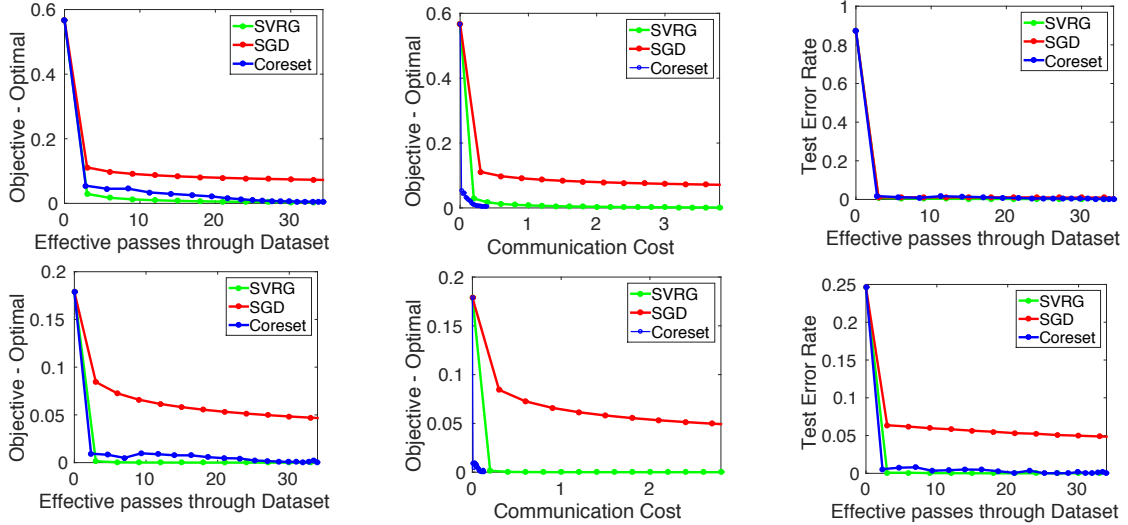

Figure 2:  $l_2$ -regularized logistic regression on more datasets w8a (top) and coverype (bottom). Similar to the previous case, we compare our algorithm with mini-batch SVRG and SGD.

sonable in the case of linearly convergent algorithms — which is the scenario we anticipate for our algorithm. As mentioned earlier, we use a clustering based algorithm instead of the cover. The main rationale behind such a choice is the availability of coresets for data clustering problems. As a heuristic, we directly use  $k$ -means coresets for Algorithm 2. The sensitivity based coreset for  $k$ -means is used in all our experiments. We refer interested reader to [4, 5] for more details of the coreset. We set the coreset size to be 500 for ijcnn1 and cod-rna datasets. This value is set to 1000 and 3000 for w8a and coverype datasets respectively. Note that these coreset sizes are much smaller in comparison to the training data.

We compare our algorithm with SVRG [7] and SGD. A mini-batch version of these methods is used in order to reduce the communication cost of these approaches. We use a mini-batch size  $b = 10$  in all our experiments. The number of inner iterations in SVRG is  $m = \lceil \frac{2n}{b} \rceil$  in all our experiments in order to limit the total inner iterations to the recommended  $2n$  iterations. For SGD, we use the learning rate of  $\alpha/\sqrt{t}$  where  $\alpha$  is the step size used for the all the algorithms for that dataset.

We report the training loss residual i.e., objective value in Equation (1) achieved by the algorithms minus the optimal objective value (obtained by running gradient descent for a very long time) and the test error rate of the algorithms with respect to the number of effective passes through the dataset. This includes the cost for calculating the gradients and the coresets. This provides information about the computation complexity of the algorithm. To measure the communication cost of the algorithm, we use the ratio of the number of  $d$  dimensional vectors communicated to the size of the training data.

Figures 1 and 2 show the performance of the algorithms on the aforementioned datasets. We have several observations from these empirical results. First, we observe that SVRG outperforms SGD in terms of all the metrics of our interest. This observation is not surprising given the linear convergence of SVRG in comparison to the sub-linear convergence of SGD (see [7] for more details). We then observe that our algorithm is competitive to SVRG in terms of training loss residual and test error rate (shown in the first and the third columns of the figures respectively). However, our major gain is in the communication cost of the algorithm. As seen in these figures, our algorithm performs much better in comparison to other algorithms in terms of communication cost. In other words, for the same communication cost, our algorithm has a much lower objective value when compared to SVRG and SGD. We believe that the performance of our algorithm can be further improved by utilizing the coresets of the previous iteration and is a part of our ongoing investigation. For future work, it will be interesting to test the performance of the algorithm on a real distributed environment.

## 6 CONCLUSION

This paper introduces a novel general strategy for designing communication efficient empirical loss minimization algorithms. The key to our approach is the concept of coresets — the idea of constructing a small summary of the training data and optimizing over this summary. We illustrated this strategy on two popular supervised learning problems — logistic regression and support vector machines. We presented convergence analysis for our algorithm. Furthermore, preliminary experiments show encouraging results in terms of both computational and communication costs.

## Abstract

We develop randomized block coordinate descent (CD) methods for linearly constrained convex optimization. Unlike other large-scale CD methods, we do not assume the constraints to be separable, but allow them be coupled linearly. To our knowledge, ours is the first CD method that allows linear coupling constraints, without making the global iteration complexity have an *exponential dependence* on the number of constraints. We present algorithms and theoretical analysis for four key (convex) scenarios: (i) smooth; (ii) smooth + separable nonsmooth; (iii) asynchronous parallel; and (iv) stochastic. We discuss some architectural details of our methods and present preliminary results to illustrate the behavior of our algorithms.

## 1 INTRODUCTION

Coordinate descent (CD) methods are conceptually among the simplest schemes for unconstrained optimization—they have been studied for a long time (see e.g., [1, 4, 28]), and are now enjoying greatly renewed interest. Their resurgence is rooted in successful applications in machine learning [15, 16], statistics [8, 17], and many other areas—see [31, 32, 35] and references therein for more examples.

A catalyst to the theoretical as well as practical success of CD methods has been randomization. (The idea of randomized algorithms for optimization methods is of course much older, see e.g., [29].) Indeed, generic non-randomized CD has resisted complexity analysis, though there is promising recent work [14, 34, 40]; remarkably for randomized CD for smooth convex optimization, Nesterov [25, 26] presented an analysis of global iteration complexity. This work triggered several improvements, such as

[32, 33], who simplified and extended the analysis to include separable nonsmooth terms. Randomization has also been crucial to a host of other CD algorithms and analyses [5, 16, 20, 23, 30, 31, 33, 35–37].

Almost all of the aforementioned CD methods assume essentially unconstrained problems, which at best allow separable constraints. In contrast, we develop, analyze, and implement randomized CD methods for the following composite objective convex problem with *non-separable* linear constraints

$$\min_x F(x) := f(x) + h(x) \quad \text{s.t.} \quad Ax = 0. \quad (1)$$

Here,  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  is assumed to be continuously differentiable and convex, while  $h : \mathbb{R}^n \rightarrow \mathbb{R} \cup \{\infty\}$  is lower semi-continuous, convex, coordinate-wise separable, but not necessarily smooth; the linear constraints (LC) are specified by a matrix  $A \in \mathbb{R}^{m \times n}$ , for which  $m \ll n$ , and a certain structure (see §4) is assumed. The reader may wonder whether one cannot simply rewrite Problem (1) in the form of  $f + h$  (without additional constraints) using suitable indicator functions. However, the resulting regularized problem then *no longer* fits the known efficient CD frameworks [32], since the nonsmooth part is *not* block-separable.

Problem (1) subsumes the usual regularized optimization problems pervasive in machine learning for the simplest ( $m = 0$ ) case. In the presence of linear constraints ( $m > 0$ ), Problem (1) assumes a form used in the classic Alternating Direction Method of Multipliers (ADMM) [9, 10]. The principal difference between our approach and ADMM is that the latter treats the entire variable  $x \in \mathbb{R}^n$  as a single block, whereas we use the structure of  $A$  to split  $x$  into  $b$  smaller blocks. Familiar special cases of Problem (1) include SVM (with bias) dual, fused Lasso and group Lasso [38], and linearly constrained least-squares regression [11, 19].

Recently, Necoara et al. [23] studied a special case of Problem (1) that sets  $h \equiv 0$  and assumes a single sum constraint. They presented a randomized CD method that starts with a feasible solution and at each iteration updates a pair

\*Indicates equal contribution.

† A part of this work was performed when the author was at Carnegie Mellon University

of coordinates to ensure descent on the objective while maintaining feasibility. This scheme is reminiscent of the well-known SMO procedure for SVM optimization [27]. For smooth convex problems with  $n$  variables, Necoara et al. [23] prove an  $O(1/\epsilon)$  rate of convergence. More recently, in [22] considered a generalization to the general case  $Ax = 0$  (assuming  $h$  is coordinatewise separable).

Unfortunately, the analysis in [22] yields an extremely pessimistic complexity result:

**Theorem 1** ([22]). *Consider Problem (1) with  $h$  being coordinatewise separable, and  $A \in \mathbb{R}^{m \times n}$  with  $b$  blocks. Then, the CD algorithm in [22] takes no more than  $O(b^m/\epsilon)$  iterations to obtain a solution of  $\epsilon$ -accuracy.*

This result is exponential in the number of constraints and too severe even for small-scale problems!

We present randomized CD methods, and prove that for important special cases (mainly  $h \equiv 0$  or  $A$  is a sum constraint) we can obtain global iteration complexity that *does not have* an intractable dependence on either the number of coordinate blocks ( $b$ ), or on the number of linear constraints ( $m$ ). Previously, Tseng and Yun [39] also studied a linearly coupled block-CD method based on the Gauss-Southwell choice; however, their complexity analysis applies only to the special  $m = 0$  and  $m = 1$  cases.

To our knowledge, ours is the first work on CD for problems with more than one ( $m > 1$ ) linear constraints that presents such results.

**Contributions.** In light of the above background, the primary contributions of this paper are as follows:

- Convergence rate analysis of a randomized block-CD method for the smooth case ( $h \equiv 0$ ) with  $m \geq 1$  general linear constraints.
- A tighter convergence analysis for the composite function optimization ( $h \neq 0$ ) than [22] in the case of sum constraint.
- An asynchronous CD algorithm for Problem (1).
- A stochastic CD method with convergence analysis for solving problems with a separable loss  $f(x) = (1/N) \sum_{i=1}^N f_i(x)$ .

Table 1 summarizes our contributions and compares it with existing state-of-the-art coordinate descent methods. The detailed proofs of all our theoretical claims are available in the appendix.

**Additional related work.** As noted, CD methods have a long history in optimization and they have gained tremendous recent interest. We cannot hope to do full justice to all the related work, but refer the reader to [32, 33] and [20] for more thorough coverage. Classically, local linear convergence was analyzed in [21]. Global rates for randomized

block coordinate descent (BCD) were pioneered by Nesterov [25], and have since then been extended by various authors [2, 32, 33, 40]. The related family of Gauss-Seidel like analyses for ADMM have also recently gained prominence [13]. A combination of randomized block-coordinate ideas with Frank-Wolfe methods was recently presented in [18], though algorithmically the Frank-Wolfe approach is very different as it relies on non projection based oracles.

## 2 PRELIMINARIES

In this section, we further explain our model and assumptions. We assume that the entire space  $\mathbb{R}^n$  is decomposed into  $b$  blocks, i.e.,  $x = [x_1^\top, \dots, x_b^\top]^\top$  where  $x \in \mathbb{R}^n$ ,  $x_i \in \mathbb{R}^{n_i}$  for all  $i \in [b]$ , and  $n = \sum_i n_i$ . For any  $x \in \mathbb{R}^n$ , we use  $x_i$  to denote the  $i^{\text{th}}$  block of  $x$ . We model communication constraints in our algorithms by viewing variables as nodes in a connected graph  $G := (V, E)$ . Specifically, node  $i \in V \equiv [b]$  corresponds to variable  $x_i$ , while an edge  $(i, j) \in E \subset V \times V$  is present if nodes  $i$  and  $j$  can exchange information. We use ‘pair’ and ‘edge’ interchangeably.

For a differentiable function  $f$ , we use  $f_{i_1 \dots i_p}$  and  $\nabla_{i_1 \dots i_p} f(x)$  (or  $\nabla_{x_{i_1} \dots x_{i_p}} f(x)$ ) to denote the restriction of the function and its partial gradient to coordinate blocks  $(x_{i_1}, \dots, x_{i_p})$ . For any matrix  $B$  with  $n$  columns, we use  $B_i$  to denote the columns of  $B$  corresponding to  $x_i$  and  $B_{ij}$  to denote the columns of  $B$  corresponding to  $x_i$  and  $x_j$ . We use  $U$  to denote the  $n \times n$  identity matrix and hence  $U_i$  is a matrix that places an  $n_i$  dimensional vector into the corresponding block of an  $n$  dimensional vector.

We make the following standard assumption on the partial gradients of  $f$ .

**Assumption 1.** The function has block-coordinate Lipschitz continuous gradient, i.e.,

$$\|\nabla_i f(x) - \nabla_i f(x + U_i h)\| \leq L_i \|h_i\| \text{ for all } x \in \mathbb{R}^n, .$$

Assumption 1 is similar to the typical Lipschitz continuous gradients assumed in first-order methods and it is necessary to ensure convergence of block-coordinate methods.

When functions  $f_i$  and  $f_j$  have Lipschitz continuous gradients with constants  $L_i$  and  $L_j$  respectively, one can show that the function  $f_{ij}$  has a Lipschitz continuous gradient with  $L_{ij} = L_i + L_j$  [22; Lemma 1]. The following result is standard.

**Lemma 2.** For any function  $g : \mathbb{R}^n \rightarrow \mathbb{R}$  with  $L$ -Lipschitz continuous gradient  $\nabla g$ , we have

$$g(x) \leq g(y) + \langle \nabla g(y), x - y \rangle + \frac{L}{2} \|x - y\|^2, \quad x, y \in \mathbb{R}^n.$$

Following [32, 39], we also make the following assumption on the structure of  $h$ .

**Assumption 2.** The nonsmooth function  $h$  is block separable, i.e.,  $h(x) = \sum_i h_i(x_i)$ .

This assumption is critical to composite optimization using CD methods. We also assume access to an oracle that returns function values and *partial gradients* at any points and iterates of the optimization algorithm.

### 3 ALGORITHM

We are now ready to present our randomized CD methods for Problem (1) in various settings. We first study composite minimization (§3.1) and later look at asynchronous (§3.2) and stochastic (§3.3) variants. The main idea underlying our algorithms is to pick a random pair  $(i, j) \in E$  of variables (blocks) at each iteration, and to update them in a manner which maintains feasibility and ensures progress in optimization.

#### 3.1 Composite Minimization

We begin with the nonsmooth setting, where  $h \neq 0$ . We start with a feasible point  $x^0$ . Then, at each iteration we pick a random pair  $(i, j) \in E$  of variables and minimize the first-order Taylor expansion of the loss  $f$  around the current iterate while maintaining feasibility. Formally, this involves performing the update

$$Z(f, x, (i, j), \alpha) := \arg \min_{A_{ij}d_{ij}=0} f(x) + \langle \nabla_{ij} f(x), d_{ij} \rangle + (2\alpha)^{-1} \|d_{ij}\|^2 + h(x + U_{ij}d_{ij}), \quad (2)$$

where  $\alpha > 0$  is a stepsize parameter and  $d_{ij}$  is the update. The right hand side of Equation (2) upper bounds  $f$  at  $x + U_{ij}d_{ij}$ , as seen by using Assumption 1 and Lemma 2. If  $h(x) \equiv 0$ , minimizing Equation (2) yields

$$\begin{aligned} \lambda &\leftarrow \alpha(A_i A_i^\top + A_j A_j^\top)^+ (A_i \nabla_i f(x) + A_j \nabla_j f(x)) \\ d_i &\leftarrow -\alpha \nabla_i f(x) + A_i^\top \lambda \\ d_j &\leftarrow -\alpha \nabla_j f(x) + A_j^\top \lambda \end{aligned} \quad (3)$$

Algorithm 1 presents the resulting method.

Note that since we start with a feasible point  $x^0$  and the update  $d^k$  satisfies  $Ad^k = 0$ , the iterate  $x^k$  is always feasible. However, it can be shown that a necessary condition for Equation (2) to result in a non-zero update is that

$A_i$  and  $A_j$  span the same column space. If the constraints are not block separable (i.e. for any partitioning of blocks  $x_1, \dots, x_b$  into two groups, there is a constraint that involves blocks from both groups), a typical way to satisfy the aforementioned condition is to require  $A_i$  to be full row-rank for all  $i \in [b]$ . This constraints the minimum block size to be chosen in order to apply randomized CD.

Theorem 3 describes convergence of Algorithm 1 for the smooth case ( $h \equiv 0$ ), while Theorem 6 considers the nonsmooth case under a suitable assumption on the structure of the interdependency graph  $G$ —both results are presented in Section 4.

```

1:  $x^0 \in \mathbb{R}^n$  such that  $Ax^0 = 0$ 
2: for  $k \geq 0$  do
3:   Select a random edge  $(i_k, j_k) \in E$  with probability
      $P^{i_k j_k}$ 
4:    $d^k \leftarrow U_{i_k j_k} Z(f, x^k, (i_k, j_k), \alpha_k / L_{i_k j_k})$ 
5:    $x^{k+1} \leftarrow x^k + d^k$ 
6:    $k \leftarrow k + 1$ 
7: end for

```

**Algorithm 1:** Composite Minimization with Linear Constraints

#### 3.2 Asynchronous Parallel Algorithm for Smooth Minimization

Although the algorithm described in the previous section solves a simple subproblem at each iteration, it is inherently sequential. This can be a disadvantage when addressing large-scale problems. To overcome this concern, we develop an asynchronous parallel method that solves Problem (1) for the smooth case.

Our parallel algorithm is similar to Algorithm 1, except for a crucial difference: now we may have multiple processors, and each of these executes the loop 2–6 *independently* without the need for coordination. This way, we can solve subproblems (i.e., multiple pairs) simultaneously in parallel, and due to the asynchronous nature of our algorithm, we can execute updates as they complete, without requiring any locking.

The critical issue, however, with implementing an asynchronous algorithm in the presence of non-separable constraints is ensuring feasibility throughout the course of the algorithm. This requires the operation  $x_i \leftarrow x_i + \delta$  to be executed in an *atomic* (i.e., sequentially consistent) fashion. Modern processors facilitate that without an additional locking structure through the “compare-and-swap” instruction [30]. Since the updates use atomic increments and each update satisfies  $Ad^k = 0$ , the net effect of  $T$  updates is  $\sum_{k=1}^T Ad^k = 0$ , which is feasible despite asynchronicity of the algorithm.

The next key issue is that of convergence. In an asynchronous setting, the updates are based on *stale* gradients

that are computed using values of  $x$  read many iterations earlier. But provided that gradient staleness is bounded, we can establish a sublinear convergence rate of the asynchronous parallel algorithm (Theorem 4). More formally, we assume that in iteration  $k$ , *stale* gradients are computed based on  $x^{D(k)}$  such that  $k - D(k) \leq \tau$ . The bound on staleness, denoted by  $\tau$ , captures the degree of parallelism in the method: such parameters are typical in asynchronous systems and provides a bound on the delay of the updates [20].

Before concluding the discussion on our asynchronous algorithm, it is important to note the difficulty of extending our algorithm to nonsmooth problems. For example, consider the case where  $h = \mathbb{I}_C$  (indicator function of some convex set). Although a pairwise update as suggested above maintains feasibility with respect to the linear constraint  $Ax = 0$ , it may violate the feasibility of being in the convex set  $C$ . This complication can be circumvented by using a convex combination of the current iterate with the update, as this would retain overall feasibility. However, it would complicate the convergence analysis. We plan to investigate this direction in future work.

### 3.3 Stochastic Minimization

An important subclass of Problem (1) assumes separable losses  $f(x) = \frac{1}{N} \sum_{i=1}^N f_i(x)$ . This class arises naturally in many machine learning applications where the loss separates over training examples. To take advantage of this added separability of  $f$ , we can derive a stochastic block-CD procedure.

Our key innovation here is the following: in addition to randomly picking an edge  $(i, j)$ , we also pick a function randomly from  $\{f_1, \dots, f_N\}$  and perform our update using this function. This choice substantially reduces the cost of each iteration when  $N$  is large, since now the gradient calculations involve only the randomly selected function  $f_i$  (i.e., we now use a stochastic-gradient). Pseudocode is given in Algorithm 2.

```

1: Choose  $x^0 \in \mathbb{R}^n$  such that  $Ax^0 = 0$ .
2: for  $k \geq 0$  do
3:   Select a random edge  $(i_k, j_k) \in E$  with probability
      $p_{i_k j_k}$ 
4:   Select random integer  $l \in [N]$ 
5:    $x^{k+1} \leftarrow x^k + U_{i_k j_k} Z(f_l, x^k, (i_k, j_k), \alpha_k / L_{i_k j_k})$ 
6:    $k \leftarrow k + 1$ 
7: end for

```

**Algorithm 2:** Stochastic Minimization with Linear Constraints

Notice that the per iteration cost of Algorithm 2 is lower than Algorithm 1 by a factor of  $N$ . However, as we will see later, this speedup comes at a price of slower convergence rate (Theorem 5). Moreover, to ensure convergence,

decaying step sizes  $\{\alpha_k\}_{k \geq 0}$  are generally chosen.

## 4 CONVERGENCE ANALYSIS

In this section, we outline convergence results for the algorithms described above. The proofs are somewhat technical, and hence left in the appendix due to lack of space; here we present only the key ideas.

For simplicity, we present our analysis for the following reformulation of the main problem:

$$\begin{aligned} \min_{y,z} \quad & f(y, z) + \sum_{i=1}^b h(y_i, z_i) \\ \text{subject to} \quad & \sum_{i=1}^b y_i = 0, \end{aligned} \quad (4)$$

where  $y_i \in \mathbb{R}^{n_y}$  and  $z_i \in \mathbb{R}^{n_z}$ . Let  $y = [y_1^\top \dots y_b^\top]^\top$  and  $z = [z_1^\top \dots z_b^\top]^\top$ . We use  $x$  to denote the concatenated vector  $[y^\top z^\top]^\top$  and hence we assume (unless otherwise mentioned) that the constraint matrix  $A$  is defined as follows

$$A \begin{pmatrix} y \\ z \end{pmatrix} = \begin{pmatrix} \sum_{i=1}^b y_i \\ 0 \end{pmatrix}. \quad (5)$$

It is worth emphasizing that this analysis *does not* result in any loss of generality. This is due to the fact that Problem (1) with a general constraint matrix  $\tilde{A}$  having full row-rank submatrices  $\tilde{A}_i$ 's can be rewritten in the form of Problem (4) by using the transformation specified in Section E of the appendix. It is important to note that this reduction is presented only for the ease of exposition. For our experiments, we directly solve the problem in Equation 2.

Let  $\eta_k = \{(i_0, j_0), \dots, (i_{k-1}, j_{k-1})\}$  denote the pairs selected up to iteration  $k - 1$ . To simplify notation, assume (without loss of generality) that the Lipschitz constant for the partial gradient  $\nabla_i f(x)$  and  $\nabla_{ij} f(x)$  is  $L$  for all  $i \in [n]$  and  $(i, j) \in E$ .

Similar to [23], we introduce a Laplacian matrix  $\mathcal{L} \in \mathbb{R}^{b \times b}$  that represents the communication graph  $G$ . Since we also have unconstrained variables  $z_i$ , we introduce a diagonal matrix  $\mathcal{D} \in \mathbb{R}^{b \times b}$ .

$$\mathcal{L}_{ij} = \begin{cases} \sum_{r \neq i} \frac{p_{ir}}{2L} & i = j \\ -\frac{p_{ij}}{2L} & i \neq j \end{cases} \quad \mathcal{D}_{ij} = \begin{cases} \frac{p_i}{L} & i = j \\ 0 & i \neq j \end{cases}$$

We use  $\mathcal{K}$  to denote the concatenation of the Laplacian  $\mathcal{L}$  and the diagonal matrix  $\mathcal{D}$ . More formally,

$$\mathcal{K} = \begin{bmatrix} \mathcal{L} \otimes I_{n_y} & 0 \\ 0 & \mathcal{D} \otimes I_{n_z} \end{bmatrix}.$$

This matrix induces a norm  $\|x\|_{\mathcal{K}} = \sqrt{x^\top \mathcal{K} x}$  on the *feasible subspace*, with a corresponding dual norm

$$\|x\|_{\mathcal{K}}^* = \sqrt{x^\top \left( \begin{bmatrix} \mathcal{L}^+ \otimes I_{n_y} & 0 \\ 0 & \mathcal{D}^{-1} \otimes I_{n_z} \end{bmatrix} \right) x}$$

Let  $X^*$  denote the set of optimal solutions and let  $x^0$  denote the initial point. We define the following distance, which quantifies how far the initial point is from the optimal, taking into account the graph layout and edge selection probabilities

$$R(x^0) := \max_{x: f(x) \leq f(x^0)} \max_{x^* \in X^*} \|x - x^*\|_{\mathcal{K}} \quad (6)$$

**Note.** Before delving into the details of the convergence results, we would like to draw the reader's attention to the impact of the communication network  $G$  on convergence. In general, the convergence results depend on  $R(x^0)$ , which in turn depends on the Laplacian  $\mathcal{L}$  of the graph  $G$ . As a rule of thumb, the larger the connectivity of the graph, the smaller the value of  $R(x^0)$ , and hence, faster the convergence.

#### 4.1 Convergence results for the smooth case

We first consider the case when  $h = 0$ . Here the subproblem at  $k^{\text{th}}$  iteration has a very simple update  $d_{i_k j_k}^k = U_{i_k} d^k - U_{j_k} d^k$  where  $d^k = \frac{\alpha_k}{2L} (\nabla_{j_k} f(x^k) - \nabla_{i_k} f(x^k))$ . We now prove that Algorithm 1 attains an  $O(1/k)$  convergence rate.

**Theorem 3.** *Let  $\alpha_k = 1$  for  $k \geq 0$ , and let  $\{x^k\}_{k \geq 0}$  be the sequence generated by Algorithm 1; let  $f^*$  denote the optimal value. Then, we have the following rate of convergence:*

$$\mathbb{E}[f(x^k)] - f^* \leq \frac{2R^2(x^0)}{k}$$

where  $R(x^0)$  is as defined in Equation 6.

*Proof Sketch.* We first prove that each iteration leads to descent in expectation. More formally, we get

$$\mathbb{E}_{i_k j_k} [f(x^{k+1}) | \eta_k] \leq f(x^k) - \frac{1}{2} \nabla f(x^k)^\top \mathcal{K} \nabla f(x^k).$$

The above step can be proved using Lemma 2. Let  $\Delta_k = \mathbb{E}[f(x^k)] - f^*$ . It can be proved that

$$\frac{1}{\Delta_k} \leq \frac{1}{\Delta_{k+1}} - \frac{1}{2R^2(x^0)}$$

This follows from the fact that

$$\begin{aligned} f(x^{k+1}) - f^* &\leq \|x^k - x^*\|_{\mathcal{K}}^* \|\nabla f(x^k)\|_{\mathcal{K}} \\ &\leq R(x^0) \|\nabla f(x^k)\|_{\mathcal{K}} \quad \forall k \geq 0 \end{aligned}$$

Telescoping the sum, we get the desired result.  $\square$

Note that Theorem 3 is a strict generalization of the analysis in [23] and [22] due to: (i) the presence of unconstrained variables  $z$ ; and (ii) the presence of a non-decomposable objective function. It is also worth emphasizing that our

convergence rates improve upon those of [22], since they do not involve an exponential dependence of the form  $b^m$  on the number of constraints.

We now turn our attention towards the convergence analysis of our asynchronous algorithm under a consistent reading model [20]. In this context we would like to emphasize that while our theoretical analysis assumes consistent reads, we do not enforce this assumption in our experiments.

**Theorem 4.** *Let  $\rho > 1$  and  $\alpha_k = \alpha$  be such that  $\alpha < 2/(1 + \tau + \tau\rho^\tau)$  and  $\alpha < (\rho - 1)/(\sqrt{2}(\tau + 2)(\rho^{\tau+1} + \rho))$ . Let  $\{x_k\}_{k \geq 0}$  be the sequence generated by asynchronous algorithm using step size  $\alpha_k$  and let  $f^*$  denote the optimal value. Then, we have the following rate of convergence for the expected values of the objective function*

$$\mathbb{E}[f(x_k)] - f^* \leq \frac{R^2(x^0)}{\mu k}$$

where  $R(x^0)$  is as defined in Equation 6 and  $\mu = \frac{\alpha_k^2}{2} \left( \frac{1}{\alpha_k} - \frac{1 + \tau + \tau\rho^\tau}{2} \right)$ .

*Proof Sketch.* For ease of exposition, we describe the case where the unconstrained variables  $z$  are absent. The analysis of case with  $z$  variables can be carried out in a similar manner. Let  $D(k)$  denote the iterate of the variables used in the  $k^{\text{th}}$  iteration (the existence of  $D(k)$  follows from the consistent reading assumption). Let  $d^k = \frac{\alpha_k}{2L} (\nabla_{y_{j_k}} f(x^{D(k)}) - \nabla_{y_{i_k}} f(x^{D(k)}))$  and  $d_{i_k j_k}^k = x^{k+1} - x^k = U_{i_k} d^k - U_{j_k} d^k$ . Using Lemma 2 and the assumption that staleness in the variables is bounded by  $\tau$ , i.e.,  $k - D(k) \leq \tau$  and definition of  $d_{i_j}^k$ , we can derive the following bound:

$$\begin{aligned} \mathbb{E}[f(x^{k+1})] &\leq \mathbb{E}[f(x^k)] - L \left( \frac{1}{\alpha_k} - \frac{1 + \tau}{2} \right) \mathbb{E}[\|d_{i_k j_k}^k\|^2] \\ &\quad + \frac{L}{2} \mathbb{E} \left[ \sum_{t=1}^{\tau} \|d_{i_{k-t} j_{k-t}}^{k-t}\|^2 \right]. \end{aligned}$$

In order to obtain an upper bound on the norms of  $d_{i_k j_k}^k$ , we prove that

$$\mathbb{E} \left[ \|d_{i_{k-1} j_{k-1}}^{k-1}\|^2 \right] \leq \rho \mathbb{E} \left[ \|d_{i_k j_k}^k\|^2 \right]$$

This can be proven using mathematical induction. Using the above bound on  $\|d_{i_k j_k}^k\|^2$ , we get

$$\begin{aligned} \mathbb{E}[f(x^{k+1})] &\leq \\ \mathbb{E}[f(x^k)] &- L \left( \frac{1}{\alpha_k} - \frac{1 + \tau + \tau\rho^\tau}{2} \right) \mathbb{E}[\|d_{i_k j_k}^k\|^2] \end{aligned}$$

This proves that the method is a descent method in expectation. Following similar analysis as Theorem 3, we get the required result.  $\square$

Note the dependence of convergence rate on the staleness bound  $\tau$ . For larger values of  $\tau$ , the stepsize  $\alpha_k$  needs to be decreased to ensure convergence, which in turn slows down the convergence rate of the algorithm. Nevertheless, the convergence rate remains  $O(1/k)$ .

The last smooth case we analyze is our stochastic algorithm.

**Theorem 5.** *Let  $\alpha_i = \sqrt{\Delta_0 L} / (M\sqrt{i+1})$  for  $i \geq 0$  in Algorithm 2. Let  $\{x^k\}_{k \geq 0}$  be the sequence generated by Algorithm 2 and let  $f^*$  denote the optimal value. We denote  $\bar{x}^k = \arg \min_{0 \leq i \leq k} f(x^i)$ . Then, we have the following rate of convergence for the expected values of the objective:*

$$\mathbb{E}[f(\bar{x}^k)] - f^* \leq O\left(\frac{1}{\sqrt[4]{k}}\right)$$

where  $\Delta_0 = f(x^0) - f^*$ .

The convergence rate is  $O(1/k^{1/4})$  as opposed to  $O(1/k)$  of Theorem 3. On the other hand, the iteration complexity is lower by a factor of  $N$ ; this kind of tradeoff is typical in stochastic algorithms, where the slower rate is the price we pay for a lower iteration complexity. We believe that the convergence rate can be improved to  $O(1/\sqrt{k})$ , the rate generally observed in stochastic algorithms, by a more careful analysis.

## 4.2 Nonsmooth case

We finally state the convergence rate for the nonsmooth case ( $h \neq 0$ ) in the case of a sum constraint. Similar to [22], we assume  $h$  is coordinatewise separable (i.e. we can write  $h(x) = \sum_{i=1}^b \sum_j x_{ij}$ ), where  $x_{ij}$  is the  $j^{\text{th}}$  coordinate in the  $i^{\text{th}}$  block. For this analysis, we assume that the graph  $G$  is a clique<sup>1</sup> with uniform probability, i.e.,  $\lambda = p_{ij} = 2/b(b-1)$ .

**Theorem 6.** *Assume  $Ax = \sum_i A_i x_i$ . Let  $\{x^k\}_{k \geq 0}$  be the sequence generated by Algorithm 1 and let  $F^*$  denote the optimal value. Assume that the graph  $G$  is a clique with uniform probability. Then we have the following:*

$$\mathbb{E}[F(x^k) - F^*] \leq \frac{b^2 L R^2(x^0)}{2k + \frac{b^2 L R^2(x^0)}{\Delta_0}},$$

where  $R(x^0)$  is as defined in Equation 6.

This convergence rate is a generalization of the convergence rate obtained in Necoara and Patrascu [22] for a single linear constraint (see Theorem 1 in [22]). It is also an

<sup>1</sup>We believe our results also easily extend to the general case along the lines of [31–33], using the concept of *Expected Separable Overapproximation* (ESO). Moreover, the assumption is not totally impractical, e.g., in a multicore setting with a zero-sum constraint (i.e.  $A_i = I$ ), the clique-assumption introduces little cost.

improvement of the rate obtained in Necoara and Patrascu [22] for general linear constraints (see Theorem 4 in [22]) when applied to the special case of a sum constraint. Our improvement comes in the form of a tractable constant, as opposed to the exponential dependence  $O(b^m)$  shown in [22].

## 5 APPLICATIONS

To gain a better understanding of our approach, we state some applications of interest, while discussing details of Algorithm 1 and Algorithm 2 for them. While there are many applications of problem (1), due to lack of space we only mention a few prominent ones here.

**Support Vector Machines:** The SVM dual (with bias term) assumes the form (1); specifically,

$$\begin{aligned} \min_{\alpha} \quad & \frac{1}{2} \sum_{i,j} \alpha_i \alpha_j y_i y_j z_i^\top z_j - \sum_{i=1}^n \alpha_i \\ \text{s.t.} \quad & \sum_i \alpha_i y_i = 0, \quad 0 \leq \alpha_i \leq C \quad \forall i \in [n]. \end{aligned} \quad (7)$$

Here,  $z_i$  denotes the feature vector of the  $i^{\text{th}}$  training example and  $y_i \in \{1, -1\}$  denotes the corresponding label. By letting  $f(\alpha) = \frac{1}{2} \sum_{i,j} \alpha_i \alpha_j y_i y_j z_i^\top z_j - \sum_i \alpha_i$  and  $h(\alpha) = \sum_i \mathbb{I}(0 \leq \alpha_i \leq C)$  and  $A = [y_1, \dots, y_n]$  this problem can be written in form of Problem (1). Using Algorithm 1 for SVM involves solving a sub-problem similar to one used in SMO in the scalar case (i.e.,  $\alpha_i \in \mathbb{R}$ ) and can be solved in linear time in the block case (see [3]).

**Generalized Lasso:** The objective is to solve the following optimization problem.

$$\min_{\beta} \quad \frac{1}{2} \|Y - X\beta\|_2^2 + \lambda \|D\beta\|_1$$

where  $Y \in \mathbb{R}^N$  denotes the output,  $X \in \mathbb{R}^{N \times n}$  is the input and  $D \in \mathbb{R}^{q \times n}$  represents a specified penalty matrix. This problem can also be seen as a specific case of Problem (1) by introducing an auxiliary variable  $t$  and slack variables  $u, v$ . Then,  $f(\beta, t) = \frac{1}{2} \|Y - X\beta\|_2^2 + \sum_i t_i$ ,  $h(u, v) = \mathbb{I}(u \geq 0) + \mathbb{I}(v \geq 0)$  and,  $t - D\beta - u = 0$  and  $t + D\beta - v = 0$  are the linear constraints. To solve this problem, we can use either Algorithm 1 or Algorithm 2. In general, optimization of convex functions on a structured convex polytope can be solved in a similar manner.

**Unconstrained Separable Optimization:** Another interesting application is for unconstrained separable optimization. For any problem  $\min_x \sum_i f_i(x)$ —a form generally encountered across machine learning—can be rewritten using variable-splitting as  $\min_{\{x_i=x, \forall i \in [N]\}} \sum_i f_i(x_i)$ . Solving the problem in distributed environment requires considerable synchronization (for the consensus constraint), which can slow down the algorithm significantly. However, the dual of the problem is

$$\min_{\lambda} \sum_i f_i^*(\lambda_i) \quad \text{s.t.} \quad \sum_{i=1}^N \lambda_i = 0.$$

where  $f_i^*$  is the Fenchel conjugate of  $f_i$ . This reformulation perfectly fits our framework and can be solved in an asynchronous manner using the procedure described in Section 3.2.

Other interesting application include constrained least square problem, multi-agent planning problems, resource allocation—see [22, 23] and references therein for more examples.

## 6 EXPERIMENTS

In this section, we present our empirical results. In particular, we examine the behavior of random coordinate descent algorithms analyzed in this paper under different communication constraints and concurrency conditions.<sup>2</sup>

### 6.1 Effect of Communication Constraints

Our first set of experiments test the affect of the connectivity of the graph on the convergence rate. In particular, recall that the convergence analysis established in Theorem 3 depends on the Laplacian of the communication graph. In this experiment we demonstrate how communication constraints affect convergence in practice. We experiment with the following graph topologies of graph  $G$ : Ring, Clique, Star + Ring (i.e., the union of edges of a star and a ring) and Tree + Ring. On each layout we run the sequential Algorithm 1 on the following quadratic problem

$$\begin{aligned} \min \quad & C \sum_{i=1}^N \|x_i - (i \bmod 10)\mathbf{1}\|^2 \\ \text{s.t.} \quad & \sum_{i=1}^N A_i x_i = 0, \end{aligned} \quad (8)$$

Note the decomposable structure of the problem. For this experiment, we use  $N = 1000$  and  $x_i \in \mathbb{R}^{50}$ . We have 10 constraints whose coefficients are randomly generated from  $U[0, 1]$  and we choose  $C$  such that the objective evaluates to 1000 when  $x = 0$ .

The results for Algorithm 1 on each topology for 10000 iterations are shown in Figure 1. The results clearly show that better connectivity implies better convergence rate. Note that while the clique topology has significantly better convergence than other topologies, acceptable long-term performance can be achieved by much sparser topologies such as Star + Ring and Tree + Ring.

Having a sparse communication graph is important to lower the cost of a distributed system. Furthermore, it is worth mentioning that the sparsity of the communication graph is also important in a multicore setting; since Algorithm 1

<sup>2</sup>All experiments were conducted on a Google Compute Engine virtual machine of type “n1-highcpu-16”, which comprises 16 virtual CPUs and 14.4 GB of memory. For more details, please refer to <https://cloud.google.com/compute/docs/machine-types#highcpu>.

Figure 1: Objective value vs. number of iterations for different graph topologies. Note that larger the connectivity of the graph, faster is the convergence.

requires computing  $(A_i A_i^T + A_j A_j^T)^+$  for each communicating pair of nodes  $(i, j)$ . Our analysis shows that this computation takes a significant portion of the running time and hence it is essential to minimize the number of variable pairs that are allowed to be updated.

### 6.2 Concurrency and Synchronization

As seen earlier, compared to Tree + Ring, Star + Ring is a low diameter layout (diameter = 2). Hence, in a sequential setting, it indeed results in a faster convergence. However, Star + Ring requires a node to be connected to all other nodes. This high-degree node could be a contention point in a parallel setting. We test the performance of our asynchronous algorithm in this setting. To assess how the performance would be affected with such contention and how asynchronous updates would increase performance, we conduct another experiment on the synthetic problem (8) but on a larger scale ( $N = 10000$ ,  $x_i \in \mathbb{R}^{100}$ , 100 constraints).

Our concurrent update follows a master/slave scheme. Each thread performs a loop where in each iteration it elects a master  $i$  and slave  $j$  and then applies the following sequence of actions:

1. Obtain the information required for the update from the master (i.e., information for calculating the gradients used for solving the subproblem).
2. Send the master information to the slave, update the slave variable and get back the information needed to update the master.
3. Update the master based (only) on the information obtained from steps 1 and 2.

We emphasize that the master is not allowed to read its own state at step 3 except to apply an increment, which is computed based on steps 1 and 2. This ensures that the master’s increment is consistent with that of the slave, even if one or both of them was being concurrently overwritten by

another thread. More details on the implementation can be found in [12].

Given this update scheme, we experiment with three levels of synchronization: (a) **Double Locking:** Locks the master and the slave through the entire update. Because the objective function is decomposable, a more conservative locking (e.g. locking all nodes) is not needed. (b) **Single Locking:** Locks the master during steps 1 and 3 (the master is unlocked during step 2 and locks the slave during step 2). (c) **Lock-free:** No locks are used. Master and slave variables are updated through atomic increments similar to Hogwild! method.

Following [30], we use spinlocks instead of mutex locks to implement locking. Spinlocks are preferred over mutex locks when the resource is locked for a short period of time, which is the case in our algorithm. For each locking mechanism, we vary the number of threads from 1 to 15. We stop when  $f_0 - f_t > 0.99(f_0 - f^*)$ , where  $f^*$  is computed beforehand up to three significant digits. Similar to [30], we add artificial delay to steps 1 and 2 in the update scheme to model complicated gradient calculations and/or network latency in a distributed setting.

Figure 2 shows the speedup for Tree + Ring and Star + Ring layouts. The figure clearly shows that a fully synchronous method suffers from contention in the Star + Ring topology whereas asynchronous method does not suffer from this problem and hence, achieves higher speedups. Although the Tree + Ring layouts achieves higher speedup than Star + Ring, the latter topology results in much less running time ( $\sim 67$  seconds vs 91 seconds using 15 threads).

### 6.3 Practical Case Study: Parallel Training of Linear SVM

In this section, we explore the effect of parallelism on randomized CD for training a linear SVM based on the dual formulation stated in (7). Necoara et. al. [22] have shown that, in terms of CPU time, a sequential randomized CD outperforms coordinate descent using Gauss-Southwell selection rule. It was also observed that randomized CD outperforms LIBSVM [6] for large datasets while maintaining reasonable performance for small datasets.

In this experiment we use a clique layout. For SVM training in a multicore setting, using a clique layout does not introduce additional cost compared to a more sparse layout. To maintain the box constraint, we use the double-locking scheme described in Section 6.2 for updating a pair of dual variables.

One advantage of coordinate descent algorithms is that they do not require the storage of the Gram matrix; instead they can compute its elements on the fly. That comes, however, at the expense of CPU time. Similar to [22], to speed up gradient computations without increasing memory require-

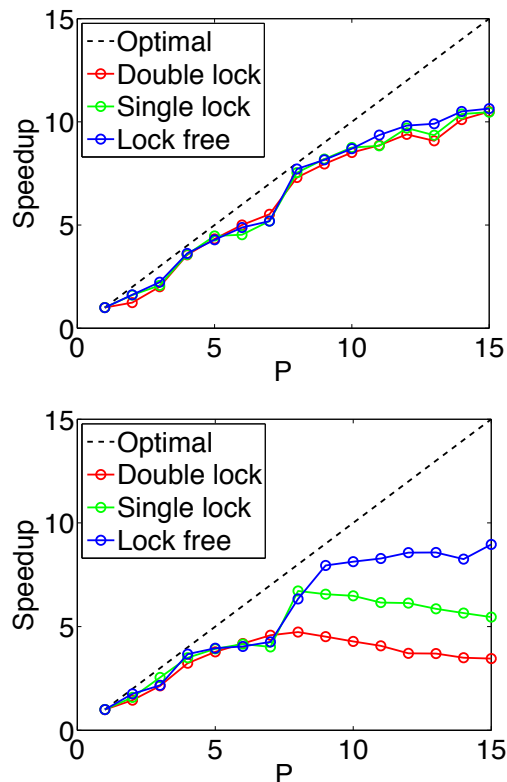

Figure 2: Speedup for Tree + Ring (top) and Star + Ring (bottom) topologies and different levels of synchronization. Note for Star + Ring topology, speedup of asynchronous algorithm is significantly higher than that of synchronous version.

ments, we maintain the primal weight vector of the linear SVM and use it to compute gradients. Basically, if we increment  $\alpha_i$  by  $\delta_i$  and  $\alpha_j$  by  $\delta_j$ , then we increment the weight vector by  $\delta_i y_i x_i + \delta_j y_j x_j$ . This increment is accomplished using atomic additions. However, this implies that all threads will be concurrently updating the primal weight vector. Similar to [30], we require these updates to be sparse with small overlap between non-zero coordinates in order to ensure convergence. In other words, we require training examples to have sparse features with small overlap between non-zero features.

We report speedups on two datasets used in [22].<sup>3</sup> Table 2 provides a description of both the datasets. For each dataset, we train the SVM model until  $f_0 - f_t > 0.9999(f_0 - f^*)$ , where  $f^*$  is the objective reported in [22]. In Figure 3, we report speedup for both the datasets. The figure shows that parallelism indeed increases the performance of randomized CD training of linear SVM.

<sup>3</sup>Datasets can be downloaded from <http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets>.

| Dataset | # of instances | # of features | Avg # of non-zero features |

## 7 DISCUSSION AND FUTURE WORK

We presented randomized coordinate descent methods for solving convex optimization problems with linear constraints that couple the variables. Moreover, we also presented composite objective, stochastic, and asynchronous versions of our basic method and provided their convergence analysis. We demonstrated the empirical performance of the algorithms. The experimental results of asynchronous algorithm look very promising.

There are interesting open problems for our problem in consideration: First, we would like to obtain high-probability results not just in expectation; another interesting direction is to extend the asynchronous algorithm to the non-smooth setting. Finally, while we obtain  $O(1/k)$  for general convex functions, obtaining an accelerated  $O(1/k^2)$  rate is a natural question.
